The total momentum of the system is conserved only because the electromagnetic field itself also carries momentum. If electromagnetic fields have momentum, they are able to *strike* objects and to be struck by them. As we will show below, light is also an electromagnetic field. Thus we should be able to move objects by shining light on to them. We should even be able to suspend particles in mid air by shining light on to them from below. Both predictions are correct, and some experiments will be presented shortly.

We conclude that any sort of field leading to particle interactions must carry energy

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

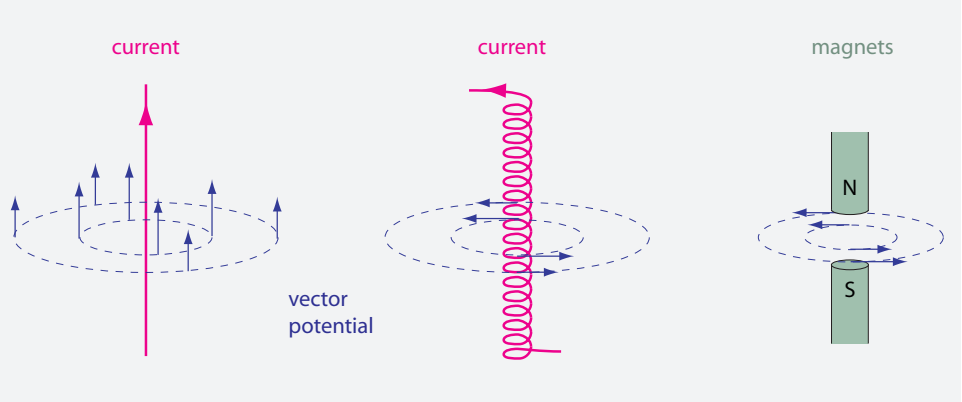

FIGURE 347 Vector potentials for selected situations

and momentum, as the argument applies to all such cases. In particular, it applies to nuclear interactions. Indeed, in the quantum part of our mountain ascent we will even find an additional result: all fields are themselves composed of particles. The energy and momentum of fields then become an obvious state of affairs.

The gauge field – the electromagnetic vector potential

The study of moving fields is called *field theory* and electrodynamics is the prime example. (The other classical example is fluid dynamics; moving electromagnetic fields and moving fluids are very similar mathematically.) Field theory is a beautiful topic; field lines, equipotential lines and vortex lines are some of the concepts introduced in this domain. They fascinate many.* However, in this mountain ascent we keep the discussion focused on motion.

We have seen that fields force us to extend our concept of motion. Motion is not only the change in state of objects and of space-time, but also the *change in state of fields*. We therefore need, also for fields, a complete and precise description of their state. The observations with amber and magnets have shown us that *fields possess energy and momentum*. They can impart it to particles. The experiments with motors have shown that objects can add energy and momentum to fields. We therefore have to define a *state function* which allows us to define energy and momentum for electric and magnetic fields. Since electric and magnetic fields transport energy, their motion follows the speed limit in nature.

Maxwell defined the state function in two standard steps. The first step is the definition of the *(magnetic) vector potential*, which describes the momentum per charge that the field provides:

Ref. 586

$$\boldsymbol{A} = \frac{\boldsymbol{p}}{q} \,. \tag{445}$$

Challenge 1062 s

* What is the relation, for static fields, between field lines and (equi-) potential surfaces? Can a field line cross a potential surface twice? For more details on topics such as these, see the *free* textbook by Bo Thidé, *Electromagnetic Field Theory*, on his www.plasma.uu.se/CED/Book website. And of course, in English, have a look at the texts by Schwinger and by Jackson.

Ref. 557, Ref. 574

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

When a charged particle moves through a magnetic potential $\boldsymbol{A}(\boldsymbol{x})$, its momentum changes by $q\Delta\boldsymbol{A}$; it changes by the difference between the potential values at the start and end points, multiplied by its charge. Owing to this definition, the vector potential has the property that

$$\mathrm{B} = \nabla \times \boldsymbol{A} = \operatorname{curl} \boldsymbol{A} \tag{446}$$

i.e., that the magnetic field is the *curl* of the magnetic potential. In most languages the curl is called the *rotation* and abbreviated rot. To visualize what the curl or rotation is, imagine that the field vectors are the velocity vectors of flowing air. Now put a tiny paddle-wheel at a point. If it turns, the curl is non-zero. The rotation speed of the paddle-wheel is maximal for some direction of the axis; this maximal speed defines both the magnitude and the direction of the curl at the point. (The right-hand rule is implied.) For example, the curl for the velocities of a rotating solid body is everywhere 2ω, or twice the angular velocity.

Challenge 1063 ny

Ref. 587

Challenge 1064 ny

The vector potential for a long straight current-carrying wire is parallel to the wire; it has the magnitude

$$A(r) = -\frac{\mu_0 I}{4\pi} \ln \frac{r}{r_0} \,, \tag{447}$$

which depends on the radial distance r from the wire and an integration constant r_0. This expression for the vector potential, pictured in Figure 347, shows how the moving current produces a linear momentum in the (electro-) magnetic field around it. In the case of a solenoid, the vector potential 'circulates' around the solenoid. The magnitude obeys

$$A(\mathrm{r}) = -\frac{\Phi}{4\pi} \frac{1}{r} \,, \tag{448}$$

where Φ is the magnetic flux inside the solenoid. We see that, in general, the vector potential is *dragged along* by moving charges. The dragging effect decreases for larger distances. This fits well with the image of the vector potential as the momentum of the electromagnetic field.

This behaviour of the vector potential around charges is reminiscent of the way honey is dragged along by a spoon moving in it. In both cases, the dragging effect decreases with distance. However, the vector potential, unlike the honey, does *not* produce any friction that slows down charge motion. The vector potential thus behaves like a frictionless liquid.

Inside the solenoid, the magnetic field is constant and uniform. For such a field B we find the vector potential

Challenge 1065 e

$$\boldsymbol{A}(\mathrm{r}) = -\frac{1}{2} \boldsymbol{B} \times \boldsymbol{r} \,. \tag{449}$$

In this case, the magnetic potential thus increases with increasing distance from the origin.* In the centre of the solenoid, the potential vanishes. The analogy of the dragged honey gives exactly the same behaviour.

* This is only possible as long as the field is constant; since all fields drop again at large distances – because the energy of a field is always finite – also the vector potential drops at large distances.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

However, there is a catch. The magnetic potential is *not* defined uniquely. If $\boldsymbol{A}(\boldsymbol{x})$ is a vector potential, then the different vector potential

$$\boldsymbol{A}'(\boldsymbol{x}) = \boldsymbol{A}(\boldsymbol{x}) + \operatorname{grad}\Lambda \,, \tag{450}$$

where $\Lambda(t, \boldsymbol{x})$ is some scalar function, is *also* a vector potential for the same situation. (The magnetic field B stays the same, though.) Worse, can you confirm that the corresponding (absolute) momentum values also change? This unavoidable ambiguity, called *gauge invariance* or *gauge symmetry*, is a central property of the electromagnetic field. We will explore it in more detail below.

Challenge 1066 ny

Not only the momentum, but also the energy of the electromagnetic field is defined ambiguously. Indeed, the second step in the specification of a state for the electromagnetic field is the definition of the *electric potential* as the energy U per charge:

Ref. 586

$$\varphi = \frac{U}{q} \tag{451}$$

In other words, the potential $\varphi(\boldsymbol{x})$ at a point $\boldsymbol{x}$ is the energy needed to move a unit charge to the point $\boldsymbol{x}$ starting from a point where the potential vanishes. The potential energy is thus given by $q\varphi$. From this definition, the electric field $\boldsymbol{E}$ is simply the *change* of the potential with position corrected by the time dependence of momentum, i.e.,

$$\boldsymbol{E} = -\nabla\varphi - \frac{\partial}{\partial t}\boldsymbol{A} \,, \tag{452}$$

Obviously, there is a freedom in the choice of the definition of the potential. If $\varphi(\boldsymbol{x})$ is a possible potential, then

$$\varphi'(\boldsymbol{x}) = \varphi(\boldsymbol{x}) - \frac{\partial}{\partial t}\Lambda \tag{453}$$

is also a potential function for the same situation. This freedom is the generalization of the freedom to define energy up to a constant. Nevertheless, the electric field $\boldsymbol{E}$ remains the same for all potentials.

Ref. 586

To be convinced that the potentials really are the energy and momentum of the electromagnetic field, we note that for a moving charge we have

Challenge 1067 ny

$$\begin{aligned} \frac{d}{\mathrm{d}t}\left(\frac{1}{2}mv^2 + q\varphi\right) &= \frac{\partial}{\partial t} q\ (\varphi - \boldsymbol{v}\boldsymbol{A}) \\ \frac{d}{\mathrm{d}t}\left(m\boldsymbol{v} + q\boldsymbol{A}\right) &= -\nabla q\left(\varphi - \boldsymbol{v}\boldsymbol{A}\right) \,, \end{aligned} \tag{454}$$

which show that the changes of generalized energy and momentum of a particle (on the left-hand side) are due to the change of the energy and momentum of the electromagnetic field (on the right-hand side).*

* This connection also shows why the expression $P^\mu - qA^\mu$ appears so regularly in formulae; indeed, it plays a central role in the quantum theory of a particle in the electromagnetic field.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In relativistic 4-vector notation, the energy and the momentum of the field appear together in one quantity. The state function of the electromagnetic field becomes

$$A^\mu = (\varphi/c, \boldsymbol{A}) \,. \tag{455}$$

It is easy to see that the description of the field is complete, since we have

$$\boldsymbol{F} = d\,A \quad \text{or} \quad \boldsymbol{F}^{\mu\nu} = \partial^\mu A^\nu - \partial^\nu A^\mu \quad (\text{and} \quad \boldsymbol{F}_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu) \,, \tag{456}$$

which means that the electromagnetic field F is completely specified by the 4-potential A.* But as just said, the 4-potential itself is *not* uniquely defined. Indeed, any other equivalent 4-potential A' is related to A by the *gauge transformation*

$$A'^\mu = A^\mu + \partial^\mu \Lambda \tag{457}$$

where $\Lambda = \Lambda(t, x)$ is any arbitrarily chosen scalar field. The new field A' leads to the *same* electromagnetic field, and to the same accelerations and evolutions. The 4-potential A is thus an *overdescription* of the physical situation as several *different* gauge choices correspond to the *same* physical situation.** Therefore we have to check that all measurement results are independent of gauge transformations, i.e., that all observables are gauge invariant quantities. Such gauge invariant quantities are, as we just saw, the fields $\boldsymbol{F}$ and $^*\boldsymbol{F}$, and in general all classical quantities. We add that many theoretical physicists use the term 'electromagnetic field' loosely for both the quantities $F^{\mu\nu}$ and A^μ.

There is a simple image, due to Maxwell, to help overcoming the conceptual difficulties of the vector potential. It turns out that the closed line integral over A_μ is gauge invariant, because

Challenge 1069 e

$$\oint A^\mu \mathrm{d}x_\mu = \oint (A^\mu + \partial^\mu \Lambda) \mathrm{d}x_\mu = \oint A'^\mu \mathrm{d}x_\mu \,. \tag{458}$$

In other words, if we picture the vector potential as a quantity allowing one to associate a number to a tiny ring at each point in space, we get a good, gauge invariant picture of the vector potential.***

Now that we have defined a state function that describes the energy and momentum of the electromagnetic field, let us look at what happens in more detail when electromagnetic fields move.

* The connection between A^μ and A^μ, the same as for every other 4-vector, was mentioned earlier on; can you restate it?

Challenge 1068 e

** Choosing a function Λ is often called *choosing a gauge*; the 4-potential A is also called the *gauge field*. This strange usage has historic reasons and is now common to all of physics.

*** In the part of the text on quantum theory we will see that the exponent of this expression, namely $\exp(iq \oint A_\mu \mathrm{d}x^\mu)/\hbar$, usually called the *phase factor*, can indeed be directly observed in experiments.

Ref. 588

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Energy and linear and angular momentum of the electromagnetic field

All moving entities have energy, momentum and angular momentum. This also applies to the electromagnetic field. Indeed, the description so far allows us to write the *total* energy E_{nergy} of the electromagnetic field as

$$E_{\text{nergy}} = \frac{1}{8\pi} \int \varepsilon_0 \boldsymbol{E}^2 + \frac{\boldsymbol{B}^2}{\mu_0} \, \mathrm{d}V \,. \tag{459}$$

Energy is thus quadratic in the fields.

For the total linear momentum we obtain

$$\boldsymbol{p} = \frac{\varepsilon_0}{4\pi} \int \boldsymbol{E} \times \boldsymbol{b} \, \mathrm{d}V \,. \tag{460}$$

The expression inside the integral, more specifically the vector $\boldsymbol{S} = \boldsymbol{E} \times \boldsymbol{b}/\mu_0$, is also called the *Poynting vector*.* The Poynting vector $\boldsymbol{S}$ is the *energy flow density*, and $c^2\boldsymbol{S}$ describes the *momentum density*, since special relativity implies that the momentum and the energy flow for electromagnetic fields are related by a factor c^2. The Poynting vector thus describes the energy flowing per area per time, in other words, the power per area. (As shown below, the Poynting vector is a part of the energy–momentum tensor.)

Page 715

For the total angular momentum we have

$$\boldsymbol{L} = \frac{\varepsilon_0}{4\pi} \int \boldsymbol{E} \times \boldsymbol{A} \, \mathrm{d}V = \frac{\varepsilon_0}{4\pi} \int \boldsymbol{r} \times (\boldsymbol{E} \times \boldsymbol{B}) \, \mathrm{d}V \,, \tag{461}$$

where $\boldsymbol{A}$ is the magnetic vector potential.

The Lagrangian of electromagnetism

The motion of a charged particle and the related motion of the electromagnetic field can also be described using a Lagrangian, instead of using the three equations given above. It is not hard to see that the action S_{CED} for a particle in classical electrodynamics can be symbolically defined by**

Challenge 1070 ny

$$S_{\text{CED}} = -mc^2 \int \mathrm{d}\tau - \tfrac{1}{4\mu_0} \int \boldsymbol{F} \wedge *\boldsymbol{F} - \int j \wedge A \,, \tag{462}$$

which in index notation becomes

$$S_{\text{CED}} = -mc \int_{-\infty}^{\infty} \sqrt{\eta_{\mu\nu} \frac{\mathrm{d}x_n^\mu(s)}{\mathrm{d}s} \frac{\mathrm{d}x_n^\nu(s)}{\mathrm{d}s}} \, \mathrm{d}s - \int_{\mathbf{M}} \left(\tfrac{1}{4\mu_0} \boldsymbol{F}_{\mu\nu} \boldsymbol{F}^{\mu\nu} + j_\mu A^\mu \right) \mathrm{d}^4 x \,, \tag{463}$$

* John Henry Poynting (1852–1914) introduced the concept in 1884.

** The product described by the symbol $\wedge$, 'wedge' or 'hat', and the duality operator $*$ have a precise mathematical meaning. The background, the concept of *(mathematical) form*, carries us too far from our walk.

Ref. 589

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

or, in 3-vector notation

$$S_{\text{CED}} = -mc^2 \int \mathrm{d}\tau + \int qvA - q\varphi + \frac{\varepsilon_0}{2}E^2 - \frac{1}{2\mu_0}B^2 \mathrm{d}t\mathrm{d}V \,. \tag{464}$$

The new part is the measure of the change – or action – due to the electromagnetic field. The pure field change is given by the term $\boldsymbol{F} \wedge *\boldsymbol{F}$, and the change due to interaction with matter is given by the term $j \wedge A$.

The least action principle, as usual, states that the change in a system is always as small as possible. The action S_{CED} leads to the evolution equations by requiring that the action be stationary under variations δ and δ' of the positions and of the fields which vanish at infinity. In other terms, the principle of least action requires that

$$\begin{aligned} \delta S = 0 \quad &\text{when} \quad x_\mu = x_\mu + \delta_\mu \quad \text{and} \quad A_\mu = A_\mu + \delta'_\mu \quad , \\ &\text{provided} \quad \delta x_\mu(\theta) \to 0 \quad \text{for} \quad |\theta| \to \infty \\ &\text{and} \quad \delta A_\mu(x_\nu) \to 0 \quad \text{for} \quad |x_\nu| \to \infty \,. \end{aligned} \tag{465}$$

Page 199
Challenge 1071 ny

In the same way as in the case of mechanics, using the variational method for the two variables A and x, we recover the evolution equations for particle position and fields

$$b^\mu = \frac{q}{m}\boldsymbol{F}^\mu_\nu \, u^\nu \quad , \quad \partial_\mu \boldsymbol{F}^{\mu\nu} = j^\nu \mu_0 \quad , \quad \text{and} \quad \varepsilon^{\mu\nu\rho\sigma} \, \partial_\nu \boldsymbol{F}_{\rho\sigma} = 0 \,, \tag{466}$$

which we know already: they are the Lorentz relation and the two field equations. Obviously, they are equivalent to the variational principle based on S_{CED}. Both descriptions have to be completed by specifying *initial conditions* for the particles and the fields, as well as *boundary conditions* for the latter. We need the first and zeroth derivatives of the position of the particles, and the zeroth derivative for the electromagnetic field.

With the Lagrangian (462) all of classical electrodynamics can be described and understood. For the rest of our exploration of electrodynamics, we look at some specific topics from this vast field.

The energy–momentum tensor and its symmetries of motion

We know from classical mechanics that we get the definition of energy and momentum by using Noether's theorem. In particular, both the definition and the conservation of energy and momentum arise from the Lorentz symmetry of the Lagrangian. For example, we found that relativistic particles have an energy–momentum *vector*. At the point at which the particle is located, it describes its energy and momentum.

Since the electromagnetic field is not a localized entity, like a point particle, but an extended entity, a full description is more involved. In order to describe the energy–momentum of the electromagnetic field completely, we need to know the *flow* of energy and momentum at every point in space, separately *for each direction*. This makes a description with a *tensor* necessary, the so-called *energy–momentum tensor* $\boldsymbol{T}$ of the

Page 550
electromagnetic field.

The electric field times a charge is the force on that charge, or equivalently, its momen-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tum increase per time. The generalization for the full electromagnetic field $\boldsymbol{F}$, and for the full power–force (4-force) vector K is

$$F^{\mu\nu} j_\mu = K^\nu = \partial_\mu \boldsymbol{T}^{\mu\nu} \quad . \tag{467}$$

This short equation, which can also be derived from the Lagrangian, contains a lot of information. In particular, it expresses that every change in energy of the field is the sum of the energy radiated away (via the energy flow described by the Poynting vector $\boldsymbol{S}$) and of changes in the kinetic energy of the charges. The equation also makes a similar statement on the momentum of the electromagnetic field.

The detailed parts of the energy–momentum tensor $\boldsymbol{T}$ are found to be

$$\begin{aligned} \boldsymbol{T}^{\mu\nu} &= \left(\begin{array}{c|c} \text{energy density} & \text{energy flow or momentum density} \\ \hline \text{energy flow or momentum density} & \text{momentum flow density} \end{array}\right) \\ &= \left(\begin{array}{c|c} u & \boldsymbol{S}/c = c\boldsymbol{p} \\ \hline c\boldsymbol{p} & T \end{array}\right) = \left(\begin{array}{c|c} (\varepsilon_0 E^2 + B^2/\mu_0)/2 & \varepsilon_0 c \boldsymbol{E} \times \boldsymbol{B} \\ \hline \varepsilon_0 c \cdot & -\varepsilon_0 E_i E_j - B_i B_j/\mu_0 \\ \boldsymbol{E} \times \boldsymbol{B} & 1/2\delta_{ij}(\varepsilon_0 E^2 + B^2/\mu_0) \end{array}\right) \end{aligned} \tag{468}$$

where $\boldsymbol{S} = \boldsymbol{E} \times \boldsymbol{B}/\mu_0$ is the *Poynting vector* that describes the energy flow density of the electromagnetic field.

We can sum up by stating that in nature, energy and momentum are conserved, if we take into account the momentum and energy of the electromagnetic field. And the energy–momentum tensor shows again that electrodynamics is a gauge invariant description: the energy and momentum values do not depend on gauge choices.

Challenge 1072 e

The energy–momentum tensor, like the Lagrangian, shows that electrodynamics is invariant under *motion inversion*. If all charges change direction of motion – a situation often confusingly called 'time inversion' – they move backwards along the same paths they took when moving forward. Every example of motion due to electric or magnetic causes can also take place backwards.

Challenge 1073 s

On the other hand, everyday life shows many electric and magnetic effects which are not time invariant, such as the breaking of bodies or the burning of electric light bulbs. Can you explain how this fits together?

We also note that charges and mass destroy a symmetry of the vacuum that we mentioned in special relativity: only the vacuum is invariant under conformal transformations. In particular, only the vacuum is invariant under the spatial inversion $r \to 1/r$. Any other physical system does not obey conformal symmetry.

To sum up, electrodynamic motion, like all other examples of motion that we have encountered so far, is deterministic, slower than c, reversible and conserved. This is no big surprise. Nevertheless, two other symmetries of electromagnetism deserve special mention.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 348 Which one is the original landscape? (courtesy NOAA)

What is a mirror?

We will study the strange properties of mirrors several times during our walk. We start with the simplest one first. Everybody can observe, by painting each of their hands in a different colour, that a mirror does *not* exchange right and left, as little as it exchanges up and down; however, a mirror does exchange right and left *handedness*. In fact, it does so by exchanging front and back.

Challenge 1074 s

Electrodynamics give a second answer: a mirror is a device that switches magnetic north and south poles. Can you confirm this with a diagram?

But is it always possible to distinguish left from right? This seems easy: this text is quite different from a ɒɘɿoɿɿiʍ version, as are many other objects in our surroundings. But take a simple landscape. Are you able to say which of the two pictures of Figure 348 is the original?

Astonishingly, it is actually impossible to distinguish an original picture of nature from its mirror image if it does not contain any human traces. In other words, everyday nature is somehow left–right symmetric. This observation is so common that all candidate exceptions, from the jaw movement of ruminating cows to the helical growth of plants, such as hops, or the spiral direction of snail shells, have been extensively studied.*

Page 1287

Challenge 1075 s

Can you name a few more?

The left–right symmetry of nature appears because everyday nature is described by gravitation and, as we will see, by electromagnetism. Both interactions share an important property: substituting all coordinates in their equations by the negative of their values leaves the equations unchanged. This means that for any solution of these equations, i.e., for any naturally occurring system, a mirror image is a possibility that can also occur

* The most famous is the position of the heart. The mechanisms leading to this disposition are still being investigated. Recent research suggests that the oriented motion of the cilia on embryos, probably in the region called the *node*, determines the right–left asymmetry. The deep origin of this asymmetry is not yet elucidated, however.

Ref. 590

Most human bodies have more muscles on the right side for right-handers, such as Albert Einstein and Pablo Picasso, and correspondingly on the left side for left-handers, such as Charlie Chaplin and Peter Ustinov. This asymmetry reflects an asymmetry of the human brain, called lateralization, which is essential to human nature.

Another asymmetry of the human body is the hair whirl on the back of the head; the majority of humans have only one, and in 80 % of the cases it is left turning. But many people have more than one.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

naturally. Everyday nature thus cannot distinguish between right and left. Indeed, there are right *and* left handers, people with their heart on the left *and* others with their heart on the right side, etc.

To explore further this strange aspect of nature, try the following experiment: imagine you are exchanging radio messages with a Martian; are you able to explain to him what right and left are, so that when you meet, you are sure you are talking about the same thing?

Challenge 1076 s

Actually, the mirror symmetry of everyday nature – also called its *parity invariance* – is so pervasive that most animals cannot distinguish left from right in a deeper sense. Most animals react to mirror stimuli with mirror responses. It is hard to teach them different ways to react, and it is possible almost only for mammals. The many experiments performed in this area gave the result that animals have symmetrical nervous systems, and possibly only humans show *lateralization*, i.e., a preferred hand and different uses for the left and the right parts of the brain.

Ref. 591

To sum up this digression, classical electrodynamics is left–right symmetric, or parity invariant. Can you show this using its Lagrangian?

Challenge 1077 s

A concave mirror shows an inverted image; so does a plane mirror if it is partly folded along the horizontal. What happens if this mirror is rotated around the line of sight?

Challenge 1078 s

Why do metals provide good mirrors? Metals are strong absorbers of light. Any strong absorber has a metallic shine. This is true for metals, if they are thick enough, but also for dye or ink crystals. Any material that strongly absorbs a light wavelength also reflects it efficiently. The cause of the strong absorption of a metal is the electrons inside it; they can move almost freely and thus absorb most visible light frequencies.

What is the difference between electric and magnetic fields?

Obviously, the standard answer is that electric fields have sources, and magnetic fields do not; moreover, magnetic fields are small relativistic effects of importance only when charge velocities are high or when electrical fields cancel out.

For situations involving matter, this clear distinction is correct. Up to the present day, no particle with a magnetic charge, called a *magnetic monopole*, has ever been found, even though its existence is possible in several unified models of nature. If found, the action (462) would have to be modified by the addition of a fourth term, namely the magnetic current density. However, no such particle has yet been detected, despite intensive search efforts.

Page 1296

In empty space, when matter is not around, it is possible to take a completely different view. In empty space the electric and the magnetic fields can be seen as two faces of the same quantity, since a transformation such as

$$\begin{aligned} \boldsymbol{E} &\to c\,\boldsymbol{B} \\ \boldsymbol{B} &\to -\boldsymbol{E}/c \end{aligned} \tag{469}$$

called (electromagnetic) *duality* transformation, transforms each vacuum Maxwell equation into the other. The minus sign is necessary for this. (In fact, there are even more such transformations; can you spot them?) Alternatively, the duality transformation transforms $\boldsymbol{F}$ into ${}^*\boldsymbol{F}$. In other words, in empty space we *cannot* distinguish electric from

Challenge 1079 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

magnetic fields.

Matter would be symmetric under duality only if magnetic charges, also called magnetic monopoles, could exist. In that case the transformation (469) could be extended to

$$c\rho_e \to \rho_m \quad , \quad \rho_m \to -c\rho_e \,. \tag{470}$$

It was one of the great discoveries of theoretical physics that even though classical electrodynamics with matter is not symmetric under duality, nature is. In 1977, Claus Montonen and David Olive showed that quantum theory allows duality transformations even *with* the inclusion of matter. It has been known since the 1930s that quantum theory allows magnetic monopoles. We will discover the important ramifications of this result in the final part of the text. This duality turns out to be one of the essential stepping stones that leads to a unified description of motion. (A somewhat difficult question: extending this duality to quantum theory, can you deduce what transformation is found for the fine structure constant, and why the result is so interesting?)

Page 1299

Challenge 1080 d

Duality, by the way, is a symmetry that works *only* in Minkowski space-time, i.e., in space-times of 3 + 1 dimensions. Mathematically, duality is closely related to the existence of quaternions, to the possibility of interpreting Lorentz boosts as rotations in 3 + 1 dimensions, and last, but not least, to the possibility of defining other smooth mathematical structures than the standard one on the space R^4. These mathematical connections are mysterious for the time being; they somehow point to the special role that *four* space-time dimensions play in nature. More details will become apparent in the last part of our mountain ascent.

Could electrodynamics be different?

Any interaction such as Coulomb's rule (428), which acts, for one given observer, between two particles independently of 3-velocity, must depend on 3-velocity for other inertial observers.* It turns out that such an interaction cannot be independent of the 4-velocity either. Such an interaction, even though it would indeed be 3-velocity dependent, would change the rest mass, since the 4-acceleration would not be 4-orthogonal to the 4-velocity.

The next simplest case is the one in which the acceleration is proportional to the 4-velocity. Together with the request that the interaction leaves the rest mass constant, we then recover electrodynamics.

Ref. 592

In fact, the requirements of gauge symmetry and of relativity symmetry also make it impossible to modify electrodynamics. In short, it does not seem possible to have a behaviour different from $1/r^2$ for a classical interaction.

An inverse square dependence implies a vanishing mass of light and light particles, the photons. Is the mass really zero? The issue has been extensively studied. A massive photon would lead to a wavelength dependence of the speed of light in vacuum, to deviations from the inverse square 'law', to deviations from Ampère's 'law', to the existence of longitudinal electromagnetic waves and more. No evidence for these effects has ever

Ref. 593

* This can be deduced from special relativity from the reasoning of page 692 or from the formula in the footnote of page 452.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

been found. A summary of these studies shows that the photon mass is below 10^{-53} kg, or maybe 10^{-63} kg. Some arguments are not universally accepted, thus the limit varies somewhat from researcher to researcher.

A small non-vanishing mass for the photon would change electrodynamics somewhat. The inclusion of a tiny mass poses no special problems, and the corresponding Lagrangian, the so-called *Proca Lagrangian*, has already been studied, just in case.

Ref. 593

Strictly speaking, the photon mass cannot be said to vanish. In particular, a photon with a Compton wavelength of the radius of the visible universe cannot be distinguished from one with zero mass through any experiment. This gives a mass of 10^{-69} kg for the photon. One notes that the experimental limits are still much larger. Photons with such a small mass value would not invalidate electrodynamics as we know it.

Interestingly, a non-zero mass of the photon implies the lack of magnetic monopoles, as the symmetry between electric and magnetic fields is broken. It is therefore important on the one hand to try to improve the experimental mass limit, and on the other hand to explore whether the limit due to the universe's size has any implications for this issue. This question is still open.

The brain: the toughest challenge for electrodynamics

Classical electrodynamics still faces a fascinating experimental and theoretical issue: understanding the process of thought. Physics faces two challenges in this domain. First, physicists must find ways to *model* the thought process. Second, the technology to *measure* the currents in the brain must be extended. In both domains, recent progress has been spectacular.

Important research has been carried out on many levels of thought modelling. For example, research using computer tomography, PET scans and MRI imaging has shown that the distinction between the *conscious* and the *unconscious* can be measured: it has a biological basis. Psychological concepts, such as *repression* of unpleasant thoughts, can actually be observed in brain scans. Modellers of brain mechanisms are learning to take some of the concepts of psychology as descriptions for actual physical processes. This research approach is still in its infancy, but very promising.

On the more fundamental aspects of the working of the brain, such as learning, storage, recognition of shapes, location of sound sources or map formation, modern neurobiology and animal experimentation have allowed to deduce models that allow quantitative predictions. More on this will be told below.

Page ??

On the experimental side, research into magnetoencephalography devices is making rapid progress. The magnetic fields produced by brain currents are as low as 10 fT, which require sensors at liquid helium temperature and a good shielding of background noise. Improving the sensitivity and the spatial resolution of these systems is a central task. Also computer models and algorithms are making rapid progress.

The whole programme would be complete as soon as, in a distant future, a sensitive measuring apparatus could detect what is going on inside the brain and then could deduce or 'read' the thoughts of a person from these measurements. Thought reading might be the most complex of all challenges that science is facing. Clearly, such a feat will require involved and expensive machinery, so that there is no danger for a misuse of the technique. (There are also good reasons to believe that actual thought reading will never

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

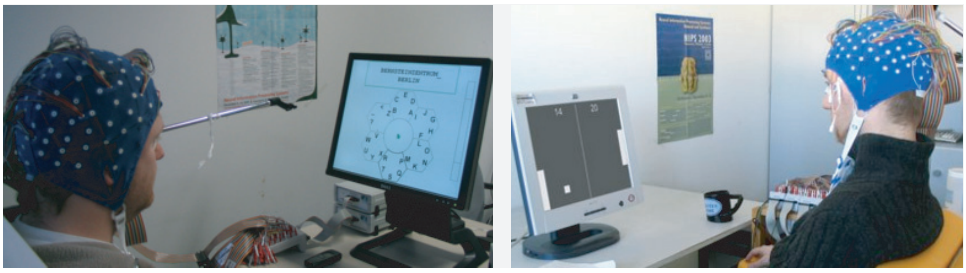

FIGURE 349 Typing a letter and playing video tennis using thought alone (© Fraunhofer FIRST)

be possible in this way, due to the lack of localization of cognitive thought inside the brain and due to the variations in cognitive processing from one person to another.) But the understanding and modelling of the brain will be a useful technology in numerous aspects of daily life, especially for the disabled.

On the path towards thought reading, the small progress that has been achieved so far is already fascinating. Wearing a cap full of electric contacts (thus without any surgery on the brain) and looking at a computer screen, it is now possible to type letters using the power of thought alone. Such a system is shown in Figure 349. The user controls the computer simply by *imagining* that he turns the arrow on the screen with his right hand. The brain currents created by the imagination process are read out and translated into computer commands by an electronic device. The system, based on neural network algorithms, works after only 20 minutes of training with a particular person. In this way, the system allows people who are fully paralysed to communicate with others again. The system is so fast that it allows to play 'mental video tennis' on a computer screen.

Ref. 594

Typing with thought alone is possible because the brain region responsible for the hand is near the skull, so that signals for hand rotation can be read out with sufficient spatial resolution by the electrodes on the cap. Researchers know that resolution problems do not allow to read out the commands for single fingers in this way. For such high resolution tasks, electrodes still need to be *implanted* inside the relevant brain region. However, at present (2008) the functional lifetime for such electrodes is only a few months, so that the dream of controlling machines or even artificial limbs in this way is still distant.

Challenges and fun curiosities about electrodynamics

Not only animals, also plants can feel electric and magnetic fields. At least for magnetic fields, the sensors seem to use very similar mechanisms to those used by animals and bacteria.

Chapter 25

WHAT IS LIGHT?

The nature of light has fascinated explorers of nature since at least the time of the ancient Greeks. In 1865, Maxwell summarized all data collected in the 2500 years before him by deducing a basic consequence of the equations of electrodynamics. He found that in the case of empty space, the equations of the electrodynamic field could be written as

Ref. 595

$$\Box \boldsymbol{A} = 0 \quad \text{or, equivalently} \quad \varepsilon_0\mu_0 \frac{\partial^2\varphi}{\partial t^2} + \frac{\partial^2 A_x}{\partial x^2} + \frac{\partial^2 A_y}{\partial y^2} + \frac{\partial^2 A_z}{\partial z^2} = 0 \,. \tag{471}$$

This is called a *wave equation*, because it admits solutions of the type

Challenge 1087 e

$$\boldsymbol{A}(t, \boldsymbol{x}) = \boldsymbol{A}_0 \sin(\omega t - \boldsymbol{k}x + \delta) = \boldsymbol{A}_0 \sin(2\pi f t - 2\pi \boldsymbol{x}/\lambda + \delta) \,, \tag{472}$$

which are commonly called *plane waves*. Such a wave satisfies equation (471) for any value of *amplitude* A_0, of *phase* δ, and of *angular frequency* ω, provided the *wave vector* $\boldsymbol{k}$ satisfies the relation

$$\omega(\boldsymbol{k}) = \frac{1}{\sqrt{\varepsilon_0\mu_0}} k \quad \text{or} \quad \omega(\boldsymbol{k}) = \frac{1}{\sqrt{\varepsilon_0\mu_0}} \sqrt{\boldsymbol{k}^2} \,. \tag{473}$$

The relation $\omega(\boldsymbol{k})$ between the angular frequency and the wave vector, the so-called *dispersion relation*, is the main property of any type of wave, be it a sound wave, a water wave, an electromagnetic wave, or any other kind. Relation (473) specifically characterizes electromagnetic waves in empty space, and distinguishes them from all other types of waves.*

Equation (471) for the electromagnetic field is *linear* in the field; this means that the sum of two situations allowed by it is itself an allowed situation. Mathematically speaking, any *superposition* of two solutions is also a solution. For example, this means that two waves can cross each other without disturbing each other, and that waves can travel across static electromagnetic fields. Linearity also means that any electromagnetic wave can be described as a superposition of pure sine waves, each of which is described by expression (472). The simplest possible electromagnetic wave, a harmonic plane wave with linear polarization, is illustrated in Figure 351. Note that for this simplest type of waves, the electric and the magnetic field are *in phase*. (Can you prove this experimentally and by calculation?) The surfaces formed by all points of maximal field intensity are

Page 728

* For completeness, we remember that a *wave* in physics is any propagating imbalance.

Page 228

FIGURE 353 Heinrich Hertz (1857–1894)

parallel planes, spaced by (half the) wavelength, which move along the direction of the propagation.

After Maxwell predicted the existence of electromagnetic waves, in the years between 1885 and 1889 Heinrich Hertz* discovered and studied them. He fabricated a very simple transmitter and receiver for 2 GHz waves. Waves around this frequency are used in the last generation of mobile phones. These waves are now called *radio waves*, since physicists tend to call all moving force fields *radiation*, recycling somewhat incorrectly a Greek term that originally meant 'light emission.'

* Heinrich Rudolf Hertz (b. 1857 Hamburg, d. 1894 Bonn), important Hamburger theoretical and experimental physicist. The unit of frequency is named after him. Despite his early death, Hertz was a central figure in the development of electromagnetism, in the explanation of Maxwell's theory and in the unfold-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 354 One of the first transmitting antennas (left) and complete receivers (right) of electromagnetic waves

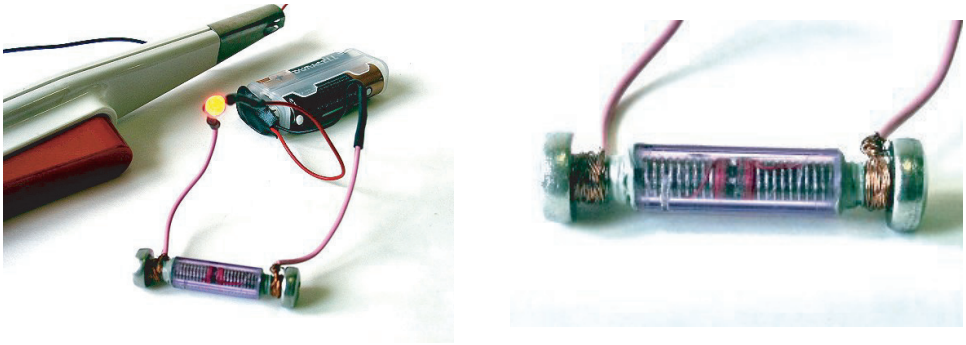

FIGURE 355 The simplest transmitter possible, a gas lighter and a wire, together with the simplest receiver possible, built from a battery pack, a light emitting diode, and a simple coherer made from a ball pen housing, two screws and some metal powder (© Guido Pegna)

Today Hertz's experiment can be repeated in a much simpler way. As shown in Figure 355, a budget of a few euro is sufficient to remotely switch on an light emitting diode with a gas lighter. (After each activation, the coherer has to be gently tapped, in order to get ready for the next activation.) Attaching longer wires as antennas and ground allows this set-up to achieve transmission distances up to 30 m.

Hertz also measured the speed of these waves. In fact, you can also measure the speed at home, with a chocolate bar and a (older) kitchen microwave oven. A microwave oven emits radio waves at 2.5 GHz – not far from Hertz's value. Inside the oven, these waves form standing waves. Just put the chocolate bar (or a piece of cheese) in the oven and switch the power off as soon as melting begins. You will notice that the bar melts at regularly spaced spots. These spots are half a wavelength apart. From the measured wavelength value and the frequency, the speed of light and radio waves simply follows as the product of the two.

If you are not convinced, you can measure the speed directly, by telephoning a friend on another continent, if you can make sure of using a satellite line (choose a low cost

ing of radio communication technology. More about him on page 184.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 356 The primary and secondary rainbow, and the supernumerary bows below the primary bow (© Antonio Martos and Wolfgang Hinz)

provider). There is about half a second additional delay between the end of a sentence and the answer of the friend, compared with normal conversation. In this half second, the signal goes up to the geostationary satellite, down again and returns the same way. This half second gives a speed of $c \approx 4 \cdot 36\,000\,\mathrm{km}/0.5\,\mathrm{s} \approx 3 \cdot 10^5\,\mathrm{km/s}$, which is close to the precise value. Radio amateurs who reflect their signals from the Moon can perform the same experiment and achieve higher precision.

But Maxwell did more. He strengthened earlier predictions that *light* itself is a solution of equation (472) and therefore an electromagnetic wave, albeit with a much higher frequency. Let us see how we can check this.

It is easy to confirm the *wave* properties of light; indeed they were known already long before Maxwell. In fact, the first to suggest that light is a (kind of) wave was, around the year 1678, the important physicist Christiaan Huygens. You can confirm that light is a wave with your own fingers. Simply place your hand one or two centimetres in front of your eye, look towards the sky through the gap between the middle and the index finger and let the two fingers almost touch. You will see a number of dark lines crossing the gap. These lines are the interference pattern formed by the light behind the slit created by the fingers. *Interference* is the name given to the amplitude patterns that appear when several waves superpose.* The interference patterns depend on the spacing between the fingers. This experiment therefore allows you to estimate the wavelength of light, and thus, if you know its speed, its frequency. Can you do this?

Page 93

Challenge 1089 s

Historically, another effect was central in convincing everybody that light was a wave: supernumerary rainbows, the additional bows below the main or primary rainbow. If we look carefully at a rainbow, below the main red–yellow–green–blue–violet bow, we observe weaker, additional green, blue and violet bows. Depending on the intensity of the rainbow, several of these supernumerary rainbows can be observed. They are due to an interference effect, as Thomas Young showed around 1803.** Indeed, the repetition

Ref. 596

Challenge 1088 s

* Where does the energy go in an interference pattern?

** Thomas Young (1773 Milverton–1829), read the bible at two, spoke Latin at four; a doctor of medicine, he became a professor of physics. He introduced the concept of *interference* into optics, explaining Newtonian rings and supernumerary rainbows; he was the first person to determine light's *wavelength*, a concept that he also introduced, and its dependence on colour. He was the first to deduce the three-colour vision explanation of the eye and, after reading of the discovery of polarization, explained light as a transverse wave. In short, Young discovered most of what people learn at secondary school about light. He was a universal talent: he also worked on the deciphering of hieroglyphs, on ship building and on engineering problems.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

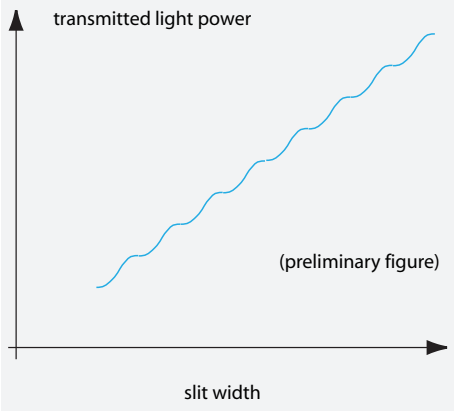

FIGURE 357 The light power transmitted through a slit as function of its width

FIGURE 358 Two Gaussian beams interfering at an angle (© Rüdiger Paschotta)

distance of the supernumerary bows depends on the radius of the average water droplets that form them. (Details about the normal rainbows are given below.) Supernumerary rainbows were central in convincing people that light is a wave. It seems that in those times scientists either did not trust their own fingers, or did not have any.

Page 748

There are many other ways in which the wave character of light can be made apparent. Maybe the most beautiful is an experiment carried out by a team of Dutch physicists in 1990. They simply measured the light transmitted through a *slit* in a metal plate. It turns out that the transmitted intensity depends on the width of the slit. Their surprising result is shown in Figure 357. Can you explain the origin of the unexpected intensity steps in the curve?

Ref. 597

Challenge 1090 ny

Numerous other experiments on the creation, detection and measurement of electromagnetic waves were performed in the nineteenth and twentieth centuries. For example, in 1800, William Herschel discovered *infrared light* using a prism and a thermometer. (Can you guess how?) In 1801, Johann Wilhelm Ritter (1776–1810) a more than colourful figure of natural Romanticism, discovered *ultraviolet light* using silver chloride, AgCl, and again a prism. The result of all these experiments is that electromagnetic waves

Challenge 1091 s

Young collaborated with Fraunhofer and Fresnel. In Britain his ideas on light were not accepted, since Newton's followers crushed all opposing views. Towards the end of his life, his results were finally made known to the physics community by Fresnel and Helmholtz.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 359 The same rainbow in the visible and in the infrared, showing how infrared comes before red (© Stefan Zeiger)

can be primarily distinguished by their wavelength or frequency. The main categories
Page 732 are listed in Table 69. For visible light, the wavelength lies between 0.4 µm (violet) and 0.8 µm (red).

At the end of the twentieth century the final confirmation of the wave character of light became possible. Using quite sophisticated experiments researchers, measured the
Ref. 598 oscillation frequency of light *directly*. The value, between 375 and 750 THz, is so high that its detection was impossible for a long time. But with these modern experiments the
Ref. 599 dispersion relation (473) of light has finally been confirmed in all its details.

Polarization and electromagnetism

We are left with one additional question about light. If light oscillates, in which direction does this occur? The answer is hidden in the parameter $\boldsymbol{A}_0$ in expression (472). Electromagnetic waves oscillate in directions *perpendicular* to their motion. Therefore, even for identical frequency and phase, waves can still differ: they can have different *polarization* directions. For example, the polarization of radio transmitters determines whether radio antennas of receivers have to be kept horizontal or vertical. Also for light, polarization is easily achieved, e.g. by shining it through a stretched plastic film. When the polarization of light was discovered in 1808 by the French physicist Louis Malus (1775–1812), it definitively established the wave nature of light. Malus discovered it when he looked at the strange double images produced by calcite, a transparent crystal found in many minerals. Calcite ($CaCO_3$) splits light beams into two – it is *birefringent* – and polarizes them differently. That is the reason that calcite is part of every crystal collection.

If you ever get hold of a piece of transparent calcite, do look through it at something

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

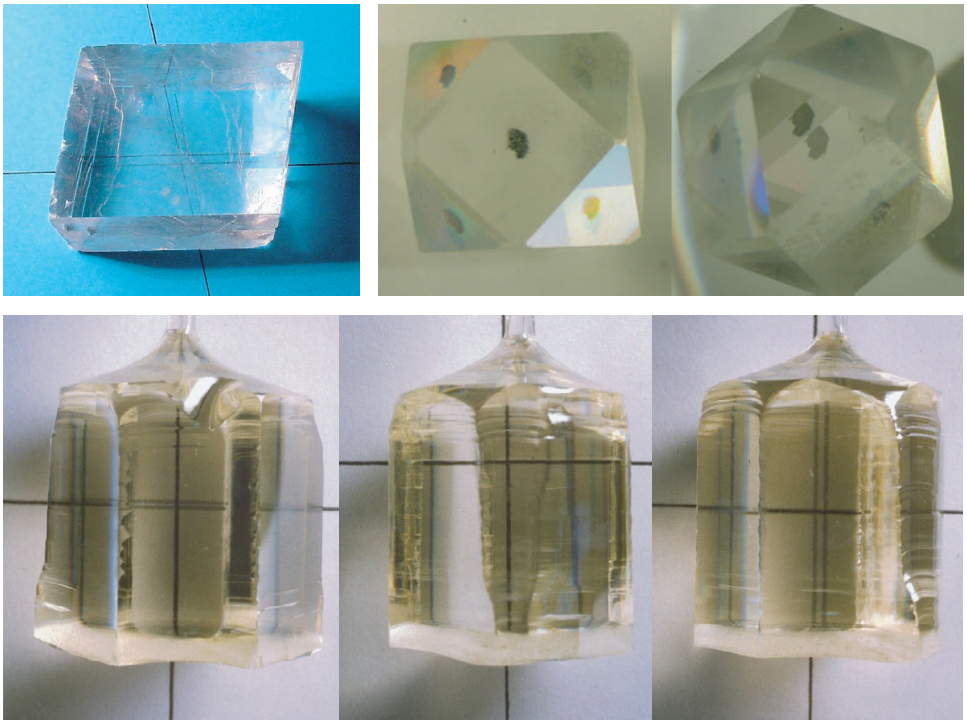

FIGURE 360 Birefringence in crystals: *calcite* lying on crossed lines (top left, crystal size around 4 cm), *rutile* lying on an ink spot, photographed along the optical axis (middle) and at an angle to it (top right, crystal size around 1 cm), and an octagonal sodium vanadate crystal doped with manganese, showing *three* different behaviours (bottom, crystal diameter 1.9 cm) (© Roger Weller/Cochise College, Brad Amos, Martin Pietralla)

written on paper. Figure 360 shows two examples. (Can you show that *trirefringence*, if defined as the appearance of three images, cannot exist?) Challenge 1092 d

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

By the way, the human eye is almost unable to detect polarization, in contrast to the eyes of many insects, spiders and certain birds. Honey bees use polarization to deduce the position of the Sun, even when it is hidden behind clouds, and use the effect for navigation. Some beetles of the genus *Scarabeus* even use the polarization of moonlight for navigation, and many insects use polarization of sunlight to distinguish water surfaces from mirages. (Can you find out how?) But in 1844, the Austrian mineralogist Wilhelm Haidinger discovered that the human eye has the same ability: there is a way to observe the polarization of light with the unaided human eye. The best way to observe the effect is by looking at a distance of about an arms's length on a white LCD screen and slowly tilt your head. You will note an *extremely faint* yellow or yellow-blue pattern, about two finger's wide, that is superimposed on the white background. This pattern is called *polarization brush* or *Haidinger's brush*. A rough illustration is given in Figure 361. The weak effect disappears after a few seconds if the head stops rotating along the line of sight. Haidinger's brush is due to the birefringence of the cornea and the lens of the human eye, together with the morphology of the macula lutea. The cornea acts as a radially oriented, colour-dependent polarizer, whereas the yellow spot acts as a radially oriented analyser. In short, the human eye is indeed able to see the directions in which the electric and magnetic field of light are oscillating.

Ref. 600 Challenge 1093 s Ref. 601 Ref. 602

Haidinger's brush, being yellow, is also visible in the blue sky, provided that the air is clear. (Indeed, it is easily drowned out by multiple scattering, and therefore provides a test of atmospheric transparency.) In the sky, Haidinger's brush is barely the size of a thumbnail at arm's length. (The angular size is the angular size of the macula.) The yellow arm of the cross points to the Sun, if you look about 90° away from it, high in the sky. To see it really clearly, hold a polaroid (or polaroid sunglasses) up to look through, and rotate it about the line of sight.

Note that all possible polarizations of light form a continuous set. However, a general plane wave can be seen as the superposition of two orthogonal, linearly polarized waves with different amplitudes and different phases. Most books show pictures of plane, linearized electrodynamic waves. Essentially, electric fields look like water waves generalized to three dimensions, the same for magnetic fields, and the two are perpendicular to each other. Can you confirm this?

Challenge 1094 ny

Interestingly, a generally polarized plane wave can also be seen as the superposition of right and left *circularly polarized waves*. An illustration of a circularly polarized wave is given in Figure 362.

So far it is clear that light is a wave. To confirm that light waves are indeed *electromagnetic* is more difficult. The first argument was given by Bernhard Riemann in 1858;* he deduced that any electromagnetic wave must propagate with a speed c given by

$$c = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \,. \tag{474}$$

Already ten years before him, in 1848, Kirchoff had noted that the measured values on

* Bernhard Riemann (b. 1826 Breselenz, d. 1866 Selasca), important German mathematician. A genial mathematician, he also studied curved space, providing several of the mathematical and conceptual foundations of general relativity, but then died at an early age.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

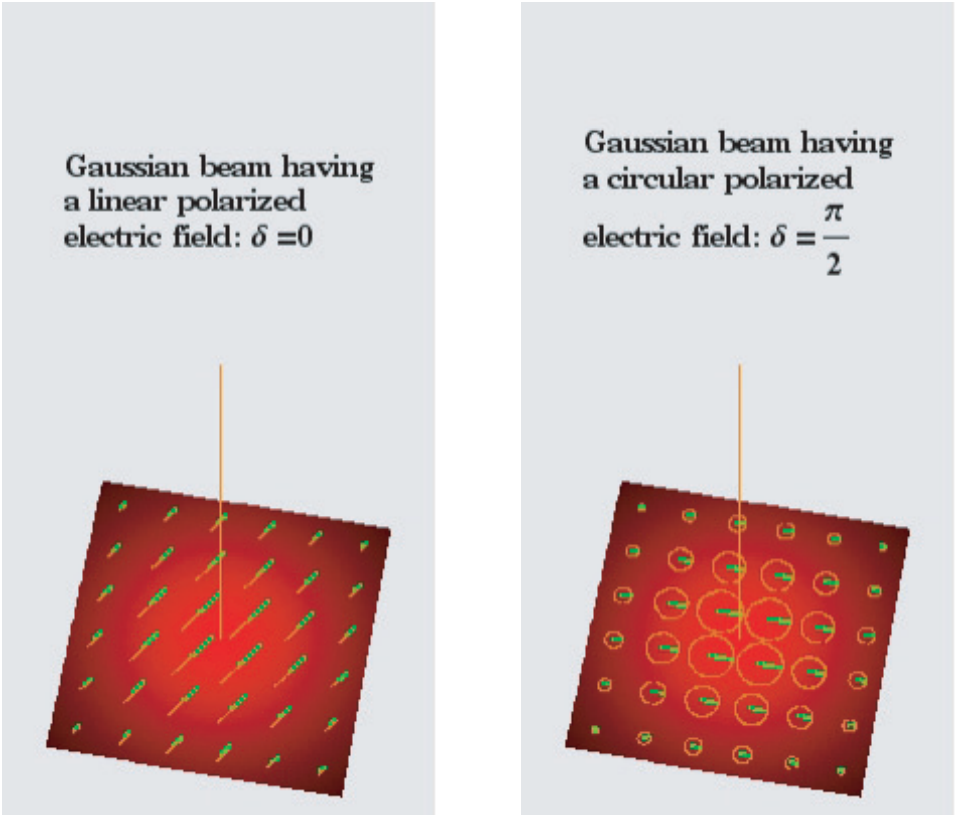

FIGURE 362 The electric field of a Gaussian, linearly polarized electromagnetic wave (a beam) next to a Gaussian, circularly polarized beam (© José Antonio Díaz Navas)

both sides agreed within measurement errors. A few years later, Maxwell gave a beautiful confirmation by deducing the expression from equation (473). You should be able to repeat the feat. Note that the right-hand side contains electric and magnetic quantities, and the left-hand side is an optical entity. Riemann's expression thus unifies electromagnetism and optics.

Challenge 1095 ny

Of course, people were not yet completely convinced. They looked for more ways to show that light is electromagnetic in nature. Now, since the evolution equations of the electrodynamic field are linear, additional electric or magnetic fields alone do not influence the motion of light. On the other hand, we know that electromagnetic waves are emitted only by accelerated charges, and that all light is emitted from matter. It thus follows that matter is full of electromagnetic fields and accelerated electric charges. This in turn implies that the influence of matter on light can be understood from its internal electromagnetic fields and, in particular, that subjecting matter to an *external* electromagnetic field should change the light it emits, the way matter interacts with light, or generally, the material properties as a whole.

Challenge 1096 e

Searching for effects of electricity and magnetism on matter has been a main effort

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of physicists for over a hundred years. For example, electric fields influence the light transmission of oil, an effect discovered by John Kerr in 1875.* The discovery that certain gases change colour when subject to a field yielded several Nobel Prizes for physics. With time, many more influences on light-related properties by matter subjected to fields were found. An extensive list is given in the table on page 787. It turns out that apart from a few exceptions the effects can *all* be described by the electromagnetic Lagrangian (462), or equivalently, by Maxwell's equations (466). In summary, classical electrodynamics indeed unifies the description of electricity, magnetism and optics; all phenomena in these fields, from the rainbow to radio and from lightning to electric motors, are found to be different aspects of the evolution of the electromagnetic field.

The slowness of progress in physics

The well-known expression

$$c = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \tag{475}$$

for the speed of light is so strange that we should be intrigued when we see it. Something essential is missing. The expression states that the speed c is *independent* of the proper motion of the observer measuring the electromagnetic field. In other words, the speed of light is independent of the speed of the lamp and independent of the speed of the observer. All this is contained in expression (475). This is in complete contrast, for example, with the speed of water ejected from a water hose: that speed depends both on the speed of the hose and on the speed of the observer. Incredibly, for five decades, *nobody* explored this strange result, until Lorentz did so. In this way, the theory of relativity remained undiscovered for two generations. As in so many other cases, the progress of physics was much slower than necessary.

The invariance of the speed of light is the essential point that distinguishes special relativity from Galilean physics. In this sense, any electromagnetic device, making use of expression (475), is a working proof of special relativity.

Another look at electromagnetic radiation

Electromagnetic waves of lower frequency are commonly also used to transmit mobile phone signals, and television, radio and satellite programs. Like light, radio waves are due to moving electrons. In everyday life, light is (usually) generated by electrons accelerated inside atoms or molecules. Radio waves are generated by electrons that are accelerated in metals.

Radio waves can easily carry signals round the Earth. Indeed, it turns out that radio waves decay in field strength as $1/r$, where r is the distance from the source. They decay much more slowly than static fields, for which the field strength decays as $1/r^2$.

The slow $1/r$ dependence can be understood qualitatively from the drawing shown in Figure 363. It shows the electric field around a charged particle that undergoes the simplest possible accelerated motion: a bounce on a wall. In fact, the last diagram is sufficient to show that the transverse field decays as $1/r$. Can you deduce the dependence? Challenge 1097 d

If we perform the construction for a charge that undergoes repeated bounces, we get a diagram with regular kinks in the field lines that move out from the source. For a charge undergoing harmonic motion, we get the motion shown in Figure 364. It shows the mech-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

anism of the simplest antenna (or light source) one can imagine.

The magnitude of the transverse electric field can be used to deduce the relation between the acceleration a of a charge q and the radiated electromagnetic power P. First, the transverse electric field (calculated in the last exercise) has to be squared, to give the local electric energy density. Then it has to be doubled, to include magnetic energy. Finally, one has to integrate over all angles; this gives a factor of 2/3. In total one gets

$$P = \frac{q^2 a^2}{6\pi\varepsilon_0 c^3} \,. \tag{476}$$

The total radiated power P depends on the square of the acceleration and on the square of the charge that is being accelerated. This is the so-called *Larmor formula*. It shows why radio transmitters need power supplies.

How does the world look when riding on a light beam?

At the end of the nineteenth century, the teenager Albert Einstein read a book discussing the speed of light. The book asked what would happen if an observer moved at the same speed as light.* Einstein thought much about the issue, and in particular, asked himself what kind of electromagnetic field he would observe in that case. Einstein later explained that this Gedanken experiment convinced him already at that young age that *nothing* could travel at the speed of light, since the field observed would have a property not found in nature. Can you find out which one he meant?

Challenge 1098 s

Riding on a light beam situation would have strange consequences.

— You would have no mirror image, like a vampire.
— Light would not be oscillating, but would be a static field.
— Nothing would move, like in the tale of sleeping beauty.

But also at speeds *near* the velocity of light observations would be interesting. You would:

— see a lot of light coming towards you and almost no light from the sides or from behind; the sky would be blue/white in the front and red/black behind;
— observe that everything around happens very very slowly;
— experience the smallest dust particle as a deadly bullet.

Challenge 1099 s

Can you think of more strange consequences? It is rather reassuring that our planet moves rather slowly through its environment.

Does light always travel in a straight line?

Usually light moves in straight lines. Indeed, we even use light to *define* 'straightness.' However, there are a number of exceptions that every expert on motion should know.

Ref. 604

In diluted sugar syrup, light beams curve, as shown in Figure 365. The reason is that in such an experiment, the sugar concentration changes with depth. More detailed ob-

* This was the book series in twenty volumes by Aaron Bernstein, *Naturwissenschaftliche Volksbücher*, Duncker, 1873-1874. The young Einstein read them, between 1892 and 1894, with 'breathless attention', as he wrote later on.

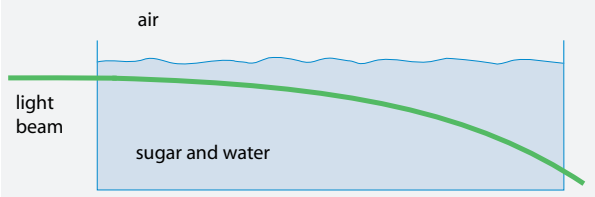

FIGURE 365 Diluted sugar syrup bends light

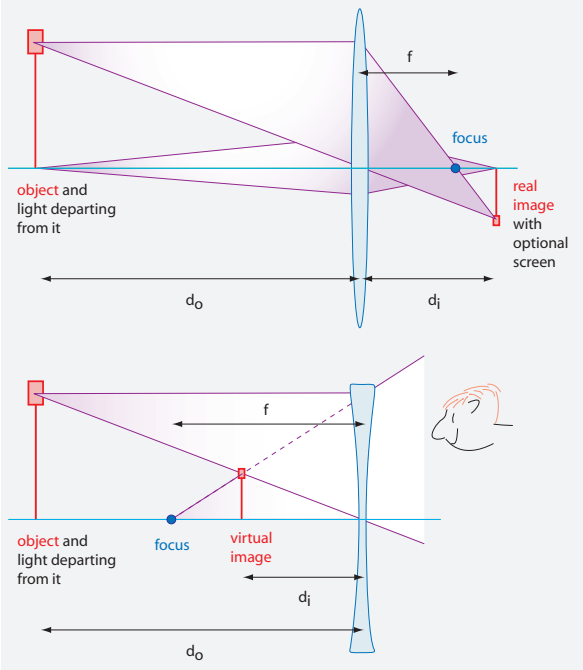

FIGURE 366 The real image produced by a converging lens (if used in the way shown) and the virtual image produced by a diverging lens

servation show that a light beam is bent at every material change it encounters on its path. This effect, called *refraction*, is quite common. Refraction changes the appearance of the shape of our feet when we are in the bath tub; refraction also makes aquaria seem less deep than they actually are. Refraction is a consequence of the change of light speed from material to material. Are you able to explain refraction, and thus explain the syrup effect?

Challenge 1100 s

Refraction is chiefly used in the design of lenses. Using glass instead of water, one can produce curved surfaces, so that light can be *focused*. Focusing devices can be used to produce images. The two main types of lenses, with their focal points and the images they produce, are shown in Figure 366. When an object is put between a converging lens and its focus, the lens works as a *magnifying glass*. The lens then produces a *real* image, i.e., an image that can be projected onto a screen. In all other cases lenses produce so-called *virtual images*: such images can be seen with the eye but not be projected onto a screen. Figure 366 also allows one to deduce the *thin lens formula* that connects the lengths d_o,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

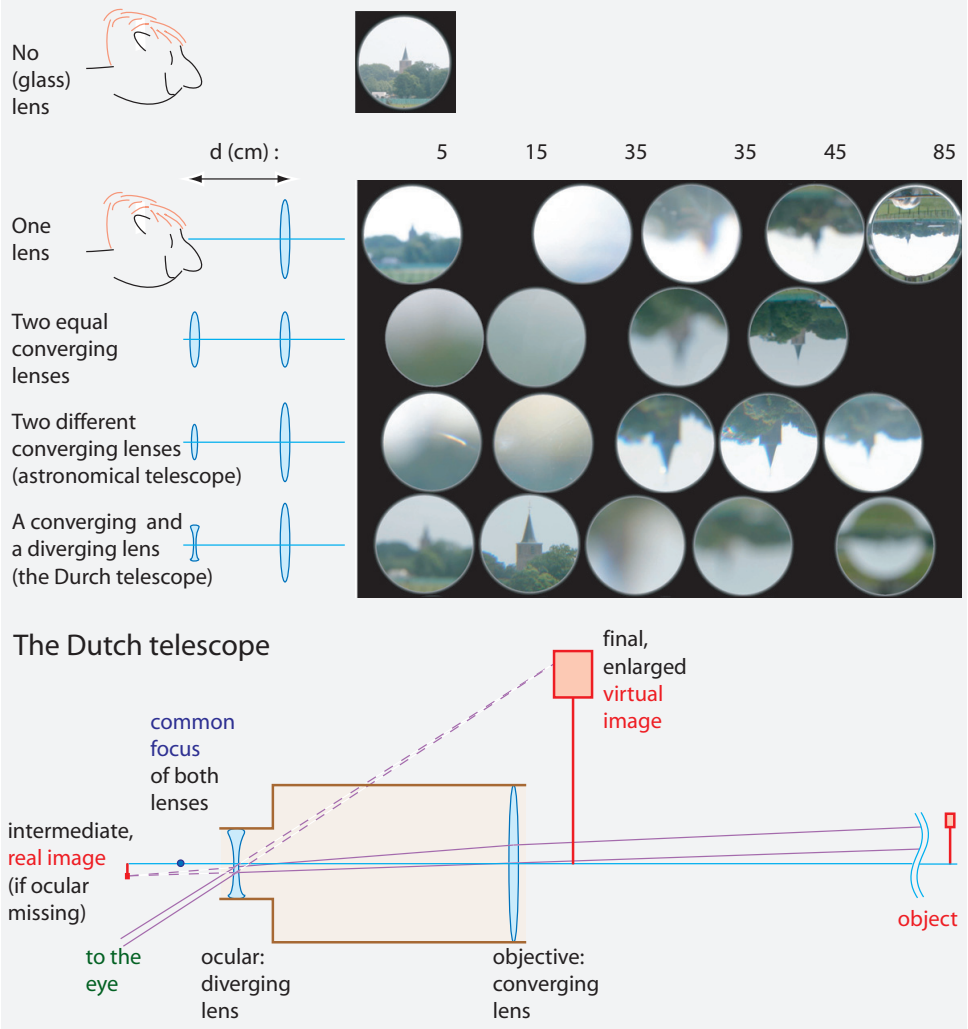

FIGURE 367 Lens refraction as the basis of the telescope: above, the experiments with lenses that lead to the development of the telecope: the object to watch compared with the images produced by a single coonverging lens, by two equal lenses, by two different converging lenses in the astronomical telescope, and by a diverging and a converging lens in the Dutch telescope, at various distances from the eye; below, the explanation of the Dutch telescope (photographs © Eric Kirchner)

Challenge 1101 s d_o and f. What is it?

Even though glasses and lenses have been known since antiquity, the Middle Ages had to pass by before two lenses were combined to make more elaborate optical instruments.

Ref. 605 The various effects that can be observed with one or two lenses are shown in Figure 367. The *telescope* was invented in, or just before, 1608 by the German–Dutch lens grinder Johannes Lipperhey (*c.* 1570–1619), who made a fortune by selling it to the Dutch military. When Galileo heard about the discovery, he quickly took it over and improved it. Already in 1609, Galileo performed the first astronomical observations; they made him

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 368 The glory produced by the droplets in a cloud

world-famous. The *Dutch telescope* design has a short tube yielding a bright and upright image, and its magnification is the ratio of the focal distances of the two lenses. It is still used today in opera glasses. Over the years, many other ways of building telescopes have been developed; in particular, many modern high-performance telescopes use mirrors. Since mirrors are cheaper and easier to fabricate for high-precision imaging, most large telescopes have a mirror instead of the first lens.

Challenge 1102 e

Ref. 606

By the way, telescopes also exist in nature. Many spiders have two types of eyes. The large ones, made to see distant objects, have two lenses arranged in the same way as in the telescope.

Another way to combine two lenses leads to the *microscope*. Can you explain to a non-physicist how a microscope works?* Werner Heisenberg almost failed his Ph.D. exam because he could not. The problem is not difficult, though. Indeed, the inventor of the microscope was an autodidact of the seventeenth century: the Dutch technician Antoni van Leeuwenhoek (1632–1723) made a living by selling over five hundred of his microscopes to his contemporaries. (This is a somewhat nasty remark: Van Leeuwenhoek only used one lens, not two, as in the modern microscope.)

Challenge 1103 s

No ray tracing diagram, be it that of a simple lens, of a telescope or a microscope, is really complete if the eye, with its lens and retina, is missing. Can you add it and convince yourself that these devices really work?

Challenge 1104 ny

Refraction is usually colour-dependent. For that reason (and also in order to compensate the other lens imaging errors called *aberrations*) microscopes or photographic cameras have *several* lenses, made of different materials. They compensate the colour effects, which otherwise yield coloured image borders. The colour dependence of refraction in water droplets is also the basis of the rainbow, as shown below, and refraction in ice crys-

Page 748

* If not, read the beautiful text by Elizabeth M. Slater & Henry S. Slater, *Light and Electron Microscopy*, Cambridge University Press, 1993.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 369 Watching this graphic at higher magnification shows the dispersion of the human eye: the letters float at different depths

tals in the atmosphere is at the basis of the halos and the many other light patterns often seen around the Sun and the Moon. Ref. 607

Also the human eye has colour-dependent refraction. (It is well known that for the working of the eye, the curvature of the cornea is more important than the refractive power of the lens, because the lens is embedded in a medium with nearly the same index of refraction, thus limiting the effects of refraction.) The colour-dependent refraction is not corrected in the eye, but in the brain. Indeed, the dispersion of the eye lens can be noticed if this correction is made impossible, for example when red or blue letters are printed on a black background, as shown in Figure 369. One gets the impression that the red letters float in front of the blue letters. Can you show how dispersion leads to the floating effect? Challenge 1105 s

A second important observation is that light goes around corners. This effect was called *diffraction* by Francesco Grimaldi, in his text *Physico-mathesis de lumine*, published in 1665. Ref. 608 Grimaldi studied shadows very carefully. He found out what everybody now learns in high school: light goes around corners in the same way that sound does, and light diffraction is due to the wave nature of light. (Newton got interested in optics after he read Grimaldi; he then wrongly dismissed his conclusions.)

Because of diffraction, it is impossible to produce strictly parallel light beams. For example, every laser beam diverges by a certain minimum amount, called the *diffraction limit*. Maybe you know that the world's most expensive Cat's-eyes are on the Moon, where they have been deposited by the Lunokhod and the Apollo missions. Ref. 609 Can you determine how wide a laser beam with minimum divergence has become when it arrives at the Moon and returns back to Earth, assuming that it was 1 m wide when it left Earth? How wide would it be when it came back if it had been 1 mm wide at the start? Challenge 1106 s In short, diffraction and the impossibility of parallel beams confirms that light is a wave.

Diffraction implies that there are no perfectly sharp images: there exists a *limit on resolution*. This is true for every optical instrument, including the eye. The resolution of the eye is between one and two minutes of arc, i.e., between 0.3 and 0.6 mrad. The limit is partly due to the finite size of the pupil. (That is why squinting helps to see more sharply.) In practice, the resolution of the eye is often limited by chromatic aberrations and shape imperfections of the cornea and lens. (Can you check the numbers and their interpretation by calculation? Is it true that the number of cones in the eye is tuned exactly to its resolution?) Therefore, for example, there is a maximum distance at which humans can distinguish the two headlights of a car. Can you estimate it? Challenge 1107 d Challenge 1108 s

Resolution limits also make it impossible to see the Great Wall in northern China from the Moon, contrary to what is often claimed. In the few parts that are not yet in ruins, the wall is about 6 metres wide, and even if it casts a wide shadow during the morning

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 370 In certain materials, light beams can spiral around each other

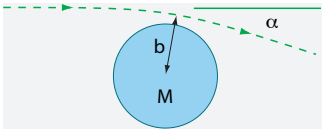

FIGURE 371 Masses bend light

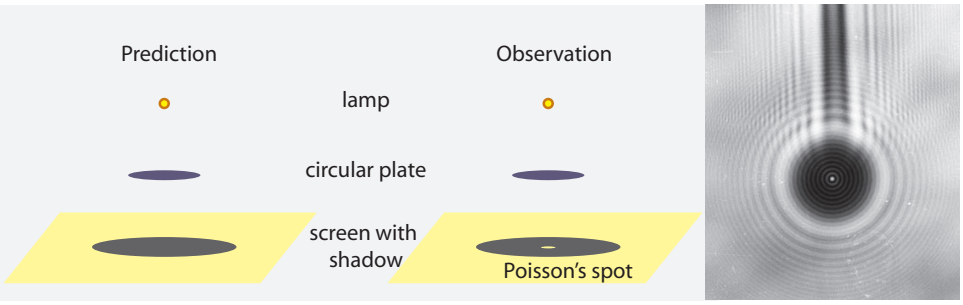

FIGURE 372 Shadows show that light is a wave: the naive expectation (left), neglecting the wave idea, and the actual observation (middle and right) of the shadow of a circular object (photo © Christopher Jones)

or the evening, the angle it subtends is way below a second of arc, so that it is completely invisible to the human eye. In fact, three different cosmonauts who travelled to the Moon performed careful searches and confirmed that the claim is absurd. The story is one of the most tenacious urban legends. (Is it possible to see the Wall from the space shuttle?) The largest human-made objects are the polders of reclaimed land in the Netherlands; they *are* visible from outer space. So are most large cities as well as the highways in Belgium at night; their bright illumination makes them stand out clearly from the dark side of the Earth.

Ref. 610

Challenge 1109 ny

Refraction also leads to a famous effect where light seems to go around corners: the *mirage*. Figure 373 shows photographs of a *superior* mirage, which relies an inversion or boundary layer in the atmosphere above the object and the observer, and a *inferior* mirage, due to a hot layer of air just above the ground. Inferior mirages are also regularly seen on hot highways. All mirage types are due to refraction; their detailed appearance depends on the given temperature profile in the air, and the relative heights of the observer, the inversion layer and the observed object.

Ref. 611

Diffraction has the consequence that behind a small disc illuminated along its axis, the centre of the shadow shows, against all expectations, a bright spot, as shown in Figure 372. This 'hole' in the shadow was predicted in 1819 by Denis Poisson (1781–1840) in order to show to what absurd consequences the wave theory of light would lead. He had just read the mathematical description of diffraction developed by Augustin Fresnel* on the

* Augustin Jean Fresnel (1788–1827), engineer and part time physicist; he published in 1818 his great paper on wave theory for which he got the prize of the French Academy of Sciences in 1819. (The 's' in his name is silent.) To improve his finances, he worked in the commission responsible for lighthouses, for which he developed the well-known Fresnel lens. He died prematurely, partly of exhaustion due to overwork.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

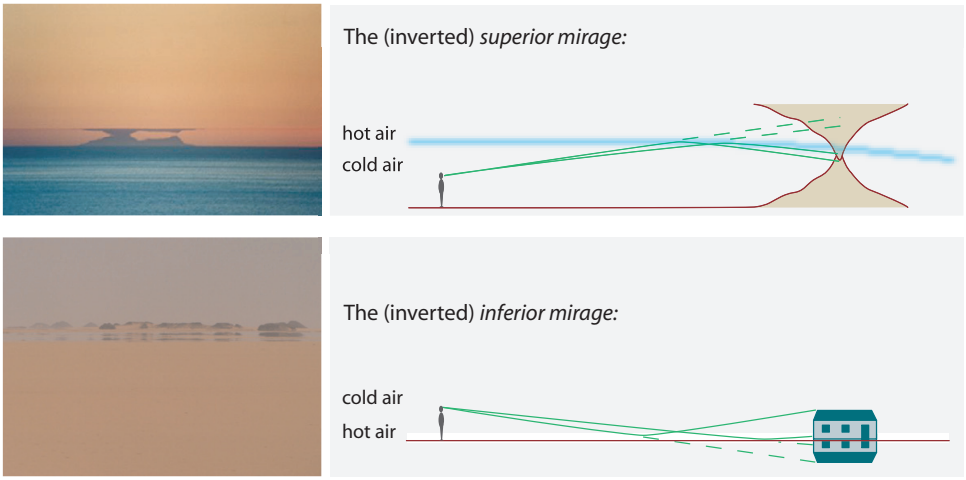

FIGURE 373 The basis of mirages is an effective reflection due to refraction in a hot air layer; it can lead to spectacular effects, such as the inverted superior mirage (top left and right), the inferior image (bottom left and right) right) (photographs © Thomas Hogan and Andy Barson)

basis of the wave description of light. But shortly afterwards, François Arago (1786–1853) actually observed Poisson's spot, converting Poisson, making Fresnel famous and starting the general acceptance of the wave properties of light.

Additional electromagnetic fields usually do not influence light directly, since light has no charge and since Maxwell's equations are linear. But in some materials the equations are non-linear, and the story changes. For example, in certain photorefractive materials, two nearby light beams can even *twist* around each other, as was shown by Segev and coworkers in 1997.

Ref. 612

A final way to bend light is gravity, as discussed already in the chapters on universal gravity and on general relativity. The effect of gravity between two light beams was also discussed there.

Page 602

A light ray that is reflected or scattered also changes direction, though it is debatable whether it is appropriate to call these processes examples of bending of light. In any case, both scattering and reflection are important: without them, we would not see almost anything around us. Seeing is detection of scattered light.

In summary, light travels straight only if it travels *far from matter*. In everyday life, 'far' simply means more than a few millimetres, because all gravitational and electromagnetic effects are negligible at these distances, mainly due to light's truly supersonic speed. However, as we have seen, in some cases larger distances from matter are necessary to ensure undisturbed motion of light.

The concentration of light

If one builds a large lens or a curved mirror, one can collect the light of the Sun and focus it on a single spot. Everybody has used a converging lens as a child to burn black spots on newspapers in this way. In Spain, wealthier researchers have even built a curved mirror as large as a house, in order to study solar energy use and material behaviour at

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 374 The last mirror of the solar furnace at Odeillo, in the French Pyrenees (© Gerhard Weinrebe)

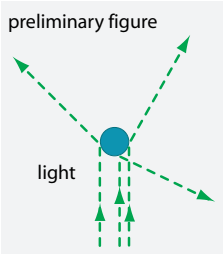

FIGURE 375 Levitating a small glass bead with a laser

high temperature. Essentially, the mirror provides a cheap way to fire an oven in its focus. (And 'focus' is the Latin word for 'hearth').

Kids find out quite rapidly that large lenses allow them to burn things more easily than small ones. It is obvious that the Spanish site is the record holder in this game. However, building a larger mirror does not make sense. Whatever its size may be, such a set-up cannot reach a higher temperature than that of the original light source. The surface temperature of the Sun is about 5800 K; indeed, the highest temperature reached so far is about 4000 K. Are you able to show that this limitation follows from the second law of thermodynamics?

Ref. 654

Challenge 1110 ny

In short, nature provides a *limit* to the concentration of light energy. In fact, we will encounter additional limits in the course of our exploration.

Can one touch light?

If a little glass bead is put on top of a powerful laser, the bead remains suspended in mid-air, as shown in Figure 375.* This means that light has momentum. Therefore, contrary to what we said in the beginning of our mountain ascent, images *can* be touched! In fact, the ease with which objects can be pushed even has a special name. For stars, it is called the *albedo*, and for general objects it is called the *reflectivity*, abbreviated as r.

Like each type of electromagnetic field, and like every kind of wave, light carries energy; the energy flow T per surface and time is

Challenge 1111 e

* The heaviest object that has been levitated with a laser had a mass of 20 g; the laser used was enormous, and the method also made use of a few additional effects, such as shock waves, to keep the object in the air.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

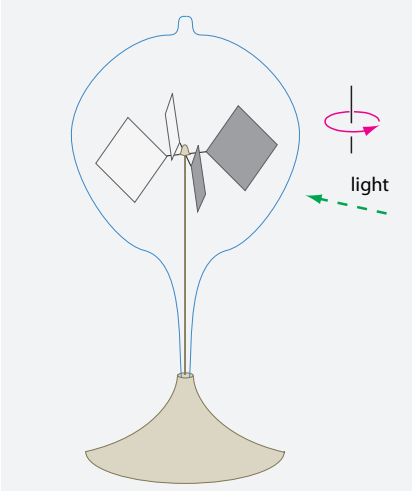

FIGURE 376 A commercial light mill turns *against* the light

$$\boldsymbol{T} = \frac{1}{\mu_0}\boldsymbol{E} \times \boldsymbol{B} \quad \text{giving an average} \quad \langle T \rangle = \frac{1}{2\mu_0} E_{\max} B_{\max} \,. \tag{477}$$

Obviously, light also has a momentum P. It is related to the energy E by

$$P = \frac{E}{c} \,. \tag{478}$$

Challenge 1112 e As a result, the pressure p exerted by light on a body is given by

$$p = \frac{T}{c}(1 + r) \tag{479}$$

where for black bodies we have that a reflectivity $r = 0$ and for mirrors $r = 1$; other bodies have values in between. What is your guess for the amount of pressure due to sunlight on Challenge 1113 s a black surface of one square metre? Is this the reason that we feel more pressure during the day than during the night?

In fact, rather delicate equipment is needed to detect the momentum of light, in other words, its radiation pressure. Already in 1619, Johannes Kepler had suggested in *De cometis* that the tails of comets exist only because the light of the Sun hits the small dust particles that detach from it. For this reason, the tail always points *away* from the Challenge 1114 e Sun, as you might want to check at the next opportunity. Today, we know that Kepler was right; but proving the hypothesis is not easy.

In 1873, William Crookes* invented the *light mill radiometer*. He had the intention of demonstrating the radiation pressure of light. The light mill consists of four thin plates, black on one side and shiny on the other, that are mounted on a vertical axis, as shown

* William Crookes (b. 1832 London, d. 1919 London), English chemist and physicist, president of the Royal Society, discoverer of thallium, and believer in spiritualism.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 377 The tail of comet McNaught, photographed in Australia in 2007 (© Flagstaffotos)

in Figure 376. However, when Crookes finished building it – it was similar to those sold in shops today – he found, like everybody else, that it turned in the wrong direction, namely with the shiny side towards the light! (Why is it wrong?) You can check it by yourself by shining a laser pointer on to it. The behaviour has been a puzzle for quite some time. Explaining it involves the tiny amount of gas left over in the glass bulb and takes us too far from the topic of our mountain ascent. It was only in 1901, with the advent of much better pumps, that the Russian physicist Pyotr/Peter Lebedew managed to create a sufficiently good vacuum to allow him to measure the light pressure with such an improved, true radiometer. Lebedew also confirmed the predicted value of the light pressure and proved the correctness of Kepler's hypothesis about comet tails. Today it is even possible to build tiny propellers that start to turn when light shines on to them, in exactly the same way that the wind turns windmills.

Challenge 1115 s

Ref. 613

Ref. 614

Ref. 615

But light cannot only touch and be touched, it can also *grab*. In the 1980s, Arthur Ashkin and his research group developed actual *optical tweezers* that allow one to grab, suspend and move small transparent spheres of 1 to 20 μm diameter using laser beams. It is possible to do this through a microscope, so that one can also observe at the same time what is happening. This technique is now routinely used in biological research around the world, and has been used, for example, to measure the force of single muscle fibres, by chemically attaching their ends to glass or Teflon spheres and then pulling them apart with such optical tweezers.

Ref. 616

But that is not all. In the last decade of the twentieth century, several groups even managed to *rotate* objects, thus realizing actual *optical spanners*. They are able to rotate particles at will in one direction or the other, by changing the optical properties of the

Ref. 616

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

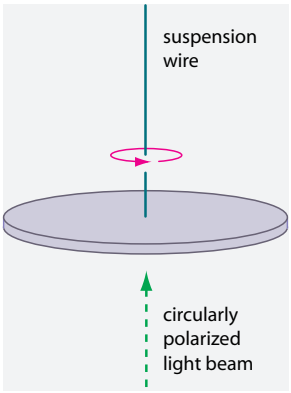

FIGURE 378 Light can rotate objects

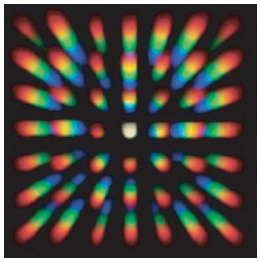

FIGURE 379 Umbrellas decompose white light

laser beam used to trap the particle.

In fact, it does not take much to deduce that if light has linear momentum, circularly polarized light also has *angular* momentum. In fact, for such a wave the angular momentum $\boldsymbol{L}$ is given by

$$\boldsymbol{L} = \frac{E_{\text{nergy}}}{\omega} \,. \tag{480}$$

Challenge 1116 e
Ref. 617
Challenge 1117 ny

Equivalently, the angular momentum of a wave is $\lambda/2\pi$ times its linear momentum. For light, this result was already confirmed in the early twentieth century: a light beam can put certain materials (which ones?) into rotation, as shown in Figure 378. Of course, the whole thing works even better with a laser beam. In the 1960s, a beautiful demonstration was performed with microwaves. A circularly polarized microwave beam from a maser – the microwave equivalent of a laser – can put a metal piece absorbing it into rotation. Indeed, for a beam with cylindrical symmetry, depending on the sense of rotation, the angular momentum is either parallel or antiparallel to the direction of propagation. All these experiments confirm that light also carries angular momentum, an effect which will play an important role in the quantum part of our mountain ascent.

We note that not for all waves angular momentum is energy per angular frequency. This is only the case for waves made of what in quantum theory will be called spin 1 particles. For example, for gravity waves the angular momentum is *twice* this value, and they are therefore expected to be made of spin 2 particles.

Ref. 618

What does this mean for the comet tails mentioned above? The issue was settled definitely in 1986. A satellite was shot up to an altitude of 110 000 km and made to release a cloud of barium. The cloud was visible from the Earth, and it soon developed a tail that was visible from Earth: that was the first artificial comet. It turns out that comet tails shapes are partly due to hitting photons, partly due to the solar wind, and partly to magnetic fields.

Challenge 1118 s

In summary, light can touch and be touched. Obviously, if light can rotate bodies, it can also *be* rotated. Could you imagine how this can be achieved?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

War, light and lies

From the tiny effects of equation (479) for light pressure we deduce that light is not an efficient tool for hitting objects. On the other hand, light is able to heat up objects, as we can feel in the sun or when the skin is touched by a laser beam of about 100 mW or more. For the same reason even cheap laser pointers are dangerous to the eye.

In the 1980s, and again in 2001, a group of people who had read too many science fiction novels managed to persuade the military – who also indulge in this habit – that lasers could be used to shoot down missiles, and that a lot of tax money should be spent on developing such lasers. Using the definition of the Poynting vector and a hitting time of about 0.1 s, are you able to estimate the weight and size of the battery necessary for such a device to work? What would happen in cloudy or rainy weather?

Challenge 1119 ny

Other people tried to persuade NASA to study the possibility of propelling a rocket using emitted light instead of ejected gas. Are you able to estimate whether this is feasible?

Challenge 1120 ny

What is colour?

We saw that radio waves of certain frequencies are visible. Within that range, different frequencies correspond to different colours. (Are you able to convince a friend about this?) But the story does not finish here. Numerous colours can be produced either by a single wavelength, i.e., by *monochromatic* light, or by a *mixture* of several different colours. For example, standard yellow can be, if it is pure, an electromagnetic beam of 575 nm wavelength or it can be a mixture of standard green of 546.1 nm and standard red of 700 nm. The eye cannot distinguish between the two cases; only spectrometers can. In everyday life, all colours turn out to be mixed, with the exceptions of those of yellow street lamps, of laser beams and of the rainbow. You can check this for yourself, using an umbrella or a compact disc: they decompose light mixtures, but not pure colours.

Challenge 1121 s

Challenge 1122 e

In particular, white light is a mixture of a continuous range of colours with a given intensity per wavelength. To check that white light is a mixture of colours, simply hold the left-hand side of Figure 380 so near to your eye that you cannot focus the stripes any more. The unsharp borders of the white stripes have a pink or a green shade. These colours are due to the imperfections of the human eye, its so-called *chromatic aberrations*. Aberrations have the consequence that not all light frequencies follow the same path through the lens of the eye, and therefore they hit the retina at different spots. This is the same effect that occurs in prisms or in water drops showing a rainbow. By the way, the shape of the rainbow tells something about the shape of the water droplets. Can you deduce the connection?

Challenge 1123 s

The right side of Figure 380 explains how rainbows form. The main idea is that internal reflection inside the water droplets in the sky is responsible for throwing back the light coming from the Sun, whereas the wavelength-dependent refraction at the air–water surface is responsible for the different paths of each colour. The first two persons to verify this explanation were Theodoricus Teutonicus de Vriberg (*c.* 1240 to *c.* 1318), in the years from 1304 to 1310 and, at the same time, the Persian mathematician Kamal al-Din al-Farisi. To check the explanation, they did something smart and simple; anybody can repeat this at home. They built an enlarged water droplet by filling a thin spherical (or cylindrical) glass container with water; then they shone a beam of white light through it. Theodoricus and al-Farisi found exactly what is shown in Figure 380. With this ex-

Ref. 619

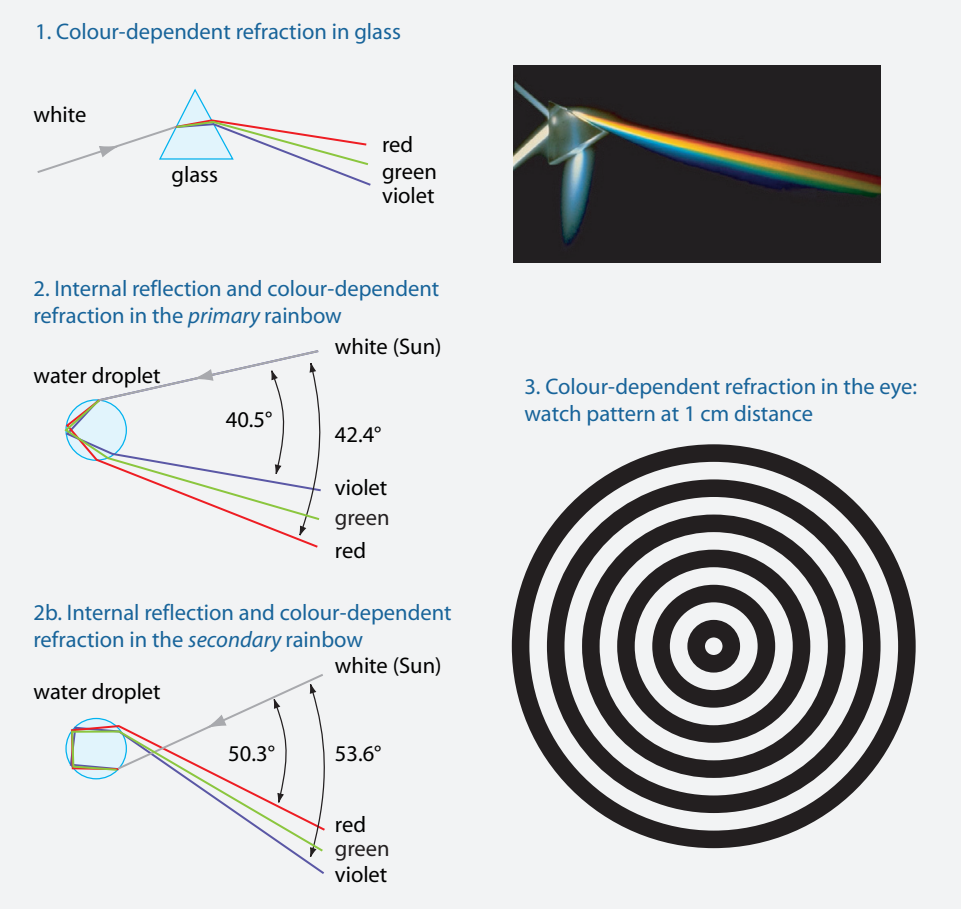

FIGURE 380 Three proofs that white light is a mixture of colours (with exaggerated angle differences): prism decomposition, rainbow formation and the coloured borders seen on a circular black and white pattern (photograph by Susan Schwartzenberg, © Exploratorium www.exploratorium.edu)

periment, each of them was able to reproduce the angle of the main or primary rainbow, its colour sequence, as well as the existence of a secondary rainbow, its observed angle and its inverted colour sequence.* All these bows are visible in Figure 356. Theodoricus's beautiful experiment is sometimes called the most important contribution of natural science in the Middle Ages.

Page 726

Incidentally, the explanation of Figure 380 is not complete. It is drawn with the light ray hitting the water droplet at a specific spot. If the light ray hits the droplet at other spots, the rainbows appear at other angles; however, all those rainbows wash out. Only

Challenge 1125 ny

* Can you guess where the tertiary and quaternary rainbows are to be seen? There are rare reported sightings of them. The hunt to observe the fifth-order rainbow is still open. (In the laboratory, bows around droplets up to the thirteenth order have been observed.) For more details, see the beautiful website at www.atoptics.co.uk. There are several formulae for the angles of the various orders of rainbows; they follow from straightforward geometric considerations, but are too involved to be given here.

FIGURE 382 Milk and water simulate the evening sky (© Antonio Martos)

the visible rainbow remains, because its deflection angles are extremal.

Incidentally, at sunset the atmosphere itself also acts as a prism, or more precisely, as a cylindrical lens affected by spherochromatism. That means that the Sun is split into different images, one for each colour, which are slightly shifted with respect to each other; the total shift is about 1% of the diameter. As a result, the rim of the Sun is coloured. If the weather is favourable, if the air is clear up to and beyond the horizon, and if the correct temperature profile is present in the atmosphere, a colour-dependent mirage will appear. As a result, for about a second it will be possible to see, after or near the red, orange and yellow images of the setting Sun, the green–blue image, sometimes even detached. This is the famous *green flash* described by Jules Verne in his novel *Le Rayon-vert*. It is often seen on tropical beaches, for example in Hawaii, and from the decks of ships in warm waters.

Ref. 621

Ref. 622

Ref. 621, Ref. 623

Even pure air splits white light. However, this is not done by dispersion, but by scattering. Wavelength-dependent scattering is the reason that the sky and far away mountains

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

look blue or that the Sun looks red at sunset and at sunrise. (The sky looks black even during the day from the Moon.) You can repeat this effect by looking through water at a black surface or at a lamp. Adding a few drops of milk to the water makes the lamp yellow and then red, and makes the black surface blue (like the sky seen from the Earth as compared to the sky seen from the Moon) as shown in Figure 382. More milk increases the effect. For the same reason, sunsets are especially red after volcanic eruptions.

To clarify the difference between colours in physics and colour in human perception and language, a famous linguistic discovery deserves to be mentioned: colours in human language have a natural *order*. Colours are ordered by all peoples of the world, whether they come from the sea, the desert or the mountains, in the following order: 1. black and white, 2. red, 3. green and yellow, 4. blue, 5. brown, 6. mauve, pink, orange, grey and sometimes a twelfth term that differs from language to language. (Colours that refer to objects, such as aubergine or sepia, or colours that are not generally applicable, such as blond, are excluded in this discussion.) The precise discovery is the following: if a particular language has a word for any of these colours, then it also has a word for all the preceding ones. The result also implies that people use these basic colour classes even if their language does *not* have a word for each of them. These strong statements have been confirmed for over 100 languages.

Ref. 624

Fun with rainbows

The width of the usual, primary rainbow is 2.25°, for the secondary rainbow it is about twice that value (which is one reason why it is less bright). The width is larger than the dispersion angle difference given in Figure 380 because the angular size of the sun, about 0.5°, has (roughly) to be added on top of the angle difference.

If the droplets are very fine, the rainbow become white; it is then called a *fogbow*. Such bows are also often seen from aeroplanes. If the droplets are not round, for example due to strong wind, one can get a so-called *irregular* or *twinned rainbow*. An example is shown in Figure 383.

Light from the rainbow is tangentially polarized. You can check that easily with polarizing sunglasses. During the internal reflection in the water droplets, as the reflection angle is very near to the angle at which total reflection sets in, light gets polarized. (Why is does this lead to polarization?) More on polarization will be told in the next section.

Challenge 1126 e

Challenge 1127 ny

If the air is full of ice crystals instead of droplets, the situation changes again. One can then get additional images of the sun in the direction of the sun. They are called *parhelia* (or sundogs). This happens most clearly with no wind, if the crystals are all oriented in the same direction. In that case one can take photographs such as the one shown in Figure 384.

What is the speed of light? – Again

Physics talks about motion. Talking is the exchange of sound; and sound is an example of a signal. A *(physical) signal* is the transport of information using the transport of energy. There are no signals without a motion of energy. Indeed, there is no way to store information without storing energy. To any signal we can thus ascribe a propagation speed. The highest possible signal speed is also the maximal velocity of the general influences, or, to use sloppy language, the maximal velocity with which effects spread causes.

Page 237

FIGURE 383 Four rare types of rainbows: a fogbow (top left), an irregular, split rainbow in a windy situation due to non-spherical rain drops (top right, shown with increased colour saturation), a six-fold rainbow (bottom left) and a red rainbow at sunset (© Michel Tournay, Eva Seidenfaden, Terje Nordvik and Zhu XiaoJin)

FIGURE 384 A composite photograph showing the parhelia, the light pillars, the halo and the upper tangent arc formed by ice crystals in the air, if all oriented in the same direction (© Phil Appleton)

If the signal is carried by matter, such as by the written text in a letter, the signal velocity is then the velocity of the material carrier, and experiments show that it is limited by the speed of light.

For a wave carrier, such as water waves, sound, light or radio waves, the situation is less evident. What is the speed of a wave? The first answer that comes to mind is the speed with which wave crests of a sine wave move. This already introduced *phase velocity* is

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

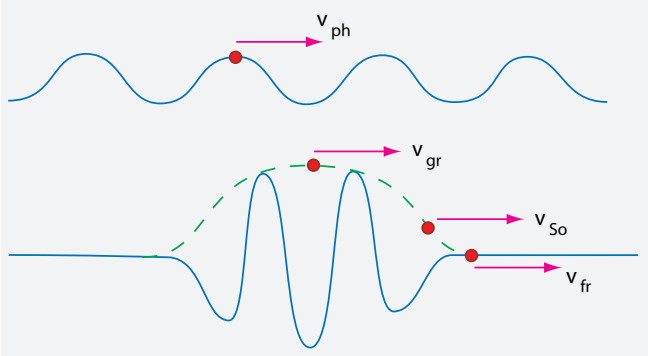

FIGURE 385 The definition of important velocities in wave phenomena

given by the ratio between the frequency and the wavelength of a monochromatic wave, i.e., by

$$v_{\text{ph}} = \frac{\omega}{k} \,. \tag{481}$$

For example, the phase velocity determines interference phenomena. Light in a vacuum has the same phase velocity $v_{\text{ph}} = c$ for all frequencies. Are you able to imagine an experiment to test this to high precision?

Challenge 1128 s

On the other hand, there are cases where the phase velocity is greater than c, most notably when light travels through an absorbing substance, and when at the same time the frequency is near to an absorption maximum. In these cases, experiments show that the phase velocity is *not* the signal velocity. For such situations, a better approximation to the signal speed is the *group velocity*, i.e., the velocity at which a group maximum will travel. This velocity is given by

Ref. 625

$$v_{\text{gr}} = \left.\frac{\mathrm{d}\omega}{\mathrm{d}k}\right|_{k_0} \,, \tag{482}$$

where k_0 is the central wavelength of the wave packet. We observe that $\omega = c(k)k = 2\pi v_{\text{ph}}/\lambda$ implies the relation

$$v_{\text{gr}} = \left.\frac{\mathrm{d}\omega}{\mathrm{d}k}\right|_{k_0} = v_{\text{ph}} - \lambda \frac{\mathrm{d}v_{\text{ph}}}{\mathrm{d}\lambda} \,. \tag{483}$$

This means that the sign of the last term determines whether the group velocity is larger or smaller than the phase velocity. For a travelling group, as shown by the dashed line in Figure 385, this means that new maxima appear either at the end or at the front of the group. Experiments show that this is only the case for light passing *through matter*; for light *in vacuum*, the group velocity has the same value $v_{\text{gr}} = c$ for all values of the wave vector k.

You should be warned that many publications are still propagating the incorrect statement that the group velocity *in a material* is never greater than c, the speed of light in vacuum. Actually, the group velocity in a material can be zero, infinite or even negative; this happens when the light pulse is very narrow, i.e., when it includes a wide range of

Challenge 1129 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

frequencies, or again when the frequency is near an absorption transition. In many (but not all) cases the group is found to widen substantially or even to split, making it difficult to define precisely the group maximum and thus its velocity. Many experiments have confirmed these predictions. For example, the group velocity in certain materials has been measured to be *ten times* that of light. The refractive index then is smaller than 1. However, in all these cases the group velocity is *not* the same as the signal speed.*

Ref. 626

What then is the best velocity describing signal propagation? The German physicist Arnold Sommerfeld** almost solved the main problem in the beginning of the twentieth century. He defined the signal velocity as the velocity v_{So} of the front slope of the pulse, as shown in Figure 385. The definition cannot be summarized in a formula, but it does have the property that it describes signal propagation for almost all experiments, in particular those in which the group and phase velocity are larger than the speed of light. When studying its properties, it was found that for no material is Sommerfeld's signal velocity greater than the speed of light in vacuum.

Ref. 625

Sometimes it is conceptually easier to describe signal propagation with the help of the energy velocity. As previously mentioned, every signal transports energy. The *energy velocity* v_{en} is defined as the ratio between the power flow density $\boldsymbol{P}$, i.e., the Poynting vector, and the energy density W, both taken in the direction of propagation. For electromagnetic fields – the only ones fast enough to be interesting for eventual superluminal signals – this ratio is

$$\boldsymbol{v}_{en} = \frac{\mathrm{Re}(\boldsymbol{P})}{W} = \frac{2c^2\, \boldsymbol{E} \times \boldsymbol{B}}{\boldsymbol{E}^2 + c^2 \boldsymbol{B}^2} \,. \tag{484}$$

However, as in the case of the front velocity, in the case of the energy velocity we have to specify if we mean the energy transported by the main pulse or by the front of it. In vacuum, neither is ever greater than the speed of light.*** (In general, the velocity of energy in matter has a value slightly different from Sommerfeld's signal velocity.)

Ref. 625

In recent years, the progress in light detector technology, allowing one to detect even the tiniest energies, has forced scientists to take the fastest of all these energy velocities to describe signal velocity. Using detectors with the highest possible sensitivity we can use as signal the first point of the wave train whose amplitude is different from zero, i.e., the first tiny amount of energy arriving. This point's velocity, conceptually similar to Sommerfeld's signal velocity, is commonly called the *front velocity* or, to distinguish it even more clearly from Sommerfeld's case, the *forerunner velocity*. It is simply given by

Challenge 1130 s

* In quantum mechanics, Schrödinger proved that the velocity of an electron is given by the group velocity of its wave function. Therefore the same discussion reappeared in quantum theory, as we will find out in the next part of our mountain ascent.

** Arnold Sommerfeld (b. 1868 Königsberg, d. 1951 München) was a central figure in the spread of special and general relativity, of quantum theory, and of their applications. A professor in Munich, an excellent teacher and text book writer, he worked on atomic theory, on the theory of metals and on electrodynamics, and was the first to understand the importance and the mystery around 'Sommerfeld's famous fine structure constant.'

*** Signals not only carry energy, they also carry negative entropy ('information'). The entropy of a transmitter increases during transmission. The receiver decreases in entropy (but less than the increase at the transmitter, of course).

Ref. 627

Note that the negative group velocity implies energy transport against the propagation velocity of light. This is possible only in *energy loaded* materials.

Ref. 628

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

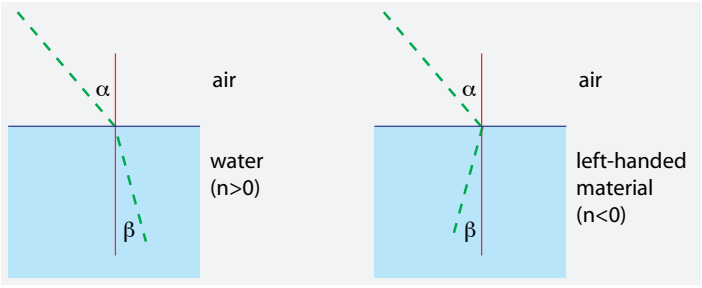

FIGURE 386 Positive and negative indices of refraction

$$v_{\mathrm{fr}} = \lim_{\omega\to\infty} \frac{\omega}{k} \,. \tag{485}$$

The forerunner velocity is *never* greater than the speed of light in a vacuum, even in materials. In fact it is precisely c because, for extremely high frequencies, the ratio ω/k is independent of the material, and vacuum properties take over. The forerunner velocity is the true signal velocity or the *true velocity of light*. Using it, all discussions on light speed become clear and unambiguous.

Challenge 1131 s To end this section, here are two challenges for you. Which of all the velocities of light is measured in experiments determining the velocity of light, e.g. when light is sent to the Moon and reflected back? And now a more difficult one: why is the signal speed of Challenge 1132 s light less inside matter, as all experiments show?

200 YEARS TOO LATE – NEGATIVE REFRACTION INDICES

In 1968 the Soviet physicist Victor Veselago made a strange prediction: the index of refraction could have *negative* values without invalidating any known law of physics. A negative index means that a beam is refracted to the same side of the vertical, as shown in Figure 386. As a result, concave lenses made of such materials focus and convex lenses disperse parallel beams, in contrast to usual lens materials.

In 1996, John Pendry and his group proposed ways of realizing such materials. In 2000, a first experimental confirmation for microwave refraction was published, but it Ref. 629 met with strong disbelief. In 2002 the debate was in full swing. It was argued that negative refraction indices imply speeds greater than that of light and are only possible for either phase velocity or group velocity, but not for the energy or true signal velocity. The conceptual problems would arise only because in some physical systems the refraction angle for phase motion and for energy motion differ.

In the meantime, negative indices of refraction have indeed been frequently observed; Ref. 630 the corresponding systems are being extensively explored all over the world. Systems with negative index of refraction do exist. The materials showing this property are called *left-handed*. The reason is that the vectors of the electric field, the magnetic field and the wave vector form a left-handed triplet, in contrast to vacuum and most usual materials, where the triplet is right-handed. Such materials consistently have *negative* magnetic Ref. 631 permeability and *negative* dielectric coefficient (permittivity).

Apart the unusual refraction properties, left-handed materials have negative phase

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

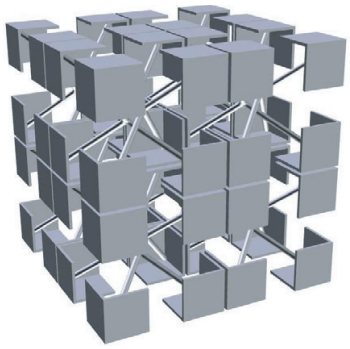

FIGURE 387 An example of an isotropic metamaterial (M. Zedler et al., © 2007 IEEE)

velocities, i.e., a phase velocity opposed to the energy velocity; they also show reversed Doppler effect and yield obtuse angles in the Vavilov–Çerenkov effect (emitting Vavilov–Çerenkov radiation in the backward instead of the forward direction).

But, most intriguing, negative refraction materials are predicted to allow the construc-
Ref. 632 tion of lenses that are completely flat. In addition, in the year 2000, John Pendry gained the attention of the whole physics community world-wide by predicting that lenses made with such materials, in particular for $n = -1$, would be *perfect*, thus beating the usual diffraction limit. This would happen because such a lens also images the evanescent parts of the waves, by amplifying them accordingly. First experiments seem to confirm the
Ref. 631 prediction. Exploration of the topic is still in full swing.

Challenge 1133 ny Can you explain how negative refraction differs from diffraction?

Metamaterials

The simplest realization of left-handed systems are metamaterials. (Left-handed) *metamaterials* are engineered metal-insulator structures that are left-handed for a certain wavelength range, usually in the radio or microwave domain.

Ref. 633 Currently, there are two basic approaches to realize metamaterials. The first is to build a metamaterial from a large array of resonant inductor-capacitor (LC-) circuits. The sec-
Ref. 634 ond approach is to build them from resonant transmission lines. The latter approach has lower losses and a wider spectral range. An example is shown in Figure 387.

Most metamaterials are conceived for the microwave range. Crystals that act as left-handed materials in the optical range, though for certain frequencies only, and only in one dimension, have been identified recently.

Research on the topic is presently in full swing. Industrial applications of left handed (meta-)materials are expected for antenna design; for example, the antenna dipole could be located just above a metamaterial, allowing flat directional antennas. The most unrealistic people are those who claim that *invisibility cloaks* can be realized with metamaterials. While this is a good marketing slogan to attract funding, it is not realistic, due inevitable signal losses in the materials, dispersion, finite cell size etc. So far, all aeroplanes that were claimed to be invisible for certain (radar) frequencies have turned out to be visible. But sources of military funding are known to have only a distant relation to reality.

TABLE 70 Experimental properties of (flat) vacuum and of the 'aether'

Physical property	Experimental value
permeability	μ_0 =1.3 μH/m
permittivity	ε_0 =8.9 pF/m
wave impedance/resistance	Z_0 = 376.7 Ω
conformal invariance	applies
spatial dimensionality	3
topology	R^3
mass and energy content	not detectable
friction on moving bodies	not detectable
motion relative to space-time	not detectable

Signals and predictions

When one person reads a text over the phone to a neighbour who listens to it and maybe repeats it, we speak of communication. For any third person, the speed of communication is always less than the speed of light. But if the neighbour already knows the text, he can recite it without having heard the readers' voice. To the third observer such a situation appears to imply motion that is faster than light. Prediction can thus *mimic* communication and, in particular, it can mimic faster-than-light (superluminal) communication. Such a situation was demonstrated most spectacularly in 1994 by Günter Nimtz, who seemingly transported music – all music is predictable for short time scales – through a 'faster-than-light' system. To distinguish between the two situations, we note that in the case of prediction, no transport of energy takes place, in contrast to the case of communication. In other words, the definition of a signal as a transporter of information is not as useful and clear-cut as the definition of a signal as a *transporter of energy*. In the above-mentioned experiment, no energy was transported faster than light. The same distinction between prediction on the one hand and signal or energy propagation on the other will be used later to clarify some famous experiments in quantum mechanics.

Ref. 635

> If the rate at which physics papers are being published continues to increase, physics journals will soon be filling library shelves faster than the speed of light. This does not violate relativity since no useful information is being transmitted.
>
> David Mermin

Does the aether exist?

Gamma rays, light and radio waves are moving electromagnetic waves. All exist in empty space. What is oscillating when light travels? Maxwell himself called the 'medium' in which this happens the *aether*. The properties of the aether measured in experiments are listed in Table 70.

Of course, the values of the permeability and the permittivity of the vacuum are related to the definition of the units henry and farad. The last item of the table is the most impor-

Page 910

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 636 tant: despite intensive efforts, nobody has been able to detect any *motion* of the aether. In other words, even though the aether supposedly oscillates, it does not move. Together with the other data, all these results can be summed up in one sentence: there is no way Challenge 1134 s to distinguish the aether from the vacuum: they are one and the same.

Sometimes one hears that certain experiments or even the theory of relativity show that the aether does not exist. This is not strictly correct. In fact, experiments show something more important. All the data show that the aether is indistinguishable from the vacuum. Of course, if we use the change of curvature as the definition for motion of the vacuum, the vacuum *can* move, as we found out in the section on general relativity; but the aether still remains indistinguishable from it.*

Later we will even find out that the ability of the vacuum to allow the propagation of light and its ability to allow the propagation of particles are equivalent: both require the same properties. Therefore the aether remains *indistinguishable* from a vacuum in Ref. 637 the rest of our walk. In other words, the aether is a superfluous concept; we will drop it from our walk from now on. Despite this result, we have not yet finished the study of the vacuum; vacuum will keep us busy for a long time, starting with the following part of our ascent. Moreover, quite a few of the aspects in Table 70 will require some amendments later.

Challenges and fun curiosities about light

Since light is a wave, something must happen if it is directed to a hole less than its wave-Challenge 1135 s length in diameter. What exactly happens?

* *

Electrodynamics shows that light beams always push; they never pull. Can you confirm Challenge 1136 e that 'tractor beams' are impossible in nature?

* *

It is well known that the glowing material in light bulbs is tungsten wire in an inert gas. This was the result of a series of experiments that began with the grandmother of all lamps, namely the cucumber. The older generation knows that a pickled cucumber, when attached to the 230 V of the mains, glows with a bright green light. (Be careful; the experiment is dirty and somewhat dangerous.)

* *

If the light emitted by the headlights of cars were polarized from the bottom left to the upper right (as seen from the car's driver) one could vastly improve the quality of driving at night: one could add a polarizer to the wind shield oriented in the same direction. As a result, a driver would see the reflection of his own light, but the light from cars coming Challenge 1137 ny towards him would be considerably dampened. Why is this not done in modern cars?

Ref. 637 * In fact, the term 'aether' has been used as an expression for several different ideas, depending on the author. First of all it was used for the idea that a vacuum is not empty, but *full*; secondly, that this fullness can be described by *mechanical models*, such as gears, little spheres, vortices, etc.; thirdly, it was imagined that a vacuum is *similar to matter*, being made of the same substrate. Interestingly, these issues will reappear in the last part of our mountain ascent.

Chapter 26

IMAGES AND THE EYE – OPTICS

How to prove you're holy

Light reflection and refraction are responsible for many effects. The originally Indian symbol of holiness, now used throughout most of the world, is the *aureole*, also called *halo* or *Heiligenschein*, a ring of light surrounding the head. You can easily observe it around your own head. You need only to get up early in the morning and look into the wet grass while turning your back to the Sun. You will see an aureole around your shadow. The effect is due to the morning dew on the grass, which reflects the light back predominantly in the direction of the light source, as shown in Figure 388. The fun part is that if you do this in a group, you will see the aureole around only *your own* head.

Ref. 638

Retroreflective paint works in the same way: it contains tiny glass spheres that play the role of the dew. A large surface of retroreflective paint, a traffic sign for example, can also show your halo if the light source is sufficiently far away. Also the so-called 'glow' of the eyes of a cat at night is due to the same effect; it is visible only if you look at the cat with a light source behind you. By the way, do Cat's-eyes work like a cat's eyes?

Ref. 639

Challenge 1138 s

Do we see what exists?

Sometimes we see *less* than there is. Close your left eye, look at the white spot in Figure 389, bring the page slowly towards your eye, and pay attention to the middle lines. At a distance of about 15 to 20 cm the middle line will seem uninterrupted. Why?

Challenge 1139 s

On the other hand, sometimes we see *more* than there is, as Figures 390 and 391 show. The first shows that parallel lines can look skewed, and the second show a so-called *Hermann lattice*, named after its discoverer.* The Hermann lattice of Figure 391, discovered by Elke Lingelbach in 1995, is especially striking. Variations of these lattices are now used to understand the mechanisms at the basis of human vision. For example, they can be used to determine how many light sensitive cells in the retina are united to one signal pathway towards the brain. The illusions are angle dependent because this number is also angle dependent.

Ref. 640

Our eyes also 'see' things *differently:* the retina sees an *inverted* image of the world. There is a simple method to show this, due to Helmholtz.** You need only a needle and

* Ludimar Hermann (1838–1914), Swiss physiologist. The lattices are often falsely called 'Hering lattices' after the man who made Hermann's discovery famous.

** See Hermann von Helmholtz, *Handbuch der physiologischen Optik*, 1867. This famous classic is available in English as *Handbook of Physiological Optics*, Dover, 1962. The Prussian physician, physicist and science politician born as Hermann Helmholtz (b. 1821 Potsdam, d. 1894 Charlottenburg) was famous for

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

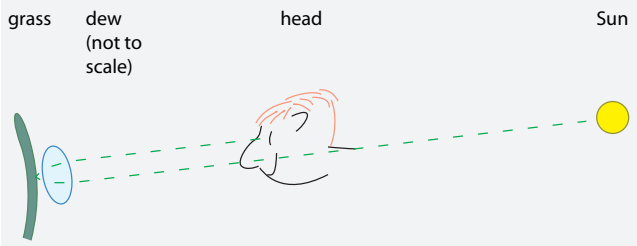

FIGURE 388 The path of light for the dew on grass that is responsible for the aureole

FIGURE 389 A limitation of the eye

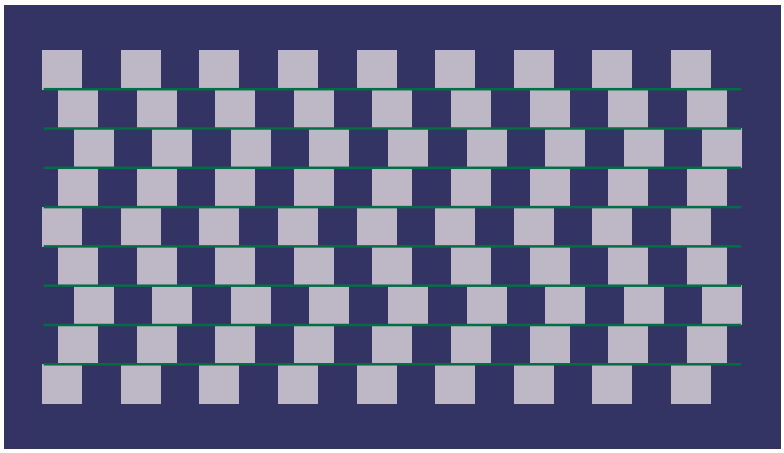

FIGURE 390 What is the angle between adjacent green lines?

his works on optics, acoustics, electrodynamics, thermodynamics, epistemology and geometry. He founded several physics institutions across Germany. He was one of the first to propagate the idea of conservation of energy. His other important book, *Die Lehre von den Tonempfindungen*, published in 1863, describes the basis of acoustics and, like the Handbook, is still worth reading.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

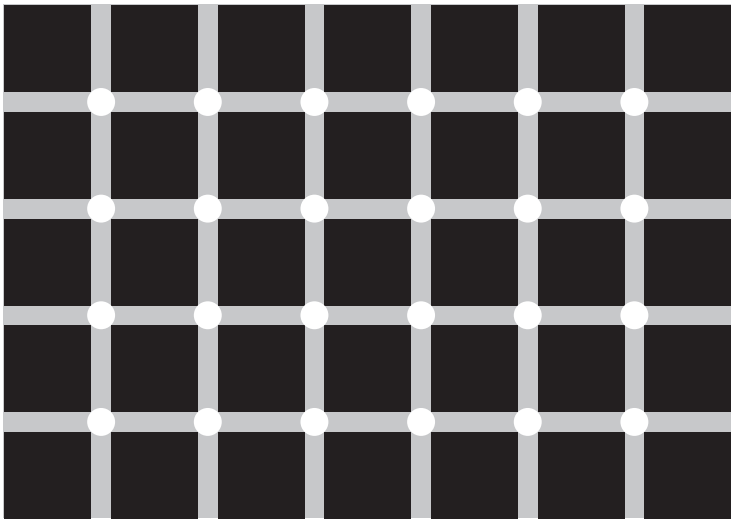

FIGURE 391 The Lingelbach lattice: do you see white, grey, or black dots?

FIGURE 392 An example of an infrared photograph, slightly mixed with a colour image (© Serge Augustin)

a piece of paper, e.g. this page of text. Use the needle to make two holes inside the two letters 'oo'. Then keep the page as close to your eye as possible, look through the two holes towards the wall, keeping the needle vertical, a few centimetres behind the paper. You will see two images of the needle. If you now cover the *left* hole with your finger, the *right* needle will disappear, and vice versa. This shows that the image inside the eye, on the retina, is inverted. Are you able to complete the proof?

Challenge 1140 ny

Two other experiments can show the same result. If you push very lightly on the *inside* of your eye (careful!), you will see a dark spot appear on the *outside* of your vision field. And if you stand in a dark room and ask a friend to look at a burning candle, explore his eye: you will see three reflections: two upright ones, reflected from the cornea and from

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 393 How the appearance of a sunflower changes with wavelength: how it looks to the human eye, how it might look to a bird, and how it looks in the ultraviolet (© Andrew Davidhazy)

the lens, and a dim third one, *upside-down*, reflected from the retina.

Another reason that we do not see the complete image of nature is that our eyes have a limited sensitivity. This sensitivity peaks around 560 nm; outside the red and the violet, the eye does not detect radiation. We thus see only part of nature. For example, infrared photographs of nature, such as the one shown in Figure 392, are interesting because they show us something different from what we see usually.

Every expert of motion should also know that the sensitivity of the eye does *not* correspond to the brightest part of sunlight. This myth has been spread around the world by the numerous textbooks that have copied from each other. Depending on whether frequency or wavelength or wavelength logarithm is used, the solar spectrum peaks at 500 nm, 880 nm or 720 nm. The human eye's spectral sensitivity, like the completely different sensitivity of birds or frogs, is due to the chemicals used for detection. In short, the human eye can only be understood by a careful analysis of its particular evolutionary history.

Ref. 641

An urban legend, spread by many medical doctors and midwives to this day, pretends that newborn babies see everything upside down. Can you explain why this idea is wrong?

Challenge 1141 s

In summary, we have to be careful when maintaining that seeing means observing. Examples such as these lead to ask whether there are other limitations of our senses which are less evident. And our walk will indeed uncover several of them.

How does one make pictures of the inside of the eye?

The most beautiful pictures so far of a *living* human retina, such as that of Figure 394, were made by the group of David Williams and Austin Roorda at the University at Rochester in New York. They used adaptive optics, a technique that changes the shape of the imaging lens in order to compensate for the shape variations of the lens in the human eye.*

Ref. 642

* Nature uses another trick to get maximum resolution: the eye continuously performs small movements, called *micronystagmus*. The eye continuously oscillates around the direction of vision with around 40 to 50 Hz. In addition, this motion is also used to allow the cells in the retina to recharge.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

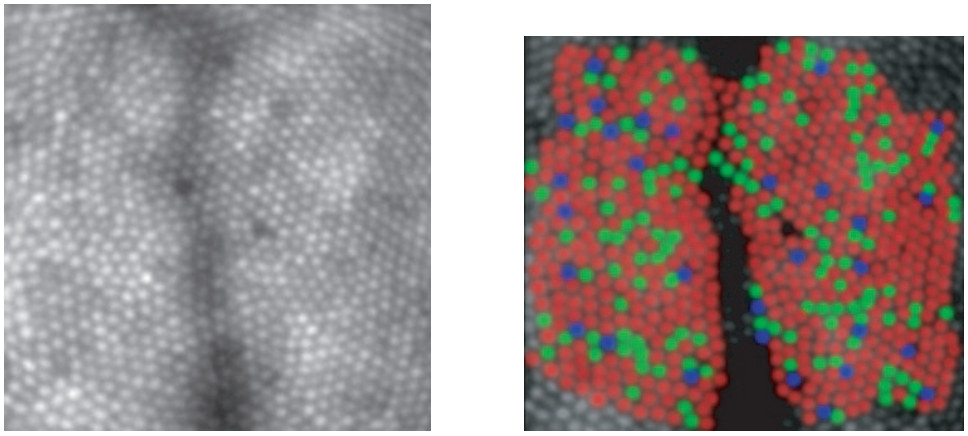

FIGURE 394 A high quality photograph of a live human retina, including a measured (false colour) indication of the sensitivity of each cone cell (© Austin Roorda)

The eyes see colour by averaging the intensity arriving at the red, blue and green sensi-
Page 748 tive cones. This explains the possibility, mentioned above, of getting the same impression of colour, e.g. yellow, either by a pure yellow laser beam, or by a suitable mixture of red and green light.

But if the light is focused on to one cone only, the eye makes mistakes. If, using this adaptive optics, a red laser beam is focused such that it hits a green cone only, a strange thing happens: even though the light is *red*, the eye sees a *green* colour!

Incidentally, Figure 394 is quite puzzling. In the human eye, the blood vessels are located *in front* of the cones. Why don't they appear in the picture? And why don't they
Challenge 1142 s disturb us in everyday life? (The picture does not show the other type of sensitive light cells, the *rods*, because the subject was in daylight; rods come to the front of the retina only in the dark, and then produce black and white pictures.)

Of all the mammals, only primates can see *colours*. Bulls for example, don't; they cannot distinguish red from blue. On the other hand, the best colour seers overall are the birds. They have cone receptors for red, blue, green, UV and, depending on the bird, for up to three more sets of colours. A number of birds (but not many) also have a better eye resolution than humans. Several birds also have a faster temporal resolution: humans see continuous motion when the images follow with 30 to 70 Hz (depending on the image content); some insects can distinguish images up to 300 Hz.

How does one make holograms and other three-dimensional images?

Our sense of sight gives us the impression of depth mainly due to three effects. First, the two eyes see different images. Second, the images formed in the eyes are position dependent. Third, our eye needs to focus differently for different distances.

A simple photograph does not capture any of the three effects. A photograph corresponds to the picture taken by one eye, from one particular spot and at one particular
Challenge 1143 e focus. In fact, all photographic cameras are essentially copies of a single static eye.

Any system wanting to produce the perception of depth must include at least one of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

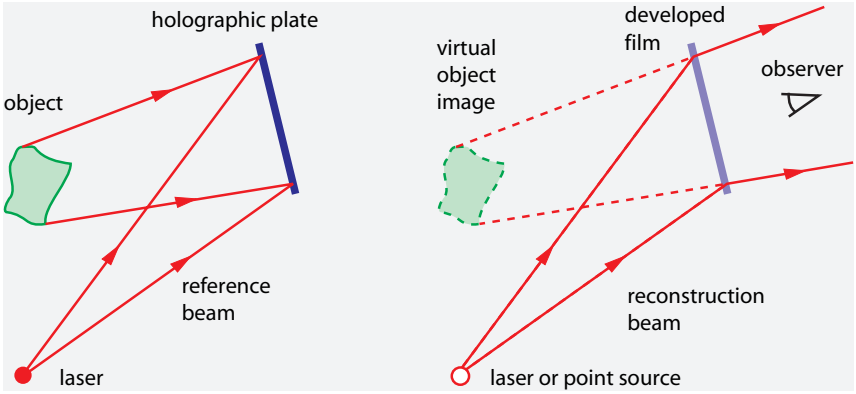

FIGURE 395 The recording and the observation of a hologram

the three effects just mentioned. In all systems so far, the third and weakest effect, varying focus with distance, is never used, as it is too weak. Stereo photography and virtual reality systems extensively use the first effect by sending two different images to the eyes. Also certain post cards and computer screens are covered by thin cylindrical lenses that allow one to send two different images to the two eyes, thus generating the same impression of depth.

But obviously the most spectacular effect is obtained whenever position dependent images can be created. Some virtual reality systems mimic this effect using a sensor attached to the head, and creating computer–generated images that depend on this position. However, such systems are not able to reproduce actual situations and thus pale when compared with the impression produced by holograms.

Holograms reproduce all that is seen from any point of a region of space. A *hologram* is thus a stored set of position dependent pictures of an object. It is produced by storing amplitude *and phase* of the light emitted by an object. To achieve this, the object is illuminated by a *coherent* light source, such as a laser, and the interference pattern is stored. Illuminating the developed photographic film by a coherent light source then allows one to see a full three-dimensional image. In particular, due to the reproduction of the situation, the image appears to float in free space. Holograms were developed in 1947 by the Hungarian physicist Dennis Gabor (1900–1979), who received the 1971 Nobel Prize for physics for this work.

Holograms can be made to work in reflection or transmission. The simplest holograms use only one wavelength. Most coloured holograms are rainbow holograms, showing false colours that are unrelated to the original objects. Real colour holograms, made with three different lasers, are rare but possible.

Is it possible to make *moving* holograms? Yes; however, the technical set-ups are still extremely expensive. So far, they exist only in a few laboratories and cost millions of euro. By the way, can you describe how you would distinguish a moving hologram from a real body, if you ever came across one, without touching it?

Challenge 1144 s

Optical imaging

Producing images is an important part of modern society. The quality of images depends on the smart use of optics, electronics, computers and materials science. Despite long experience in this domain, there are still new results in the field. Images, i.e., two or three-dimensional reproductions, can be taken by at least six groups of techniques:

— *Photography* uses a light source, lenses and film – or another large area detector. Photography can be used in reflection, in transmission, with phase-dependence, with various illuminations, with detectors sensitive to various wavelengths, and in many other ways.
— *Optical microscopy* uses a light source, lenses and film (or another large area detector). If the illumination is through the sample, in transmission, one speaks of *bright-field microscopy*. (Variations use coloured or polarizing filters.) If the illumination is from the side, one speaks of *oblique microscopy*. If the illumination is confined to an outer ring of light, one speaks of *dark-field microscopy*. An even more elaborate illumination system, using plane waves, allows *phase-contrast microscopy*. (It was invented by Frits Zernike in the 1930s and earned him the Nobel Prize in Physics in 1953.) If one splits a polarized illumination beam into two components that pass the sample at close (but not identical) locations, and then recombines them afterwards, one speaks of *differential interference contrast microscopy*. If a sample is treated with a fluorescent dye, the illuminating light is filtered out, and only the fluorescence is observed, one speaks of *fluorescence microscopy*. The image quality of expensive microscopes can be further improved with the help of a computer, with deconvolution techniques.
— *Holography* uses lasers and large area detectors, as explained in the previous section. Holography allows to take three-dimensional images of objects. It is usually used in reflection, but can also be used in transmission.
— *Scanning techniques* construct images point by point through the motion of the detector, the light source or both. There are also several scanning microscopy techniques: *confocal laser scanning microscopy*, the fibre-based *near-field scanning optical*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

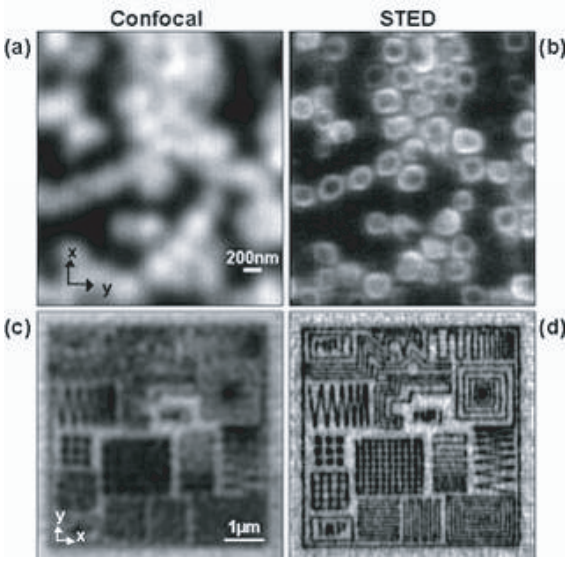

FIGURE 397 Sub-wavelength optical microscopy using stimulated emission depletion (right) compared to conventional confocal microscopy (left) (© MPI für biophysikalische Chemie/Stefan Hell)

microscopy, and combinations of them with fluorescence techniques or various deconvolution techniques. Many of these scanning microscopy techniques allow resolutions much lower than the wavelength of light, which is impossible with usual optical microscopy.

— *Tomography*, usually performed in transmission, uses a source and a line detector that are rotated together around an object. This allows to image cross sections of materials.

— *Telescopy* is used most of all in geodesy and astronomy. The most advanced astronomical telescopes can compensate star images for the effects of the turbulence of the atmosphere; they can also take images at various wavelengths, ranging from radio frequencies, infrared, visible, ultraviolet to X-rays. X-ray telescopes have to be operated outside the atmosphere, to avoid absorption by air, for example on rockets, satellites or high-altitude balloons.

In all methods, the race is for images with the highest resolution possible. The techniques of producing images with resolutions *less* than the wavelength of light have made great progress in recent years.

A recent technique, called *stimulated emission depletion microscopy*, allows spot sizes of molecular size. The conventional diffraction limit for microscopes is

$$d \geqslant \frac{\lambda}{2n \sin\alpha} \,, \tag{486}$$

where λ is the wavelength, n the index of refraction and α is the angle of observation. The new technique, a special type of fluorescence microscopy developed by Stefan Hell, modifies this expression to

$$d \geqslant \frac{\lambda}{2n \sin\alpha \sqrt{I/I_{\text{sat}}}} \,, \tag{487}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

so that a properly chosen saturation intensity allows one to reduce the diffraction limit to arbitrary low values. So far, light microscopy with a resolution of 16 nm has been performed, as shown in Figure 397. This and similar techniques should become commonplace in the near future.

Ref. 643

Why can we see each other?

Physicists have a strange use of the term 'black'. Most bodies at temperatures at which they are red hot or even hotter are excellent approximations of black bodies. For example, the tungsten in incandescent light bulbs, at around 2000 K, emits almost pure black body radiation; however, the glass then absorbs much of the ultraviolet and infrared components. Black bodies are also used to define the colour *white*. What we commonly call pure white is the colour emitted by a black body of 6500 K, namely the Sun. This definition is used throughout the world, e.g. by the Commission Internationale d'Eclairage. Hotter black bodies are bluish, colder ones are yellow, orange or red.* The stars in the sky are classified in this way, as summarized on page 205.

Ref. 696

Let us make a quick summary of black body radiation. Black body radiation has two important properties: first, the emitted light power increases with the fourth power of the temperature. With this relation alone you can check the temperature of the Sun, mentioned above, simply by comparing the size of the Sun with the width of your thumb when your arm is stretched out in front of you. Are you able to do this? (Hint: use the excellent approximation that the Earth's average temperature of about 14.0 °C is due to the Sun's irradiation.)

Challenge 1145 d

Ref. 697

The precise expression for the emitted energy density u per frequency ν can be deduced from the radiation law for black bodies discovered by Max Planck**

$$u(\nu, T) = \frac{8\pi h}{c^3} \frac{\nu^3}{e^{h\nu/kT} - 1} \,. \tag{488}$$

He made this important discovery, which we will discuss in more detail in the quantum part of our mountain ascent, simply by comparing this curve with experiment. The new constant h, *quantum of action* or *Planck's constant*, turns out to have the value $6.6 \cdot 10^{-34}$ Js, and is central to all quantum theory, as we will see. The other constant Planck introduced, the Boltzmann constant k, appears as a prefactor of temperature all over thermodynamics, as it acts as a conversion unit from temperature to energy.

Page 977

The radiation law gives for the total emitted energy density the expression

Challenge 1146 ny

* Most bodies are not black, because colour is not only determined by emission, but also by absorption of light.

** Max Planck (1858–1947), professor of physics in Berlin, was a central figure in thermostatics. He discovered and named *Boltzmann's constant k* and the *quantum of action h*, often called Planck's constant. His introduction of the quantum hypothesis gave birth to quantum theory. He also made the works of Einstein known in the physical community, and later organized a job for him in Berlin. He received the Nobel Prize for physics in 1918. He was an important figure in the German scientific establishment; he also was one of the very few who had the courage to tell Adolf Hitler *face to face* that it was a bad idea to fire Jewish professors. (He got an outburst of anger as answer.) Famously modest, with many tragedies in his personal life, he was esteemed by everybody who knew him.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$u(T) = T^4 \frac{8\pi^5 k^4}{15c^3 h^3} \tag{489}$$

Challenge 1147 ny from which equation (497) is deduced using $I = uc/4$. (Why?)

The second property of black body radiation is the value of the peak wavelength, i.e., the wavelength emitted with the highest intensity. This wavelength determines their Challenge 1148 ny colour; it is deduced from equation (488) to be

$$\lambda_{\max} = \frac{hc}{4.956\,k}\frac{1}{T} = \frac{2.90\,\mathrm{mm\,K}}{T} \quad \text{but} \quad \hbar\nu_{\max} = 2.82\,kT/h = (5.9 \cdot 10^{10}\,\mathrm{Hz/K}) \cdot T\,. \tag{490}$$

Either of these expressions is called *Wien's colour displacement rule* after its discoverer.* The colour change with temperature is used in optical thermometers; this is also the way the temperatures of stars are measured. For 37 °C, human body temperature, it gives a peak wavelength of 9.3 µm or 115 THz, which is therefore the colour of the bulk of the radiation emitted by every human being. (The peak wavelength does not correspond to Challenge 1149 s the peak frequency. Why?) On the other hand, following the telecommunication laws of many countries, any radiation emitter needs a licence to operate; it follows that strictly in Germany only dead people are legal, and only if their bodies are at absolute zero temperature.

Note that a black body or a star can be blue, white, yellow, orange or red. It is never Challenge 1150 ny green. Can you explain why?

Above, we predicted that any material made of charges emits radiation. Are you able to find a simple argument showing whether heat radiation is or is not this classically Challenge 1151 ny predicted radiation?

But let us come back to the question in the section title. The existence of thermal radiation implies that any hot body will cool, even if it is left in the most insulating medium there is, namely in vacuum. More precisely, if the vacuum is surrounded by a wall, the temperature of a body in the vacuum will gradually approach that of the wall.

Interestingly, when the temperature of the wall and of the body inside have become the same, something strange happens. The effect is difficult to check at home, but impres- Ref. 698 sive photographs exist in the literature.

One arrangement in which walls and the objects inside them are at the same temperature is an *oven*. It turns out that it is *impossible* to see objects in an oven using the light coming from thermal radiation. For example, if an oven and all its contents are red hot, taking a picture of the inside of the oven (without a flash!) does not reveal anything; no contrast nor brightness changes exist that allow one to distinguish the objects from the Challenge 1152 s walls or their surroundings. Can you explain the finding?

In short, we are able to see each other only because the light sources we use are at a *different* temperature from us. We can see each other only because we do *not* live in thermal equilibrium with our environment.

* Wilhelm Wien (b. 1864 Gaffken, d. 1928 München), East-Prussian physicist; he received the Nobel Prize for physics in 1911 for the discovery of this relation.

Note that the value appearing in Wien's rule can be uniquely calculated from equation (488), but cannot be expressed as a formula. Indeed, Wien's constant contains the solution of the equation $x = 5(1 - \mathrm{e}^{(} - x))$.

Light as weapon?

In many countries, there is more money to study assault weapons than to increase the education and wealth of their citizen. Several types of assault weapons using electromagnetic radiation are being researched. Two are particularly advanced.

The first weapon is a truck with a movable parabolic antenna on its roof, about 1 m in size, that emits a high power (a few kW) microwave (95 GHz) beam. The beam, like all microwave beams, is invisible; depending on power and beam shape, it is painful or lethal, up to a distance of a 100 m. This terrible device, with which the operator can make many many victims without even noticing, was ready in 2006. (Who expects that a parabolic antenna is dangerous?) Efforts to ban it across the world are slowly gathering momentum.

The second weapon under development is the so-called *pulsed impulse kill laser*. The idea is to take a laser that emits radiation that is not absorbed by air, steam or similar obstacles. An example is a pulsed deuterium fluoride laser that emits at 3.5 μm. This laser burns every material it hits; in addition, the evaporation of the plasma produced by the burn produces a strong hit, so that people hit by such a laser are hurt and hit at the same time. Fortunately, it is still difficult to make such a device rugged enough for practical use. Nevertheless, experts expect battle lasers to appear soon. In short, it is probable that radiation weapons will appear in the coming years.*

Chapter 27

CHARGES ARE DISCRETE – THE LIMITS OF CLASSICAL ELECTRODYNAMICS

One of the most important results of physics has already been mentioned a number of times: *electric charge is discrete*. Charge does not vary continuously, but changes in fixed steps. Not only does nature show a smallest value of entropy and smallest amounts of matter; nature also shows a smallest charge. Electric charge is quantized.

In metals, the quantization of charge is noticeable in the flow of electrons. In electrolytes, i.e. electrically conducting liquids, the quantization of charge appears in the flow of charged atoms, usually called *ions*. All batteries have electrolytes inside; also water is an electrolyte, though a poorly conducting one. In plasmas, like fire or fluorescent lamps, both ions and electrons move and show the discreteness of charge. Also in radiation – from the electron beams inside TVs, channel rays formed in special glass tubes, and cosmic radiation, up to radioactivity – charges are quantized.

From all known experiments, the same smallest value for charge change has been found. The result is

$$\Delta q \geqslant e = 1.6 \times 10^{-19}\,\mathrm{C}\,. \tag{491}$$

In short, like all flows in nature, the flow of electricity is due to a flow of discrete particles.

A smallest charge change has a simple implication: classical electrodynamics is *wrong*. A smallest charge implies that no infinitely small test charges exist. But such infinitely small test charges are necessary to define electric and magnetic fields. The limit on charge size also implies that there is no correct way of defining an instantaneous electric current and, as a consequence, that the values of electric and magnetic field are always somewhat fuzzy. Maxwell's evolution equations are thus only approximate.

We will study the main effects of the discreteness of charge in the part on quantum theory. Only a few effects of the quantization of charge can be treated in classical physics. An instructive example follows.

Page 1041

How fast do charges move?

In vacuum, such as inside a colour television, charged particles accelerated by a voltage of 30 kV move with a third of the speed of light. In modern particle accelerators charges move so rapidly that their speed is indistinguishable from that of light for all practical purposes.

Challenge 1158 s

Inside a metal, electric signals move with speeds of the order of the speed of light. The precise value depends on the capacity and impedance of the cable and is usually in the range $0.3c$ to $0.5c$. This high speed is due to the ability of metals to easily take in arriving

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

charges and to let others depart. The ability for rapid reaction is due to the high mobility of the charges inside metals, which in turn is due to the small mass and size of these charges, the electrons.

The high signal speed in metals appears to contradict another determination. The drift speed of the electrons in a metal wire obviously obeys

$$v = \frac{I}{Ane} \,, \tag{492}$$

where I is the current, A the cross-section of the wire, e the charge of a single electron and n the number density of electrons. The electron density in copper is $8.5 \cdot 10^{28}\ \mathrm{m}^{-3}$. Using a typical current of 0.5 A and a typical cross-section of a square millimetre, we get a drift speed of 0.37 μm/s. In other words, electrons move a thousand times slower than ketchup inside its bottle. Worse, if a room lamp used direct current instead of alternate current, the electrons would take several days to get from the switch to the bulb! Nevertheless, the lamp goes on or off almost immediately after the switch is activated. Similarly, the electrons from an email transported with direct current would arrive much later than a paper letter sent at the same time; nevertheless, the email arrives quickly. Are you able to explain the apparent contradiction between drift velocity and signal velocity?

Challenge 1159 s

Inside liquids, charges move with a different speed from that inside metals, and their charge to mass ratio is also different. We all know this from direct experience. Our *nerves* work by using electric signals and take (only) a few milliseconds to respond to a stimulus, even though they are metres long. A similar speed is observed inside semiconductors and inside batteries. In all these systems, moving charge is transported by *ions*; they are charged atoms. Ions, like atoms, are large and composed entities, in contrast to the tiny electrons.

In other matter systems, charges move both as electrons and as ions. Examples are neon lamps, fire, plasmas and the Sun. Inside atoms, electrons behave even more strangely. One tends to think that they orbit the nucleus (as we will see later) at a rather high speed, as the orbital radius is so small. However, it turns out that in most atoms many electrons do not orbit the nucleus at all. The strange story behind atoms and their structure will be told in the quantum part of our mountain ascent.

Page 1042

Challenges and curiosities about charge discreteness

Challenge 1160 s How would you show experimentally that electrical charge comes in smallest chunks?

* *

The discreteness of charge implies that one can estimate the size of atoms by observing galvanic deposition. How?

Challenge 1161 ny

* *

Cosmic radiation consists of charged particles hitting the Earth. (We will discuss this in more detail later.) Astrophysicists explain that these particles are accelerated by the magnetic fields around the Galaxy. However, the expression of the Lorentz acceleration shows that magnetic fields can only change the direction of the velocity of a charge, not

Page 1222
Ref. 644

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1162 ny its magnitude. How can nature get acceleration nevertheless?

* *

What would be the potential of the Earth in volt if we could take away all the electrons
Challenge 1163 s of a drop of water?

* *

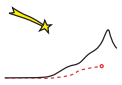
When a voltage is applied to a resistor, how long does it take until the end value of the current, given by Ohm's 'law', is reached? The first to answer this question was Paul Drude.* in the years around 1900. He reasoned that when the current is switched on, the speed v of an electron increases as $v = (eE/m)t$, where E is the electrical field, e the charge and m the mass of the electron. Drude's model assumes that the increase of electron speed stops when the electron hits an atom, loses its energy and begins to be accelerated again. Drude deduced that the average time τ up to the collision is related to the specific resistance by

$$\rho = \frac{E}{j} = \frac{E}{envv} = \frac{2m}{\tau e^2 n} \,, \tag{493}$$

with n being the electron number density. The right side does not depend on E any more; it is a constant. Drude had thus explained *Ohm's relation* $U = RI$ (or $E = j\rho$) from material properties, by assuming that resistance is due to moving electrons that continuously collide and speed up again. Inserting numbers for copper ($n = 10.3 \cdot 10^{28}\,/\mathrm{m}^{-3}$ and $\rho = 0.16 \cdot 10^{-7}\,\Omega\mathrm{m}$), one gets a time $\tau = 42\,\mathrm{ps}$. This time is so short that the switch-on process can usually be neglected.

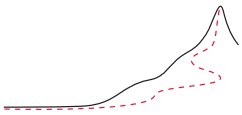
* *

Does it make sense to write Maxwell's equations in vacuum? Both electrical and magnetic fields require charges in order to be measured. But in vacuum there are no charges at all. Worse, fields are defined by using infinitesimally small test charges. But such charges do not exist. In fact, only quantum theory solves this apparent contradiction. Are you able
Challenge 1164 d to imagine how?



* Paul Karl Ludwig Drude (1863–1906), German physicist. A result of his electron gas model of metals was the prediction, roughly correct, that the ratio between the thermal conductivity and the electric conductivity at a given temperature should be the same for all metals. Drude also introduced c as the symbol for the speed of light.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 28

ELECTROMAGNETIC EFFECTS

Is lightning a discharge? – Electricity in the atmosphere

Looking carefully, the atmosphere is full of electrical effects. The most impressive electrical phenomenon we observe, lightning, is now reasonably well understood. Inside a thunderstorm cloud, especially inside tall *cumulonimbus* clouds,* charges are separated by collision between the large 'graupel' ice crystals falling due to their weight and the small 'hail' ice crystallites rising due to thermal upwinds. Since the collision takes part in an electric field, charges are separated in a way similar to the mechanism in the Kelvin generator. Discharge takes place when the electric field becomes too high, taking a strange path influenced by ions created in the air by cosmic rays. It seems that cosmic rays are at least partly responsible for the zigzag shape of lightning.

Ref. 655 Ref. 657 Page 673

Lightning flashes have strange properties. First, they appear at fields around 200 kV/m (at low altitude) instead of the 2 MV/m of normal sparks. Second, lightning emits radio pulses. Third, they emit gamma rays. Russian researchers, from 1992 onwards explained all three effects by a newly discovered discharge mechanism. At length scales of 50 m and more, cosmic rays can trigger the appearance of lightning; the relativistic energy of these rays allows for a discharge mechanism that does not exist for low energy electrons. At relativistic energy, so-called runaway breakdown leads to discharges at much lower fields than usual laboratory sparks. The multiplication of these relativistic electrons also leads to the observed radio and gamma ray emissions.

Ref. 658

Incidentally, you have a 75 % chance of survival after being hit by lightning, especially if you are completely wet, as in that case the current will flow outside the skin. Usually, wet people who are hit lose all their clothes, as the evaporating water tears them off. Rapid resuscitation is essential to help somebody to recover after a hit.**

* Clouds have Latin names. They were introduced in 1802 by the English explorer Luke Howard (1772–1864), who found that all clouds could be seen as variations of three types, which he called *cirrus*, *cumulus* and *stratus*. He called the combination of all three, the rain cloud, *nimbus* (from the Latin 'big cloud'). Today's internationally agreed system has been slightly adjusted and distinguishes clouds by the height of their lower edge. The clouds starting above a height of 6 km are the cirrus, the cirrocumulus and the cirrostratus; those starting at heights of between 2 and 4 km are the altocumulus, the altostratus and the nimbostratus; clouds starting below a height of 2 km are the stratocumulus, the stratus and the cumulus. The rain or thunder cloud, which crosses all heights, is today called *cumulonimbus*. For beautiful views of clouds, see the www.goes.noaa.gov and www.osei.noaa.gov websites.

Ref. 656

** If you are ever hit by lightning and survive, go to the hospital! Many people died three days later having failed to do so. A lightning strike often leads to coagulation effects in the blood. These substances block the kidneys, and one can die three days later because of kidney failure. The remedy is to have dialysis treatment.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 400 Cumulonimbus clouds from ground and from space (NASA)

As a note, you might know how to measure the distance of a lightning by counting the seconds between the lightning and the thunder and multiplying this by the speed of sound, 330 m/s; it is less well known that one can estimate the *length* of the lightning bolt by measuring the *duration* of the thunder, and multiplying it by the same factor.

In the 1990s more electrical details about thunderstorms became known. Airline pilots and passengers sometime see weak and coloured light emissions spreading from the top of thunderclouds. There are various types of such emissions: blue *jets* and mostly red *sprites* and *elves*, which are somehow due to electric fields between the cloud top and the ionosphere. The details are still under investigation, and the mechanisms are not yet clear.*

All these details are part of the electrical circuit around the Earth. This fascinating part of geophysics would lead us too far from the aim of our mountain ascent. But every physicist should know that there is a vertical electric field of between 100 and 300 V/m on a clear day, as discovered already in 1752. (Can you guess why it is not noticeable in everyday life? And why despite its value it cannot be used to extract large amounts of energy?) The field is directed from the ionosphere down towards the ground; in fact the Earth is permanently negatively charged, and in clear weather current flows downwards through the clear atmosphere, trying to *discharge* our planet. The current of about 1 kA is spread over the whole planet; it is possible due to the ions formed by cosmic radiation. (The resistance between the ground and the ionosphere is about 200 Ω, so the total voltage drop is about 200 kV.) At the same time, the Earth is constantly being *charged* by several effects: there is a dynamo effect due to the tides of the atmosphere and there are currents induced by the magnetosphere. But the most important effect is lightning. In other words, contrary to what one may think, lightning does not discharge the ground, it actually charges it up!** Of course, lightning does discharge the cloud to ground potential difference; but by doing so, it actually sends a negative charge down to the Earth as a whole. Thunderclouds are batteries; the energy from the batteries comes from the thermal uplifts mentioned above, which transport charge *against* the global ambient electrical field.

Challenge 1165 s

Ref. 659

* For images, have a look at the interesting sprite.gi.alaska.edu/html/sprites.htm, www.fma-research.com/spriteres.htm and paesko.ee.psu.edu/Nature websites.

Challenge 1166 s ** The Earth is thus charged to about −1 MC. Can you confirm this?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Using a few electrical measurement stations that measure the variations of the electrical field of the Earth it is possible to locate the position of all the lightning that comes down towards the Earth at a given moment. Present research also aims at measuring the activity of the related electrical sprites and elves in this way. Ref. 660

The ions in air play a role in the charging of thunderclouds via the charging of ice crystals and rain drops. In general, all small particles in the air are electrically charged. When aeroplanes and helicopters fly, they usually hit more particles of one charge than of the other. As a result, aeroplanes and helicopters are charged up during flight. When a helicopter is used to rescue people from a raft in high seas, the rope pulling the people upwards must first be earthed by hanging it in the water; if this is not done, the people on the raft could die from an electrical shock when they touch the rope, as has happened a few times in the past.

The charges in the atmosphere have many other effects. Recent experiments have confirmed what was predicted back in the early twentieth century: lightning emits X-rays. The confirmation is not easy though; it is necessary to put a detector near the lightning flash. To achieve this, the lightning has to be directed into a given region. This is possible using a missile pulling a metal wire, the other end of which is attached to the ground. These experimental results are now being collated into a new description of lightning which also explains the red-blue sprites above thunderclouds. In particular, the processes also imply that inside clouds, electrons can be accelerated up to energies of a few MeV. Ref. 661 Ref. 662

Why are sparks and lightning blue? This turns out to be a material property: the colour comes from the material that happens to be excited by the energy of the discharge, usually air. This excitation is due to the temperature of 30 kK inside the channel of a typical lightning flash. For everyday sparks, the temperature is much lower. Depending on the situation, the colour may arise from the gas between the two electrodes, such as oxygen or nitrogen, or it may due to the material evaporated from the electrodes by the discharge. For an explanation of such colours, as for the explanation of all colours due to materials, we need to wait for the next part of our walk, on quantum theory.

But not only electric fields are dangerous. Also time-varying electromagnetic fields can be. In 1997, in beautiful calm weather, a Dutch hot air balloon approached the powerful radio transmitter in Hilversum. After travelling for a few minutes near to the antenna, the gondola suddenly detached from the balloon, killing all the passengers inside.

An investigation team reconstructed the facts a few weeks later. In modern gas balloons the gondola is suspended by high quality nylon ropes. To avoid damage by lightning and in order to avoid electrostatic charging problems all these nylon ropes contain thin metal wires which form a large equipotential surface around the whole balloon. Unfortunately, in the face of the radio transmitter, these thin metal wires absorbed radio energy from the transmitter, became red hot, and melted the nylon wires. It was the first time that this had ever been observed.

Does ball lightning exist?

For hundreds of years, people have reported sightings of so-called *ball lightning*. Usually they were noticed during thunderstorms, often after a lightning had struck. With a few exceptions, nobody took these reports seriously, because no reproducible data existed. Ref. 663

When microwave ovens become popular, several methods to produce ball-shaped dis-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

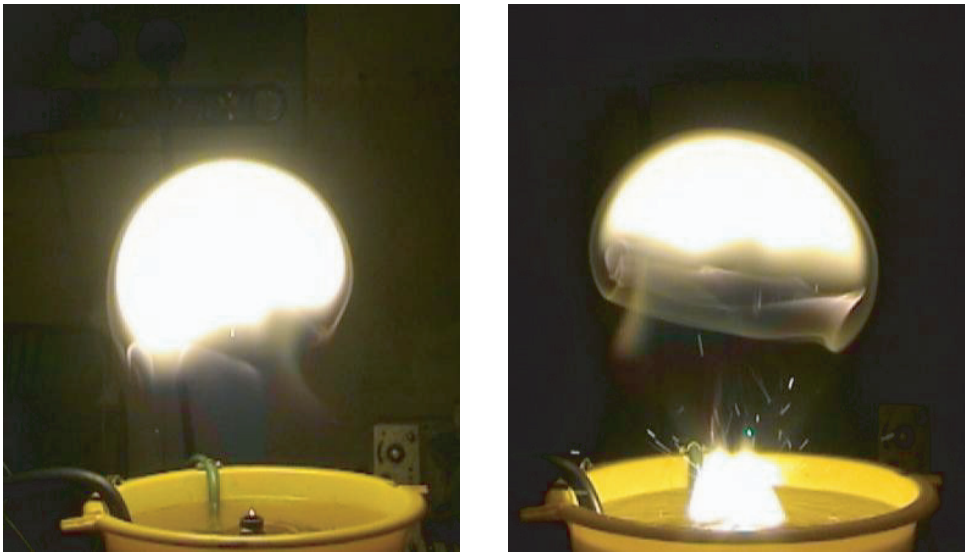


FIGURE 401 A floating plasma cloud produced in the laboratory (© Sergei Emelin and Alexei Pirozerski)

charges became known. To observe one, just stick a toothpick into a candle, light the toothpick, and put it into (somebody else's) microwave oven at maximum power. This set-up produces a beautiful ball-like discharge. However, humans do not live in a microwave oven.

Ref. 664 The experimental situation changed completely in the years 1999 to 2001. In those years the Russian physicists Anton Egorov and Gennady Shabanov discovered a way to produce plasma clouds, or *plasmoids*, floating in air, using three main ingredients: water, metal and high voltage. If high voltage is applied to submerged metal electrodes of the proper shape and make, plasma clouds emerge from the water, about 10 to 20 cm in size, float above the surface, and disappear after about half a second. Two examples can be seen in Figure 401.

The phenomenon of floating plasmoids is still being studied. There are variations in shape, colour, size and lifetime. The spectrum of observations and techniques will surely evolve in the coming years.

Ref. 665 An even more astonishing effect was published in 2007. A Brazilian research team found a way to make golf-ball sized discharges that seem to roll along the floor for as long as 8 s. Their method was beautifully simple: with the help of a 25 V power supply, they passed a current of 140 A through an arc at the surface of a silicon wafer. They discovered that small silicon particles detach and move away, while being surrounded by a luminous glow. These luminous clouds can wander around the table and floor of the laboratory, until they extinguish.

It seems that these phenomena could explain a number of ball lightning observations.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Does gravity make charges radiate?

We learned in the section on general relativity that gravitation has the same effects as acceleration. This means that a charge kept fixed at a certain height is equivalent to a charge accelerated by $9.8\,\mathrm{m/s^2}$, which would imply that it radiates electromagnetically, since all accelerated charges radiate. However, the world around us is full of charges at fixed heights, and there is no such radiation. How is this possible?

Ref. 666 The question has been a pet topic for many years. Generally speaking, the concept of radiation is not observer invariant: If one observer detects radiation, a second one does not necessarily do so as well. The exact way a radiation field changes from one observer to the other depends on the type of relative motion and on the field itself.

A precise solution of the problem shows that for a uniformly accelerated charge, an observer undergoing the same acceleration only detects an electrostatic field. In contrast, an Ref. 667 inertial observer detects a radiation field. Since gravity is (to a high precision) equivalent to uniform acceleration, we get a simple result: gravity does not make electrical charges radiate for an observer at rest with respect to the charge, as is observed. The results holds true also in the quantum theoretical description.

Research questions

The classical description of electrodynamics is coherent and complete; nevertheless there are still many subjects of research. Here are a few of them.

The origin of the magnetic field of the Earth, the other planets, the Sun and even of the galaxy is a fascinating topic. The way that the convection of fluids inside the planets generates magnetic fields, an intrinsically three-dimensional problem, the influence of turbulence, of nonlinearities and of chaos makes it a surprisingly complex question.

The details of the generation of the magnetic field of the Earth, usually called the *geodynamo*, began to appear only in the second half of the twentieth century, when the knowl- Ref. 582 edge of the Earth's interior reached a sufficient level. The Earth's interior starts below the Earth's crust. The *crust* is typically 30 to 40 km thick (under the continents), though it is thicker under high mountains and thinner near volcanoes or under the oceans. As already mentioned, the crust consists of large segments, the *plates*, that move with respect to one other. The Earth's interior is divided into the *mantle* – the first 2900 km from the surface – and the *core*. The core is made up of a liquid *outer* core, 2210 km thick, and a solid *inner* core of 1280 km radius. (The temperature of the core is not well known; it is Challenge 1167 d believed to be 6 to 7 kK. Can you find a way to determine it? The temperature might have decreased a few hundred kelvin during the last 3000 million years.)

The Earth's core consists mainly of iron that has been collected from the asteroids that collided with the Earth during its youth. It seems that the liquid and electrically conducting outer core acts as a dynamo that keeps the magnetic field going. The magnetic energy comes from the kinetic energy of the outer core, which rotates with respect to the Earth's surface; the fluid can act as a dynamo because, apart from rotating, it also *convects* from deep inside the Earth to more shallow depths, driven by the temperature gradients between the hot inner core and the cooler mantle. Huge electric currents flow in complex ways through these liquid layers, maintained by friction, and create the magnetic field. Why this field switches orientation at irregular intervals of between a few tens of thousands and a few million years, is one of the central questions. The answers are difficult;

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

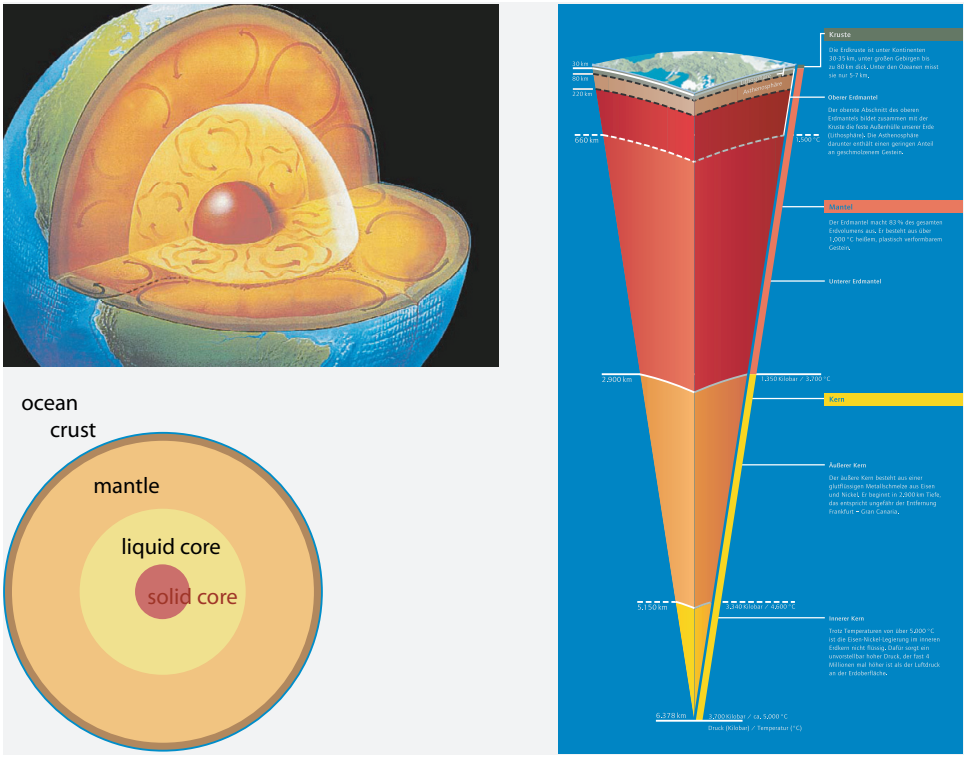

FIGURE 402 The structure of our planet (© MPI-Chemie, Mainz/GEO)

experiments are not yet possible, 150 years of measurements is a short time when compared with the last transition – about 730 000 years ago – and computer simulations are extremely involved. Since the field measurements started, the dipole moment of the magnetic field has steadily diminished, presently by 5% a year, and the quadrupole moment has steadily increased. Maybe we are heading towards a surprise.* (By the way, the study of *galactic* magnetic fields is even more complex, and still in its infancy.)

Another important puzzle about electricity results from the equivalence of mass and energy. It is known from experiments that the size d of electrons is surely smaller than Ref. 669 10^{-22} m. This means that the electric field surrounding it has an energy content E given Challenge 1168 e by at least

$$E_{\text{nergy}} = \frac{1}{2}\varepsilon_0 \int E^2_{\text{lectric field}}\, \mathrm{d}V = \frac{1}{2}\varepsilon_0 \int_d^\infty \left(\frac{1}{4\pi\varepsilon_o}\frac{q}{r^2}\right)^2 4\pi r^2 \mathrm{d}r$$
$$= \frac{q^2}{8\pi\varepsilon_o}\frac{1}{d} > 1.2\,\mu\mathrm{J}\,. \qquad (494)$$

On the other hand, the *mass* of an electron, usually given as $511\,\mathrm{keV/c^2}$, corresponds to

* In 2005, it has been reported that the inner core of the Earth seems to rotate faster than the Earth's crust Ref. 668 by up to half a degree per year.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

an energy of only 82 fJ, ten million times *less* than the value just calculated. In other words, classical electrodynamics has considerable difficulty describing electrons. In fact, a consistent description of charged point particles within classical electrodynamics is impossible. This pretty topic receives only a rare – but then often passionate – interest nowadays, because the puzzle is solved in a different way in the upcoming, quantum part of our mountain ascent.

Ref. 670

Even though the golden days of materials science are over, the various electromagnetic properties of matter and their applications in devices do not seem to be completely explored yet. About once a year a new effect is discovered that merits inclusion in the list of electromagnetic matter properties of Table 71. Among others, some newer semiconductor technologies will still have an impact on electronics, such as the recent introduction of low cost light detecting integrated circuits built in CMOS (complementary metal oxide silicon) technology.

Page 787

The building of light sources of high quality has been a challenge for many centuries and remains one for the future. Light sources that are intense, tunable and with large coherence length or sources that emit extreme wavelengths are central to many research pursuits. As one example of many, the first X-ray lasers have recently been built; however, they are several hundred metres in size and use modified particle accelerators. The construction of compact X-ray lasers is still many years off – if it is possible at all.

Electrodynamics and general relativity interact in many ways. Only a few cases have been studied up to now. They are important for black holes and for empty space. For example, it seems that magnetic fields increase the stiffness of empty space. Many such topics will appear in the future.

Ref. 671

But maybe the biggest challenge imaginable in classical electrodynamics is to decode the currents inside the brain. Will it be possible to read our thoughts with an apparatus placed outside the head? One could start with a simpler challenge: Would it be possible to distinguish the thought 'yes' from the thought 'no' by measuring electrical or magnetic fields around the head? In other words, is mind-reading possible? Maybe the twenty-first century will come up with a positive answer. If so, the team performing the feat will be instantly famous.

Challenge 1169 r

Levitation

We have seen that it is possible to move certain objects without touching them, using a magnetic or electric field or, of course, using gravity. Is it also possible, without touching an object, to keep it fixed, floating in mid-air? Does this type of rest exist?

It turns out that there are several methods of levitating objects. These are commonly divided into two groups: those that consume energy and those who do not. Among the methods that consume energy is the floating of objects on a jet of air or of water, the floating of objects through sound waves, e.g. on top of a siren, or through a laser beam coming from below, and the floating of conducting material, even of liquids, in strong radio-frequency fields. Levitation of liquids or solids by strong ultrasound waves is presently becoming popular in laboratories. All these methods give *stationary* levitation. Another group of energy consuming methods sense the way a body is falling and kick it up again in the right way via a feedback loop; these methods are *non-stationary* and usually use magnetic fields to keep the objects from falling. The magnetic train being built in Shang-

Ref. 672

Ref. 673

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 674 hai by a German consortium is levitated this way. The whole train, including the passengers, is levitated and then moved forward using electromagnets. It is thus possible, using magnets, to levitate many tens of tonnes of material.

For levitation methods that do *not* consume energy – all such methods are necessarily stationary – a well-known limitation can be found by studying Coulomb's 'law' of electrostatics: no static arrangement of electric fields can levitate a *charged* object in free space or in air. The same result is valid for gravitational fields and *massive* objects;* in other words, we cannot produce a local minimum of potential energy in the middle of a Ref. 675 box using electric or gravitational fields. This impossibility is called *Earnshaw's theorem*. Speaking mathematically, the solutions of the Laplace equation $\Delta\varphi = 0$, the so-called *harmonic functions*, have minima or maxima only at the border, and never inside the domain of definition. (You proved this yourself on page 149.) The theorem can also be proved by noting that given a potential minimum in free space, Gauss' theorem for a sphere around that minimum requires that a source of the field be present inside, which is in contradiction with the original assumption.

We can deduce that it is also impossible to use electric fields to levitate an electrically *neutral* body in air: the potential energy U of such a body, with volume V and dielectric constant ε, in an environment of dielectric constant ε_0, is given by

$$\frac{U}{V} = -\frac{1}{2}(\varepsilon - \varepsilon_0) E^2 \quad . \tag{495}$$

Challenge 1170 ny Since the electric field E never has a maximum in the absence of space charge, and since for all materials $\varepsilon > \varepsilon_0$, there cannot be a minimum of potential energy in free space for a neutral body.**

To sum up, using static electric or static gravitational fields it is impossible to keep an object from falling; neither quantum mechanics, which incorporates phenomena such as antimatter, nor general relativity, including phenomena such as black holes, change this basic result.

For static *magnetic* fields, the argument is analogous to electrical fields: the potential energy U of a magnetizable body of volume V and permeability μ in a medium with Challenge 1172 ny permeability μ_0 containing no current is given by

$$\frac{U}{V} = -\frac{1}{2}\left(\frac{1}{\mu} - \frac{1}{\mu_0}\right) B^2 \tag{496}$$

and due to the inequality $\Delta B^2 \geqslant 0$, isolated maxima of a static magnetic field are not possible, only isolated minima. Therefore, it is impossible to levitate paramagnetic ($\mu > \mu_0$) or ferromagnetic ($\mu \gg \mu_0$) materials such as steel, including bar magnets, which are Challenge 1173 e all attracted, and not repelled to magnetic field maxima.

Page 95 * To the disappointment of many science-fiction addicts, this would even be true if a negative mass existed. And even though gravity is not really due to a field, but to space-time curvature, the result still holds in general relativity.

Ref. 676 ** It is possible, however, to 'levitate' gas bubbles in liquids – 'trap' them to prevent them from rising would be a better expression – because in such a case the dielectric constant of the environment is higher than that Challenge 1171 ny of the gas. Can you find a liquid–gas combination where bubbles fall instead of rise?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

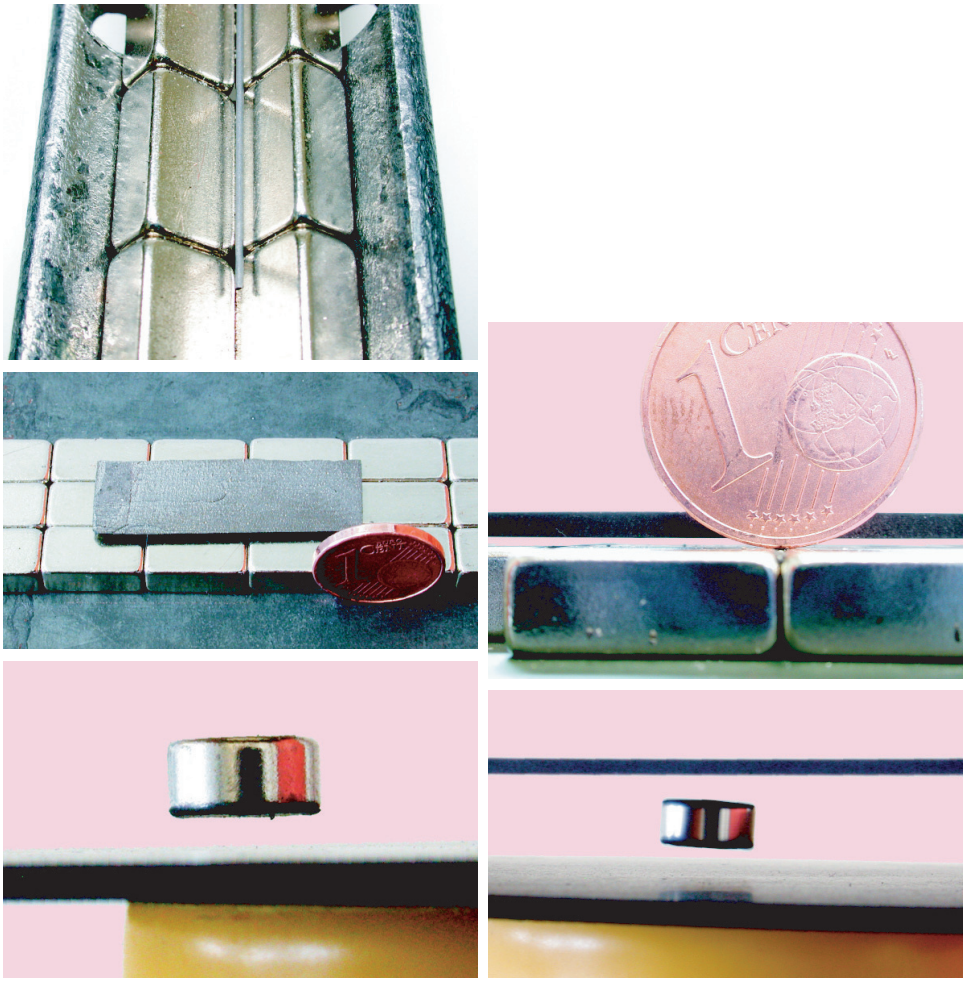

FIGURE 403 Stable diamagnetic levitation of a graphite bar over rectangular permanent magnets (above) and of two graphite plates, one seen from above and another from the side (center); below, levitation of a 4 mm diamater NdFeB permanent magnet, above a graphite plate and between two graphite plates, near a large ring magnet (not shown) (© Joachim Schlichting from Ref. 678)

There are thus two ways to realize magnetic levitation: levitating a diamagnet or using a time-dependent field. Diamagnetic materials ($\mu < \mu_0$, or $\mu_r = \mu/\mu_0 < 1$) were discovered shortly after Earnshaw published his theorem, and allow to circumvent it. Indeed, diamagnetic materials, such as graphite or water, can be levitated by static magnetic fields because they are attracted to magnetic field minima. In fact, it is possible to levitate magnets if one uses a combination containing diamagnets. A few cases that can easily be replicated on a kitchen table are shown in Figure 403.

Page 688
Ref. 677
Ref. 678

Another well-known example of diamagnetic levitation is the levitation of superconductors. Indeed, superconductors, at least those of type I, are perfects diamagnets ($\mu = 0$). In some cases, superconductors can even be *suspended* in mid-air, below a magnet. Also

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

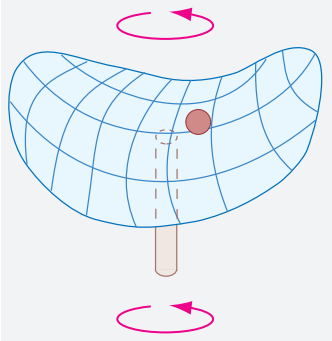

FIGURE 404 Trapping a metal sphere using a variable speed drill and a plastic saddle

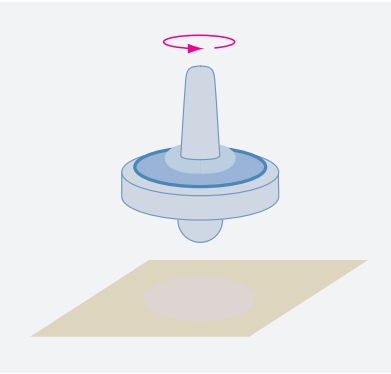

FIGURE 405 Floating 'magic' nowadays available in toy shops, left, with a spinning top and, right, with a spinning magnetic sphere levitating above a large ring magnet (© Kay Kublenz)

single atoms with a magnetic moment are diamagnets; they are routinely levitated this way and have also been photographed in this state. Single neutrons, which have a magnetic dipole moment, have been kept in magnetic bottles through magnetic levitation, until they decay.

Ref. 679

Diamagnets levitate if $\nabla B^2 > 2\mu_0\rho g/\chi$, where ρ is the mass density of the object and $\chi = 1 - \mu/\mu_0$ its magnetic susceptibility. Since χ is typically about 10^{-5} and ρ of order $1000\,\mathrm{kg/m^3}$, field gradients of about $1000\,\mathrm{T^2/m}$ are needed. In other words, levitation requires fields changes of 10 T over 10 cm, which is nowadays common for high field laboratory magnets.

Challenge 1174 ny

Recently, scientists have levitated pieces of wood and of plastic, strawberries, water droplets, liquid helium droplets as large as 2 cm, grasshoppers, fish and frogs (all alive and without any harm) using magnetic levitation. Indeed, animals, like humans, are all made of diamagnetic material. Humans themselves have not yet been levitated, but the feat, expected to require 40 T and large amounts of electrical power, is being planned and worked on. In fact, a similar feat has already been achieved: diamagetic levitation is being explored for the levitation of passenger trains, especially in Japan, though with little commercial success.

Ref. 680

Ref. 674

Time-dependent electrical or magnetic fields, e.g. periodic fields, can lead to levitation

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 672 in many different ways without any consumption of energy. This is one of the methods used in the magnetic bearings of turbomolecular vacuum pumps. Also single charged particles, such as ions and electrons, are now regularly levitated with Paul traps and Pen-
Ref. 672 ning traps. The mechanical analogy is shown in Figure 404.

Ref. 681 Figure 405 shows a toy that allows you to personally levitate a spinning top or a spinning magnetic sphere in mid-air above a ring magnet, a quite impressive demonstration of levitation for anybody looking at it. The photo shows that is not hard to build such a
Ref. 682 device yourself.

Even free electrons can be levitated, letting them float above the surface of fluid he-
Ref. 683 lium. In the most recent twist of the science of levitation, in 1995 Stephen Haley predicted that the suspension height of small magnetic particles above a superconducting ring should be quantized. However, the prediction has not been verified by experiment yet.

For the sake of completeness we mention that nuclear forces cannot be used for levitation in everyday life, as their range is limited to a few femtometres. However, we will
Page 1250 see later that the surface matter of the Sun is prevented from falling into the centre by these interactions; we could thus say that it is indeed levitated by nuclear interactions.

Matter, levitation and electromagnetic effects

The levitation used by magicians mostly falls into another class. When David Copperfield, a magician performing for the MTV generation at the end of the twentieth century, 'flies' during his performances, he does so by being suspended on thin fishing lines that are
Challenge 1175 s rendered invisible by clever lighting arrangements. (How could one check this?) In fact, if we want to be precise, we should count fishing lines, plastic bags, as well as every table and chair as levitation devices. (Tabloid journalists would even call them 'anti-gravity' devices.) Contrary to our impression, a hanging or lying object is not really in contact with the suspension, if we look at the critical points with a microscope.* More about this in the quantum part of our walk.

But if this is the case, why don't we fall through a table or through the floor? We started the study of mechanics by stating that a key property of matter its *solidity*, i.e., the impossibility of having more than one body at the same place at the same time. But what is the origin of solidity? Again, we will be able to answer the question only in the
Page 1152 upcoming, quantum part of our adventure, but we can already collect the first clues at this point.

Solidity is due to electricity. Many experiments show that matter is constituted of charged particles; indeed, matter can be moved and influenced by electromagnetic fields
Ref. 684 in many ways. Over the years, material scientists have produced a long list of such effects, all of which are based on the existence of charged constituents. Can you find or imagine
Challenge 1177 r a new one? For example, can electric charge change the colour of objects?

Challenge 1176 ny * The issue is far from simple: which one of the levitation methods described above is used by tables or chairs?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 71 Selected matter properties related to electromagnetism, showing among other things the role it plays in the constitution of matter; at the same time a short overview of atomic, solid state, fluid and business physics

Property	Example	Definition
thermal radiation or heat radiation or incandescence	every object	temperature-dependent radiation emitted by any macroscopic amount of matter
Interactions with charges and currents		
electrification	separating metals from insulators	spontaneous charging
triboelectricity	glass rubbed on cat fur	charging through rubbing
barometer light	mercury slipping along glass	gas discharge due to triboelectricity Ref. 685
insulation	air	no current flow below critical voltage drop
semiconductivity	diamond, silicon or gallium arsenide	current flows only when material is impure ('doped')
conductivity	copper, metals	current flows easily
superconductivity	niobium	current flows indefinitely
ionization	fire flames	current flows easily
localization (weak, Anderson)	disordered solids	resistance of disordered solids
resistivity, Joule effect	graphite	heating due to current flow
thermoelectric effects: Peltier effect, Seebeck effect, Thomson effect	ZnSb, PbTe, PbSe, BiSeTe, Bi_2Te_3, etc.	cooling due to current flow, current flow due to temperature difference, or due to temperature gradients
acoustoelectric effect	CdS	sound generation by currents, and vice versa
magnetoresistance	iron, metal multilayers	resistance changes with applied magnetic field Ref. 686
recombination	fire alarms	charge carriers combine to make neutral atoms or molecules
annihilation	positron tomography	particle and antiparticle, e.g. electron and positron, disappear into photons
Penning effect	Ne, Ar	ionization through collision with metastable atoms
Richardson effect, thermal emission	BaO_2, W, Mo, used in tv and electron microscopes	emission of electrons from hot metals
skin effect	Cu	high current density on exterior of wire
pinch effect	InSb, plasmas	high current density on interior of wire
Josephson effect	Nb-Oxide-Nb	tunnel current flows through insulator between two superconductors
Sasaki–Shibuya effect	n-Ge, n-Si	anisotropy of conductivity due to applied electric field
switchable magnetism	InAs:Mn	voltage switchable magnetization Ref. 687

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

PROPERTY	EXAMPLE	DEFINITION
Interactions with magnetic fields		
Hall effect	silicon; used for magnetic field measurements	voltage perpendicular to current flow in applied magnetic field
Zeeman effect	Cd	change of emission frequency with magnetic field
Paschen–Back effect	atomic gases	change of emission frequency in strong magnetic fields
ferromagnetism	Fe, Ni, Co, Gd	spontaneous magnetization; material strongly attracted by magnetic fields
paramagnetism	Fe, Al, Mg, Mn, Cr	induced magnetization parallel to applied field; attracted by magnetic fields
diamagnetism	water, Au, graphite, NaCl	induced magnetization opposed to applied field; repelled by magnetic fields
magnetostriction	CeB_6, $CePd_2Al_3$	change of shape or volume by applied magnetic field
magnetoelastic effect	Fe, Ni	change of magnetization by tension or pressure
acoustomagnetic effect	metal alloys, anti-theft stickers	excitation of mechanical oscillations through magnetic field
spin valve effect	metal multilayers	electrical resistance depends on spin direction of electrons with respect to applied magnetic field
magneto-optical activity or Faraday effect or Faraday rotation	flint glass	polarization angle is rotated with magnetic field; different refraction index for right and left circularly polarized light, as in magneto-optic (MO) recording
magnetic circular dichroism	gases	different absorption for right- and left-circularly polarized light; essentially the same as the previous one
Majorana effect	colloids	specific magneto-optic effect
photoelectromagnetic effect	InSb	current flow due to light irradiation of semiconductor in a magnetic field
Voigt effect	vapours	birefringence induced by applied magnetic field
Cotton–Mouton effect	liquids	birefringence induced by applied magnetic field
Hanle effect	Hg	change of polarization of fluorescence with magnetic field
Shubnikov–de Haas effect	Bi	periodic change of resistance with applied magnetic field

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

PROPERTY	EXAMPLE	DEFINITION
thermomagnetic effects: Ettinghausen effect, Righi–Leduc effect, Nernst effect, magneto–Seebeck effect	BiSb alloys	relation between temperature, applied fields and electric current
Ettinghausen–Nernst effect	Bi	appearance of electric field in materials with temperature gradients in magnetic fields
photonic Hall effect	CeF_3	transverse light intensity depends on the applied magnetic field Ref. 688
magnetocaloric effect	gadolinium, GdSiGe alloys	material cools when magnetic field is switched off Ref. 689
cyclotron resonance	semiconductors, metals	selective absorption of radio waves in magnetic fields
magnetoacoustic effect	semiconductors, metals	selective absorption of sound waves in magnetic fields
magnetic resonance	most materials, used for imaging in medicine for structure determination of molecules	selective absorption of radio waves in magnetic fields
magnetorheologic effect	liquids, used in advanced car suspensions	change of viscosity with applied magnetic fields
Meissner effect	type 1 superconductors, used for levitation	expulsion of magnetic field from superconductors
Interactions with electric fields		
polarizability	all matter	polarization changes with applied electric field
ionization, field emission, Schottky effect	all matter, tv	charges are extracted at high fields
paraelectricity	$BaTiO_3$	applied field leads to polarization in same direction
dielectricity	water	in opposite direction
ferroelectricity	$BaTiO_3$	spontaneous polarization below critical temperature
piezoelectricity	the quartz lighter used in the kitchen, human bones	polarization appears with tension, stress, or pressure
electrostriction	platinum sponges in acids	shape change with applied voltage Ref. 690

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

PROPERTY	EXAMPLE	DEFINITION
pyroelectricity	$CsNO_3$, tourmaline, crystals with polar axes; used for infrared detection	change of temperature produces charge separation
electro-osmosis or electrokinetic effect	many ionic liquids	liquid moves under applied electric field Ref. 691
electrowetting	salt solutions on gold	wetting of surface depends on applied voltage
electrolytic activity	sulphuric acid	charge transport through liquid
liquid crystal effect	watch displays	molecules turn with applied electric field
electro-optical activity: Kerr effect, Pockels effect	liquids (e.g. oil), crystalline solids	material in electric field rotates light polarization, i.e., produces birefringence
Freederichsz effect, Schadt–Helfrichs effect	nematic liquid crystals	electrically induced birefringence
Stark effect	hydrogen, mercury	colour change of emitted light in electric field
field ionization	helium near tungsten tips in field ion microscope	ionization of gas atoms in strong electric fields
Zener effect	Si	energy-free transfer of electrons into conduction band at high fields
field evaporation	W	evaporation under strong applied electric fields
Interactions with light		
absorption	coal, graphite	transformation of light into heat or other energy forms (which ones?)Challenge 1178 s
blackness	coal, graphite	complete absorption in visible range
colour, metallic shine	ruby	absorption depending on light frequency
photostriction	PbLaZrTi	light induced piezoelectricity
photography	AgBr, AgI	light precipitates metallic silver
photoelectricity, photoeffect	Cs	current flows into vacuum due to light irradiation
internal photoelectric effect	Si p–n junctions, solar cells	voltage generation and current flow due to light irradiation
photon drag effect	p-Ge	current induced by photon momentum
emissivity	all bodies	ability to emit light
transparency	glass, quartz, diamond	low reflection, low absorption, low scattering
reflectivity	metals	light bounces on surface
polarization	pulled polymer sheets	light transmission depending on polarization angle
optical activity	sugar dissolved in water, quartz	rotation of polarization

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Property	Example	Definition
birefringence	calcite,cornea	refraction index depends on polarization direction, light beams are split into two beams
dichroism	aminoacids, andalusite	absorption depends on circular polarization
optically induced anisotropy, Weigert effect	AgCl	optically induced birefringence and dichroism
second harmonic generation	$LiNbO_3$, KPO_4	light partially transformed to double frequency
luminescence: general term for opposite of incandescence	GaAs, tv	cold light emission
fluorescence	CaF_2, X-ray production, light tubes, cathode ray tubes	light emission during and after light absorption or other energy input
phosphorescence	$TbCl_3$	light emission due to light, electrical or chemical energy input, continuing *long after* stimulation
electroluminescence	ZnS	emission of light due to alternating electrical field
photoluminescence	ZnS : Cu, $SrAlO_4$: Eu, Dy, hyamine	light emission triggered by UV light, used in safety signs
chemoluminescence	H_2O_2, phenyl oxalate ester, dye	cold light emission used in light sticks for divers and fun
bioluminescence	glow-worm, deep sea fish	cold light emission in animals
triboluminescence	sugar	light emission during friction or crushing
thermoluminescence	quartz, feldspar	light emission during heating, used e.g. for archaeological dating of pottery Ref. 692
bremsstrahlung	X-ray generation	radiation emission through fast deceleration of electrons
Compton effect	momentum measurements	change of wavelength of light, esp. X-rays and gamma radiation, colliding with matter
Čerenkov effect	water, polymer particle detectors	light emission in a medium due to particles, e.g. emitted by radioactive processes, moving faster than the speed of light in that medium
transition radiation	any material	light emission due to fast particles moving from one medium to a second with different refractive index
electrochromicity	wolframates	colour change with applied electric field
scattering	gases, liquids	light changes direction

PROPERTY	EXAMPLE	DEFINITION
Mie scattering	dust in gases	light changes direction
Raleigh scattering	sky	light changes direction, sky is blue
Raman effect or Smekal–Raman effect	molecular gases	scattered light changes frequency
laser activity, superradiation	beer, ruby, He–Ne	emission of stimulated radiation
sonoluminescence	air in water	light emission during cavitation
gravitoluminescence	does not exist; Challenge 1179 s why?	
switchable mirror	LaH	voltage controlled change from reflection to transparency Ref. 693
radiometer effect	bi-coloured windmills	irradiation turns mill (see page 745)
luminous pressure	*idem*	irradiation turns mill directly
solar sail effect	future satellites	motion due to solar wind
acoustooptic effect	$LiNbO_3$	diffraction of light by sound in transparent materials
photorefractive materials	$LiNbO_3$, GaAs, InP	light irradiation changes refractive index
Auger effect	Auger electron spectroscopy	electron emission due to atomic reorganization after ionization by X-rays
Bragg reflection	crystal structure determination	X-ray diffraction by atomic planes
Mößbauer effect	Fe, used for spectroscopy	recoil-free resonant absorption of gamma radiation
pair creation	Pb	transformation of a photon in a charged particle–antiparticle pair
photoconductivity	Se, CdS	change of resistivity with light irradiation
optoacoustic affect, photoacoustic effect	gases, solids	creation of sound due to absorption of pulsed light
optogalvanic effect	plasmas	change of discharge current due to light irradiation
optical nonlinear effects: parametric amplification, frequency mixing, saturable absorption, *n*-th harmonic generation, optical Kerr effect, etc.		
phase conjugated mirror activity	gases	reflection of light with opposite phase
Material properties		
solidity, impenetrability	floors, columns, ropes, buckets	at most one object per place at a given time
Interactions with vacuum		
Casimir effect	metals	attraction of uncharged, conducting bodies

All matter properties in the list can be influenced by electric or magnetic fields or

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

directly depend on them. This shows that the nature of all these material properties is electromagnetic. In other words, charges and their interactions are an essential and fundamental part of the structure of objects. The table shows so many different electromagnetic properties that the motion of charges inside each material must be complex indeed. Most effects are the topic of solid state physics,* fluid and plasma physics.

Solid state physics is by far the most important part of physics, when measured by the impact it has on society. Almost all effects have applications in technical products, and give employment to many people. Can you name a product or business application for any randomly chosen effect from the table?

Challenge 1180 e

In our mountain ascent however, we look at only one example from the above list: thermal radiation, the emission of light by hot bodies.

Earnshaw's theorem about the impossibility of a stable equilibrium for charged particles at rest implies that the charges inside matter must be *moving*. For any charged particle in motion, Maxwell's equations for the electromagnetic field show that it radiates energy by emitting electromagnetic waves. In short, classical mechanics thus predicts that matter must radiate electromagnetic energy.

Interestingly, everybody knows from experience that this is indeed the case. Hot bodies light up depending on their temperature; the working of light bulbs thus proves that metals are made of charged particles. *Incandescence*, as it is called, requires charges. Actually, *every* body emits radiation, even at room temperature. This radiation is called *thermal radiation*; at room temperature it lies in the infrared. Its intensity is rather weak in everyday life; it is given by the general expression

Ref. 694

$$I(T) = f\,T^4\,\frac{2\pi^5 k^4}{15c^2h^3} \quad \text{or} \quad I(T) = f\sigma T^4 \quad \text{with} \quad \sigma = 56.7\,\text{nW/K}^4\text{m}^2\,, \tag{497}$$

where f is a material-, shape- and temperature-dependent factor, with a value between zero and one, and is called the *emissivity*. The constant σ is called the *Stefan–Boltzmann black body radiation constant* or *black body radiation constant*. A body whose emissivity is given by the ideal case $f = 1$ is called a *black body*, because at room temperature such a body also has an ideal absorption coefficient and thus appears black. (Can you see why?) The heat radiation such a body emits is called *black body radiation*.

Challenge 1181 s

Ref. 695

By the way, which object radiates more energy: a human body or an average piece of the Sun of the same mass? Guess first!

Challenge 1182 s

Challenges and fun curiosities about electromagnetic effects

'Inside a conductor there is no electric field.' This statement is often found. In fact the truth is not that simple. First, a *static* field or a *static* charge on the metal surface of a body does not influence fields and charges inside it. A closed metal surface thus forms a shield against an electric field. Can you give an explanation? In fact, a tight metal layer is not required to get the effect; a cage is sufficient. One speaks of a *Faraday cage*.

Challenge 1183 s

The detailed mechanism allows you to answer the following question: do Faraday cages for gravity exist? Why?

* Probably the best and surely the most entertaining introductory English language book on the topic is the one by Neil Ashcroft & David Mermin, *Solid State Physics*, Holt Rinehart & Winston, 1976.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

For *moving* external fields or charges, the issue is more complex. Fields due to accelerated charges – radiation fields – decay exponentially through a shield. Fields due to charges moving at constant speed are strongly reduced, but do not disappear. The reduction depends on the thickness and the resistivity of the metal enclosure used. For sheet metal, the field suppression is very high; it is not necessarily high for metal sprayed plastic. Such a device will not necessarily survive a close lightning stroke. Ref. 649

In practice, there is no danger if lightning hits an aeroplane or a car, as long they are made of metal. (There is one film on the internet of a car hit by lightning; the driver does not even notice.) However, if your car is hit by lightning in dry weather, you should wait a few minutes before getting out of it. Can you imagine why?

Faraday cages also work the other way round. (Slowly) changing electric fields that are inside a Faraday cage are not felt outside. For this reason, radios, mobile phones and computers are surrounded by boxes made of metal or metal-sprayed plastics. The metal keeps the so-called *electromagnetic smog* to a minimum.

There are thus three reasons to surround electric appliances by a grounded shield: to protect the appliance from outside fields, to protect people and other machines from electromagnetic smog, and to protect people against the mains voltage accidentally being fed into the box (for example, when the insulation fails). In high precision experiments, these three functions can be realized by three separate cages.

For purely magnetic fields, the situation is more complex. It is quite difficult to shield the inside of a machine from outside magnetic fields. How would you do it? In practice one often uses layers of so-called *mu-metal*; can you guess what this material does? Challenge 1184 ny

* *

Researchers are trying to detect tooth decay with the help of electric currents, using the observation that healthy teeth are bad conductors, in contrast to teeth with decay. How would you make use of this effect in this case? (By the way, it might be that the totally unrelated technique of imaging with terahertz waves could yield similar results.) Ref. 650 Challenge 1185 ny

* *

Human bone is piezoelectric: it produces electric signals when stressed. When we move and grow, the electric signals are used by the body to reinforce the bones in the regions that are in need. The piezoelectricity of the bones thus controls and guides their growth. This connection is also used to make fractured bones heal more rapidly: by applying *pulsed* magnetic fields to a broken bone, the healing is stimulated and accelerated. (Static magnetic fields obviously do not work for this aim.) Also teeth are piezoelectric, and the effect plays a role in their growth.

* *

In shops, one can buy piezoelectric devices – similar to a gas lighter – that are applied to mosquito bites and are said to reduce itching and even swelling. (Some product names are 'zanza click' and 'skeeter click') Can this be true? Challenge 1186 e

* *

A team of camera men in the middle of the Sahara were using battery-driven electrical equipment to make sound recordings. Whenever the microphone cable was a few tens

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of metres long, they also heard a 50 Hz power supply noise, even though the next power supply was thousands of kilometres away. An investigation revealed that the high voltage lines in Europe lose a considerable amount of power by irradiation; these 50 Hz waves are reflected by the ionosphere around the Earth and thus can disturb recording in the middle of the desert. Can you estimate whether this observation implies that living directly near a high voltage line is dangerous? Challenge 1187 s

* *

When solar plasma storms are seen on the Sun, astronomers first phone the electricity company. They know that about 24 to 48 hours later, the charged particles ejected by the storms will arrive on Earth, making the magnetic field on the surface fluctuate. Since power grids often have closed loops of several thousands of kilometres, additional electric currents are induced, which can make transformers in the grid overheat and then switch off. Other transformers then have to take over the additional power, which can lead to their overheating, etc. On several occasions in the past, millions of people have been left without electrical power due to solar storms. Today, the electricity companies avoid the problems by disconnecting the various grid sections, by avoiding large loops, by reducing the supply voltage to avoid saturation of the transformers and by disallowing load transfer from failed circuits to others.

* *

If the electric field is described as a sum of components of different frequencies, its so-called *Fourier components*, the amplitudes are given by Ref. 652

$$\hat{\boldsymbol{E}}(k,t) = \frac{1}{(2\pi)^3/2} \int \boldsymbol{E}(x,t) \mathrm{e}^{-i\boldsymbol{k}x} \, \mathrm{d}^3x \tag{498}$$

and similarly for the magnetic field. It then turns out that a Lorentz invariant quantity N, describing the energy per circular frequency ω, can be defined:

$$N = \frac{1}{8\pi} \int \frac{|\boldsymbol{E}(k,t)|^2 + |\boldsymbol{B}(k,t)|^2}{c|\boldsymbol{k}|} \, \mathrm{d}^3k \,. \tag{499}$$

Can you guess what N is physically? (Hint: think about quantum theory.) Challenge 1188 s

* *

Faraday discovered how to change magnetism into electricity, knowing that electricity could be transformed into magnetism. (The issue is subtle. Faraday's law is not the dual of Ampère's, as that would imply the use of magnetic monopoles; neither is it the reciprocal, as that would imply the displacement current. But he was looking for a link and he found a way to relate the two observations – in a novel way, as it turned out.) Faraday also discovered how to transform electricity into light and into chemistry. He then tried to change gravitation into electricity. But he was not successful. Why not? Challenge 1189 ny

* *

At high altitudes above the Earth, gases are completely ionized; no atom is neutral. One

Challenge 1193 s How can you give somebody an electrical shock using a 4.5 V battery and some wire?

A summary of classical electrodynamics and of its limits

All of classical electrodynamics can be summarized in three principles:

▷ Electric charges exert forces on other charges; for charges at rest, the force falls off as the inverse square of the distance.*
▷ Electric charges are conserved.
▷ Charges, like all matter, move slower than light.

From these principles we can deduce all of electrodynamics. Electrodynamics is thus built on the definition of charge, the conservation of charge, and the invariance of the speed of light. In particular, we can deduce the following basic statements.

Ref. 578

— The electromagnetic field is a physical observable, as shown e.g. by compass needles.
— The field sources are the (moving) charges, as shown by amber, lodestone or remote controls.
— The electromagnetic field changes the motion of electrically charged objects via the Lorentz expression as, for example, shown by electric motors.
— The field can exist in empty space and moves in it as a wave, as shown, for example, by the stars.
— The field behaves like a continuous quantity and is described by Maxwell's evolution equations, as shown, for example, by mobile phones and electric toothbrushes.

As usual, the motion of the sources and the field is reversible, continuous, conserved and deterministic. However, there is quite some fun in the offing; even though this description is correct in everyday life, during the rest of our mountain ascent we will find that the last bullet point must be wrong. A simple example shows this.

* Quantum theory will show that the first principle can be rephrased as: electric charges at rest emit virtual photons with a constant average rate.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

At a temperature of zero kelvin, when matter does not radiate thermally, we have the paradoxical situation that the charges inside matter cannot be moving, since no emitted radiation is observed, but they cannot be at rest either, due to Earnshaw's theorem. In short, the simple existence of matter – with its discrete charge values – shows that classical electrodynamics is wrong.

Page 787

In fact, the overview of material properties of Table 71 makes the same point even more strongly; classical electrodynamics can describe many of the effects listed, *but it cannot explain the origin of any of them*. Even though few of the effects will be studied in our walk – they are not essential for our adventure – the general concepts necessary for their description will be the topic of the upcoming part of this mountain ascent, that on quantum theory.

Chapter 29

CLASSICAL PHYSICS IN A NUTSHELL

With the description of mechanics, thermodynamics, general relativity and classical electrodynamics, our walk through classical physics is complete. Let summarize what we have found out and what we did not.

In nature, we learned to distinguish and to characterize objects, radiation and spacetime. All three can move. In all motion we distinguish the fixed, intrinsic properties from the varying state. All motion happens in such a way as to minimize change.

Looking for all the *fixed, intrinsic* aspects of objects, we find that all sufficiently small objects or particles are described completely by their mass and their electric charge. There is no magnetic charge. Mass and electric charge are thus the only localized intrinsic properties of classical, everyday objects. Both mass and electric charge are defined by the accelerations they produce around them. Both quantities are conserved; thus they can be added (with certain precautions). Mass, in contrast to charge, is always positive. Mass describes the interaction of objects with their environment, charge the interaction with radiation.

All *varying* aspects of objects, i.e., their state, can be described using momentum and position, as well as angular momentum and orientation. All four quantities can vary continuously in amount and direction. Therefore the set of all possible states forms a space, the so-called *phase space*. The state of extended objects is given by the states of all its constituent particles. These particles make up all objects and somehow interact electromagnetically.

The state of a particle depends on the observer. The state is useful to calculate the change that occurs in motion. For a given particle, the change is independent of the observer, but the states are not. The states found by different observers are related: the relations are called the 'laws' of motion. For example, for different times they are called *evolution equations*, for different places and orientations they are called *transformation relations*, and for different gauges they are called *gauge transformations*. All can be condensed in the principle of least action.

We also observe the motion of a massless entity: *radiation*. Everyday types of radiation, such as light, radio waves and their related forms, are travelling electromagnetic waves. They are described by same equations that describe the interaction of charged or magnetic objects. The speed of massless entities is the maximum possible speed in nature and is the same for all observers. The *intrinsic properties* of radiation are its dispersion relation and its energy–angular momentum relation. The *state* of radiation is described by its electromagnetic field strength, its phase, its polarization and its coupling to matter. The motion of radiation describes the motion of images.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The space-time *environment* is described by space and time coordinates. Space-time is also able to move, by changing its curvature. The intrinsic properties of space-time are the number of dimensions, its signature and its topology. The state is given by the metric, which describes distances and thus the local warpedness. The warpedness can oscillate and propagate, so that empty space can move like a wave.

Our environment is finite in age. It has a long history, and on large scales, all matter in the universe moves away from all other matter. The large scale topology of our environment is unclear, as is unclear what happens at its spatial and temporal limits.

Motion follows a simple rule: change is always as small as possible. This applies to matter, radiation and space-time. All energy moves in the way space-time dictates it, and space moves the way energy dictates it. This relation describes the motion of the stars, of thrown stones, of light beams and of the tides. Rest and free fall are the same, and gravity is curved space-time. Mass breaks conformal symmetry and thus distinguishes space from time.

Energy and mass speed is bound from above by a universal constant c, and energy change per time is bound from above by a universal constant $c^5/4G$. The speed value c is realized for the motion of massless particles. It also relates space to time. The power value $c^5/4G$ is realized by horizons. They are found around black holes and at the border of the universe. The value also relates space-time curvature to energy flow and thus describes the elasticity of space-time.

No two objects can be at the same spot at the same time. This is the first statement that humans encounter about electromagnetism. More detailed investigation shows that electric charge accelerates other charges, that charge is necessary to define length and time intervals, and that charges are the source of electromagnetic fields. Also light is such a field. Light travels at the maximum possible velocity. In contrast to objects, light can interpenetrate. In summary, we learned that of the two naive types of object motion, namely motion due to gravity – or space-time curvature – and motion due to the electromagnetic field, only the latter is genuine.

Above all, classical physics showed us that motion, be it linear or rotational, be it that of matter, radiation or space-time, is conserved. Motion is continuous. More than that, motion is similar to a continuous substance: it is never destroyed, never created, but always redistributed. Owing to conservation, all motion, that of objects, images and empty space, is predictable and reversible. Owing to conservation of motion, time and space can be defined. In addition, we found that classical motion is also right–left symmetric. Classical physics showed us that motion is predictable: there are *no* surprises in nature.

The future of planet Earth

Maybe nature shows no surprises, but it still provides many adventures. On the 8th of March 2002, a 100 m sized body almost hit the Earth. It passed at a distance of only 450 000 km from our planet. On impact, it would have destroyed a region the size of London. A few months earlier, a 300 m sized body missed the Earth by 800 000 km; the record for closeness so far was in 1994, when the distance was only 100 000 km.* Several other adventures can be predicted by classical physics, as shown in Table 72. Many are

* The web pages around cfa-www.harvard.edu/iau/lists/Closest.html provide more information on such events.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

problems facing humanity in the distant future, but some, such as volcanic eruptions or asteroid impacts, could happen at any time. All are research topics. Ref. 699

TABLE 72 Examples of disastrous motion of possible future importance

CRITICAL SITUATION	YEARS FROM NOW
End of fundamental physics	*c.* 30 (around year 2030)
Giant tsunami from volcanic eruption at Canary islands	*c.* 10-200
Major nuclear material accident or weapon use	unknown
Ozone shield reduction	*c.* 100
Mini ice age due to collapse of gulf stream	unknown
Rising ocean levels due to greenhouse warming	*c.* 100-1 000
End of applied physics	> 200
Explosion of volcano in Greenland, leading to long darkening of sky	unknown
Earth's mantle instability leading to massive volcanic activity	unknown
Several magnetic north and south poles appear, allowing solar storms to disturb radio and telecommunications, to interrupt electricity supplies, to increase animal mutations and to disorient migrating animals such as wales, birds and tortoises	*c.* 800
Our interstellar gas cloud detaches from the solar systems, changing the size of the heliosphere, and thus expose us more to aurorae and solar magnetic fields	*c.* 3 000
Reversal of Earth's magnetic field, implying a time with almost no magnetic field, with increased cosmic radiation levels and thus more skin cancers and miscarriages	unknown
Atmospheric oxygen depletion due to forest reduction and exaggerated fuel consumption	> 1000
Upcoming ice age	*c.* 15 000
Possible collision with interstellar gas cloud assumed to be crossed by the Earth every 60 million years, maybe causing mass extinctions	*c.* 50 000
Explosion of Yellowstone or other giant volcano leading to year-long volcanic winter	0 to 100 000
Possible genetic degeneration of homo sapiens due to Y chromosome reduction	*c.* 200 000
Africa collides with Europe, transforming the Mediterranean into a lake that starts evaporating	around $3 \cdot 10^6$
Gamma ray burst from within our own galaxy, causing radiation damage to many living beings	between 0 and $5 \cdot 10^6$
Asteroid hitting the Earth, generating tsunamis, storms, darkening sunlight, etc.	between 0 and $50 \cdot 10^6$
Neighbouring star approaching, starting comet shower through destabilization of Oort cloud and thus risk for life on Earth	$> 10^6$
American continent collides with Asia	$> 100 \cdot 10^6$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

CRITICAL SITUATION	YEARS FROM NOW
Molecular cloud engulfs the solar system	unknown
Instability of solar system	$> 100 \cdot 10^6$
Low atmospheric CO_2 content stops photosynthesis	$> 100 \cdot 10^6$
Collision of Milky Way with star cluster or other galaxy	$> 150 \cdot 10^6$
Sun ages and gets hotter, evaporating seas	$> 250 \cdot 10^6$
Ocean level increase due to Earth rotation slowing/stopping (if not evaporated before)	$> 10^9$
Temperature rise/fall (depending on location) due to Earth rotation stop	$> 10^9$
Sun runs out of fuel, becomes red giant, engulfs Earth	$5.0 \cdot 10^9$
Sun stops burning, becomes white dwarf	$5.2 \cdot 10^9$
Earth core solidifies, removing magnetic field and thus Earth's cosmic radiation shield	$10.0 \cdot 10^9$
Nearby nova (e.g. Betelgeuse) bathes Earth in annihilation radiation	unknown
Nearby supernova (e.g. Eta Carinae) blasts over solar system	unknown
Galaxy centre destabilizes rest of galaxy	unknown
Universe recollapses – if ever (see page 498)	$> 20 \cdot 10^9$
Matter decays into radiation – if ever (see Appendix E)	$> 10^{33}$
Problems with naked singularities	unknown, controversial
Vacuum becomes unstable	unknown, controversial

Despite the fascination of the predictions, we leave aside these literally tremendous issues and continue on our adventure.

THE ESSENCE OF CLASSICAL PHYSICS – THE INFINITELY SMALL AND THE LACK OF SURPRISES

We can summarize classical physics with two simple statements: First, *classical physics is the description of motion using the concept of the infinitely small*. Secondly, *nature lack surprises*.

All concepts used so far, be they for motion, space, time or observables, assume that the infinitely small exists. Special relativity, despite the speed limit, still allows infinitely small velocities; general relativity, despite its black hole limit, still allows infinitely small force and power values. Similarly, in the description of electrodynamics and gravitation, both integrals and derivatives are abbreviations of mathematical processes that use infinitely small distances and time intervals. In other words, the classical description of nature introduces the infinitely small in the description of motion.

Using the infinitely small as a research tool, the classical description of motion discovers that energy, momentum, angular momentum and charge are conserved. They are conserved also for infinitely small dimensions or time intervals. In other words, there are no surprises in motion.

The detailed study of conservation lead us to a strong conclusion: exploring the infinitely small shows that motion is deterministic. Surprises would contradict determin-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ism.*

On the other hand, this result leaves us with some open questions. Both special and general relativity have eliminated the existence of the infinitely large. There is no infinitely large force, power, size, age or speed. Why should the infinitely small exist, but the infinitely large not?

In fact, there are more open questions.

Why have we not yet reached the top of the mountain?

> The more important fundamental laws and facts of physical science have all been discovered, and these are now so firmly established that the possibility of their ever being supplanted in consequence of new discoveries is exceedingly remote... Our future discoveries must be looked for in the sixth place of decimals.
>
> Albert Michelson.**

We might think that we know nature now, as did Albert Michelson at the end of the nineteenth century. He claimed that electrodynamics and Galilean physics implied that the major laws of physics were well known. The statement is often quoted as an example of flawed predictions, since it reflects an incredible mental closure to the world around him. General relativity was still unknown, and so was quantum theory.

At the end of the nineteenth century, the progress in technology due to the use of electricity, chemistry and vacuum technology had allowed better and better machines and apparatuses to be built. All were built with classical physics in mind. In the years between 1890 and 1920, these classical machines completely destroyed the foundations of classical physics. Experiments with these apparatuses showed that matter is made of atoms, that electrical charge comes in the smallest amounts and that nature behaves randomly. In short, precise experiments show that nature does produce surprises – through in a restricted sense, as we will see. Like the British Empire, the reign of classical physics collapsed. Speaking simply, classical physics does not describe nature correctly at small scales.

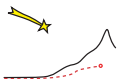
But even without machines, the Victorian physicist could have predicted the situation. (In fact, many more progressive minds did so.) He had overlooked a contradiction between electrodynamics and nature for which he had no excuse. In our walk so far we found that clocks and metre bars are necessarily made of matter and based on electromagnetism. But as we just saw, classical electrodynamics does not explain the stability of matter. Matter is made of small particles, but the relation between these particles, electricity and the smallest charges is not clear. If we do not understand matter, we do not yet understand space and time, since they are defined using measurement devices made of matter.

* No surprises also imply no miracles. Classical physics is thus in opposition to many religions. Indeed, many religions argue that infinity is the necessary ingredient to perform miracles. Classical physics shows that this is not the case.

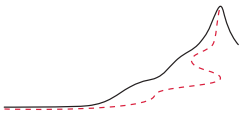
** From his 1894 address at the dedication ceremony for the Ryerson Physical Laboratory at the University of Chicago.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Worse, the Victorian physicist overlooked a simple fact: the classical description of nature does not allow one to understand *life*. The abilities of living beings – growing, seeing, hearing, feeling, thinking, being healthy or sick, reproducing and dying – are all unexplained by classical physics. In fact, all these abilities *contradict* classical physics. Understanding matter and its interactions, including life itself, is therefore the aim of the upcoming part of our ascent of Motion Mountain. The understanding will take place at small scales; to understand nature, we need to study particles. Indeed, the atomic structure of matter, the existence of a smallest charge and the existence of a smallest entropy makes us question the existence of the infinitely small. There is something to explore. Doing so will lead us from surprise to surprise. To be well prepared, we first take a break.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 30

THE STORY OF THE BRAIN

> Alles was überhaupt gedacht werden kann,
> kann klar gedacht werden.*
>
> Ludwig Wittgenstein, *Tractatus*, 4.116

In our quest for increased precision in the description of all motion around us, it is time to take a break, sit down and look back. In our walk so far, which has led us to investigate mechanics, general relativity and electrodynamics, we used several concepts without defining them. Examples are 'information', 'memory', 'measurement', 'set', 'number', 'infinity', 'existence', 'universe' and 'explanation'. Each of these is a common and important term. In this intermezzo, we take a look at these concepts and try to give some simple, but sufficiently precise definitions, keeping them as provocative and entertaining as possible. For example, can you explain to your parents what a concept is?

Challenge 1194 e

The reason for studying definitions is simple. We need the clarifications in order to get to the top of Motion Mountain, i.e., to the full description of motion. In the past, many have lost their way because of lack of clear concepts. In order to avoid these difficulties, physics has a special guiding role. All sciences share one result: every type of change observed in nature is a form of motion. In this sense, but in this sense *only*, physics, focusing on motion itself, forms the basis for all the other sciences. In other words, the search for the famed 'theory of everything' is an arrogant expression for the search for a *theory of motion*. Even though the knowledge of motion is basic, its precise description does not imply a description of 'everything': just try to solve a marriage problem using the Schrödinger equation to note the difference.

Given the basic importance of motion, it is necessary that in physics all statements on observations be as precise as possible. For this reason, many thinkers have investigated physical statements with particular care, using all criteria imaginable. Physics is detailed prattle by curious people about moving things. The criteria for precision appear once we ask: which abilities does this prattle require? You might want to fill in the list yourself.

Challenge 1195 e

The abilities necessary for talking are a topic of research even today. The way that the human species acquired the ability to chat about motion is studied by evolutionary biologists. Child psychologists study how the ability develops in a single human being. Physiologists, neurologists and computer scientists are concerned with the way the brain and the senses make this possible; linguists focus on the properties of the language we

* 'Everything that can be thought at all can be thought clearly.' This and other quotes of Ludwig Wittgenstein are from the equally short and famous *Tractatus logico-philosophicus*, written in 1918, first published in 1921; it has now been translated into many other languages.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 406 Ludwig Wittgenstein (1889–1951)

use, while logicians, mathematicians and philosophers of science study the general properties of statements about nature. All these fields investigate tools that are essential for the development of physics, the understanding of motion and the specification of the undefined concepts listed above. The fields structure the following exploration.

Evolution

> A hen is only an egg's way of making another egg.
>
> Samuel Butler, *Life and Habit*.

The evolution of the human species is the result of a long story that has been told in many excellent books. A summarizing table on the history of the universe is given in the chapter on general relativity. The almost incredible chain of events that has lead to one's own existence includes the formation of atoms, of the galaxies, the stars, the planets, the Moon, the atmosphere, the first cells, the water animals, the land animals, the mammals, the hominids, the humans, the ancestors, the family and finally oneself.

Ref. 700 Page 577 Ref. 701

The way the atoms we are made of moved during this sequence, being blown through space, being collected on Earth, becoming organized to form people, is one of the most awe-inspiring examples of motion. Remembering and meditating about this fantastic sequence of motion every now and then can be an enriching experience.

Challenge 1196 e

In particular, without biological evolution, we would not be able to talk about motion; only moving bodies can study moving bodies. And without a brain, we would not be able to think or talk. Evolution was also the fount of childhood and curiosity. In this chapter we will discover that most concepts of classical physics are already introduced by every little child, in the experiences it has while growing up.

Children, laws and physics

> Physicists also have a shared reality. Other than that, there isn't really a lot of difference between being a physicist and being a schizophrenic.
>
> Richard Bandler

Ref. 702

During childhood, everybody is a physicist. When we follow our own memories backwards in time as far as we can, we reach a certain stage, situated before birth, which forms the starting point of human experience. In that magic moment, we sensed somehow that apart from ourselves, there is something else. The first observation we make about the world, during the time in the womb, is thus the recognition that we can distinguish two

Ref. 703

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

parts: ourselves and the rest of the world. This distinction is an example – perhaps the first – of a large number of 'laws' of nature that we stumble upon in our lifetime. By discovering more and more distinctions we bring structure in the chaos of experience. We quickly find out that the world is made of related parts, such as mama, papa, milk, Earth, toys, etc.

Later, when we learn to speak, we enjoy using more difficult words and we call the surroundings the *environment*. Depending on the context, we call the whole formed by oneself and the environment together the (physical) *world*, the (physical) *universe*, *nature*, or the *cosmos*. These concepts are not distinguished from each other in this walk;* they are all taken to designate the sum of all parts and their relations. They are simply taken here to designate the *whole*.

The discovery of the first distinction starts a chain of similar discoveries. We extract the numerous distinctions that are possible in the environment, in our own body and in the various types of interactions between them. The ability to distinguish is the central ability that allows us to change our view from that of the world as *chaos*, i.e., as a big mess, to that of the world as a *system*, i.e., a structured set, in which parts are related in specific ways. (If you like precision, you may ponder whether the two choices of 'chaos' and 'system' are the only possible ones. We will return to this issue in the final part of our mountain ascent.)

Challenge 1197 s

In particular, the observation of the differences between oneself and the environment goes hand in hand with the recognition that not only are we not independent of the environment, but we are firmly tied to it in various inescapable ways: we can fall, get hurt, feel warm, cold, etc. Such relations are called *interactions*. Interactions express the observation that even though the parts of nature can be distinguished, they cannot be isolated. In other words, interactions describe the difference between the whole and the sum of its parts. No part can be defined without its relation to its environment. (Do you agree?)

Page 855

Challenge 1198 e

Interactions are not arbitrary; just take touch, smell or sight as examples. They differ in reach, strength and consequences. We call the characteristic aspects of interactions *patterns of nature*, or *properties of nature*, or *rules of nature* or, equivalently, with their historical but unfortunate name, *'laws' of nature*. The term 'law' stresses their general validity; unfortunately, it also implies design, aim, coercion and punishment for infringement. However, no design, aim or coercion is implied in the properties of nature, nor is infringement possible. The ambiguous term 'law of nature' was made popular by René Descartes (1596–1650) and has been adopted enthusiastically because it gave weight to the laws of the state – which were far from perfect at that time – and to those of other organizations – which rarely are. The expression is an anthropomorphism coined by an authoritarian world view, suggesting that nature is 'governed'. We will therefore use the term as rarely as possible in our walk and it will, if we do, be always between 'ironical' parentheses. Nature cannot be forced in any way. The 'laws' of nature are not obligations for nature or its parts, they are obligations only for physicists and all other people: the

* The differences in usage can be deduced from their linguistic origins. 'World' is derived from old Germanic 'wer' – person – and 'ald' – old – and originally means 'lifetime'. 'Universe' is from the Latin, and designates the one – 'unum' – which one sees turning – 'vertere', and refers to the starred sky at night which turns around the polar star. 'Nature' comes also from the Latin, and means 'what is born'. 'Cosmos' is from Greek κόσμος and originally means 'order'.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

patterns of nature oblige us to use certain descriptions and to discard others. Whenever one says that 'laws govern nature' one is talking nonsense; the correct expression is *rules describe nature*.

During childhood we learn to distinguish between interactions with the environment (or *perceptions*): some are shared with others and called *observations*, others are uniquely personal and are called *sensations*.* A still stricter criterion of 'sharedness' is used to divide the world into 'reality' and 'imagination' (or 'dreams'). Our walk will show that this distinction is not essential, provided that we stay faithful to the quest for ever increasing precision: we will find that the description of motion that we are looking for does not Page 1519 depend on whether the world is 'real' or 'imagined', 'personal' or 'public'.

Humans enjoy their ability to distinguish parts, which in other contexts they also call *details*, *aspects* or *entities*, and enjoy their ability to associate them or to observe the *re-* Ref. 705 *lations* between them. Humans call this activity *classification*. Colours, shapes, objects, mother, places, people and ideas are some of the entities that humans discover first.

Our anatomy provides a handy tool to make efficient use of these discoveries: *memory*. It stores a large amount of input that is called *experience* afterwards. Memory is a tool used by both young and old children to organize their world and to achieve a certain security in the chaos of life.

Memorized classifications are called *concepts*. Jean Piaget was the first researcher to describe the influence of the environment on the concepts that a child forms. Step by step, children learn that objects are localized in space, that space has three dimensions, that objects fall, that collisions produce noise, etc. In particular, Piaget showed that space and time are not a priori concepts, but result from the interactions of every child with its environment.**

---

* A child that is unable to make this distinction among perceptions – and who is thus unable to lie – almost Ref. 704 surely develops or already suffers from *autism*, as recent psychological research has shown.

** An overview of the origin of developmental psychology is given by J. H. Flavell, *The Developmental Psychology of Jean Piaget*, 1963. This work summarizes the observations by the French speaking Swiss Jean Piaget (1896–1980), the central figure in the field. He was one of the first researchers to look at child development in the same way that a physicist looks at nature: carefully observing, taking notes, making experiments, extracting hypotheses, testing them, deducing theories. His astonishingly numerous publications, based on his extensive observations, cover almost all stages of child development. His central contribution is the detailed description of the stages of development of the cognitive abilities of humans. He showed that all cognitive abilities of children, the formation of basic concepts, their way of thinking, their ability to talk, etc., result from the continuous interaction between the child and the environment.

In particular, Piaget described the way in which children first learn that they are different from the external environment, and how they then learn about the physical properties of the world. Of his many books related to physical concepts, two especially related to the topic of this walk are J. Piaget, *Les notions de mouvement et de vitesse chez l'enfant*, Presses Universitaires de France, 1972 and *Le developpement de la notion de temps chez l'enfant*, Presses Universitaires de France, 1981, this last book being born from a suggestion by Albert Einstein. These texts should be part of the reading of every physicist and science philosopher interested in these questions.

Piaget also describes how in children the mathematical and verbal intelligence derives from sensomotorial, practical intelligence, which itself stems from habits and acquired associations to construct new concepts. Practical intelligence requires the system of reflexes provided by the anatomical and morphological structure of our organism. Thus his work shows in detail that our faculty for mathematical description of the world is based, albeit indirectly, on the physical interaction of our organism with the world.

Some of his opinions on the importance of language in development are now being revised, notably Ref. 706 through the rediscovery of the work of Lev Vigotsky, who argues that all higher mental abilities, emotions,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Around the time that a child goes to school, it starts to understand the idea of *permanence of substances*, e.g. liquids, and the concept of *contrary*. Only at that stage does its subjective experience becomes *objective*, with abstract comprehension. Still later, the child's description of the world stops to be animistic: before this step, the Sun, a brook or a cloud are *alive*. In short, only after puberty does a human become ready for physics.

Ref. 707

Even though everyone has been a physicist in their youth, most people remain *classical* physicists. In this adventure we continue, using all the possibilities of a toy with which nature provides us: the brain.

> Experience is the name everyone gives to their mistakes.
>
> Oscar Wilde, *Lady Windermere's Fan*.

Polymer electronics

The brain is electrical. This was proven in 1924, when the neurologist Hans Berger (b. 1873 Neuses, d. 1941 Jena) recorded and named the first *electroencephalogram*. In more detail, the brain is a flexible, polymer-based, metal-free, short-lived, sensitive, unreliable and electronic device. Incidentally, all these properties are shared by polymer electronics, whether alive or not. That is the reason that commercial electronics is usually silicon-based instead.

The polymer electronics that forms the brain is organized like a computer. Some details are shown in Table 73. Though the functional blocks of a brain and a computer are similar, the specific mechanisms they use are usually completely different.

Ref. 708

Why a brain?

> Denken ist bereits Plastik.*
>
> Joseph Beuys, sculptor.

Ref. 709

Numerous observations show that sense input is processed, i.e., classified, stored and retrieved in the brain. Notably, lesions of the brain can lead to the loss of part or all of these functions. Among the important consequences of these basic abilities of the brain are thought and language. All such abilities result from the construction, from the 'hardware' of the brain.

Ref. 710

Ref. 711

Systems with the ability to deduce classifications from the input they receive are called *classifiers*, and are said to be able to *learn*. Our brain shares this property with many complex systems; the brain of many animals, but also certain computer algorithms, such as the so-called 'neural networks', are examples of such classifiers. Such systems are studied in several fields, from biology to neurology, mathematics and computer science. Classifiers have the double ability to discriminate and to associate; both are fundamental to thinking.

Ref. 712

Ref. 714

Machine classifiers have a lot in common with the brain. As an example, following an important recent hypothesis in evolutionary biology, the necessity to cool the brain in an effective way is responsible for the upright, bipedal walk of humans. The brain needs

Ref. 713

recollective memory, rational thought, voluntary attention and self-awareness, are not innate, but learned. This learning takes place through language and culture, and in particular through the process of talking to

TABLE 73 Some aspects of the human brain

Aspect	Details	Computer equivalent
Hardware		
Ultrashort term memory	5 to 9 concepts	cache
Hippocampus	novelty detector, spatial memory, learning	RAM and Flash memory
Amygdala	emotions, learning	priority scheduler of operating system
Ventral striatum, dopamine and opiod provider	rewards system	priority scheduler of operating system
Neurons in cortex	women *c.* $19 \cdot 10^9$, men *c.* $22 \cdot 10^9$	hard disk
Neuron number decay	women $e^{3.05-0.00145 \cdot age/a} \cdot 10^9$, men $e^{3.2-0.00145 \cdot age/a} \cdot 10^9$	hard disk
Pulses exchanged between both brain halves	$4 \cdot 10^9/s$	internal bus speed
Synapses per neuron	10^4	
Total synapse connections	*c.* $2 \cdot 10^{14}$	memory cells
Input pathways from the eye	*c.* $2 \cdot 10^6$	camera wire
Input pathways from the ear	*c.* $2 \cdot 3000$	microphone line
Input pathways from skin, mouth, and nose	*c.* $0.5 \cdot 10^6$	sensor interfaces
Input signal capacity (total, 300 pulses/s per pathway)	*c.* 100 MB/s	input bandwidth
Output pathways (muscles, organs)	*c.* $1.5 \cdot 10^6$	actuator interfaces
Output signal capacity (total, 300 pulses/s per pathway)	*c.* 50 MB/s	output bandwith
Typical mass (Einstein's brain)	1.230 kg	
Power consumption (average)	1600 to 2200 kJ/d or 18 to 25 W	
Lifetime	130 years	often only 2 years
Software and processing		
Learning	changing synapse strength through long-term potentiation	activate, classify, store
Deep sleep	structured writing from hippocampus to cortex	back-up to hard disk
REM (dream) sleep	offline processing	data compression in batch process

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

a powerful cooling system to work well. In this it resembles modern computers, which usually have powerful fans or even water cooling systems built into them. It turns out that the human species has the most powerful cooling system of all mammals. An upright posture allowed the air to cool the body most effectively in the tropical environment where humans evolved. For even better cooling, humans have also no body hair, except on their head, where it protects the brain from direct heating by the Sun.*

All classifiers are built from smallest classifying entities, sometimes large numbers of them. Usually, the smallest units can classify input into only two different groups. The larger the number of these entities, often called 'neurons' by analogy to the brain, the more sophisticated classifications can be produced by the classifier.** Classifiers thus work by applying more or less sophisticated combinations of 'same' and 'different'. The distinction by a child of red and blue objects is such a classification; the distinction of compact and non-compact gauge symmetry groups in quantum theory is a more elaborate classification, but relies on the same fundamental ability.

In all classifiers, the smallest classifying units interact with each other. Often these interactions are channelled via connections, and the set is then called a *network*. In these connections, signals are exchanged, via moving objects, such as electrons or photons. Thus we arrive at the conclusion that the ability of the brain to classify the physical world, for example to distinguish moving objects interacting with each other, is a consequence of the fact that it itself consists of moving objects interacting with each other. Without a powerful classifier, humans would not have become such a successful animal species. And only the motion inside our brain allows us to talk about motion in general.

Numerous researchers are identifying the parts of the brain used when different intellectual tasks are performed. The experiments become possible using magnetic resonance imaging and other methods. Other researchers are studying how thought processes can be modelled from the brain structure. Neurology is still making regular progress. In particular, it is steadily destroying the belief that thinking is *more* than a physical process. This belief results from personal fears, as you might want to test by introspection. It will disappear as time goes by. How would you argue that thought is just a physical process?

Page 1222

Challenge 1199 s

What is information?

> These thoughts did not come in any verbal formulation. I rarely think in words at all. A thought comes, and I may try to express it in words afterward.
>
> Albert Einstein

We started by stating that studying physics means to talk about motion. To talk is to transmit information. Can information be measured? Can we measure the progress of physics in this way? Is the universe made of information?

oneself.

* 'Thinking is already sculpture.' Joseph Beuys (1920–1986).

* The upright posture in turn allowed humans to take breath independently of their steps, a feat that many animals cannot perform. This in turn allowed humans to develop speech. Speech in turn developed the brain.

** A good introduction to neural nets is J. Hertz, A. Krogh & R. Palmer, *Introduction to the Theory of Neural Computation*, Addison Wesley, 1991.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Information is the result of classification. A classification is the answer to one or to several yes–no questions. Such yes–no questions are the simplest classifications possible; they provide the basic *units* of classification, from which all others can be built. The simplest way to measure information is therefore to count the implied yes–no questions, the *bits*, leading to it. Are you able to say how many bits are necessary to define the place where you live? Obviously, the number of bits depends on the set of questions with which we start; that could be the names of all streets in a city, the set of all coordinates on the surface of the Earth, the names of all galaxies in the universe, the set of all letter combinations in the address. What is the most efficient method you can think of? A variation of the combination method is used in computers. For example, the story of this walk required about a thousand million bits. But since the amount of information in a normal letter depends on the set of questions with which we start, it is impossible to define a precise measure for information in this way.

Challenge 1200 s

The only way to measure information precisely is to take the largest possible set of questions that can be asked about a system, and to compare it with what is known about the system. In this case, the amount of unknown information is called entropy, a concept that we have already encountered. With this approach you should able to deduce yourself whether it is really possible to measure the advance of physics.

Page 282

Challenge 1201 s

Since categorization is an activity of the brain and other, similar classifiers, information as defined here is a concept that applies to the result of activities by people and by other classifiers. In short, information is produced when talking about the universe – the universe itself is *not the same* as information. There is a growing number of publications based on the opposite of this view; however, this is a conceptual short circuit. Any transmission of information implies an interaction; physically speaking, this means that any information needs *energy* for transmission and *matter* for storage. Without either of these, there is no information. In other words, the universe, with its matter and energy, has to exist *before* transmission of information is possible. Saying that the universe is made of information is as meaningful as saying that it is made of toothpaste.

The aim of physics is to give a *complete* classification of all types and examples of motion, in other words, to know everything about motion. Is this possible? Or are you able to find an argument against this endeavour?

Challenge 1202 s

What is memory?

> The brain is my second favorite organ.
>
> Woody Allen

Memory is the collection of records of perceptions. The production of such records is the essential aspect of observation. Records can be stored in human memory, i.e., in the brain, or in machine memory, as in computers, or in object memory, such as notes on paper. Without memory, there is no science, no life – since life is based on the records inside the DNA – and especially, no fun, as proven by the sad life of those who lose their memory.

Ref. 710

Obviously every record is an object. But under which conditions does an object qualify as a record? A signature can be the record of the agreement on a commercial transaction. A single small dot of ink is not a record, because it could have appeared by mistake,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

for example by an accidental blot. In contrast, it is improbable that ink should fall on paper exactly in the shape of a signature. (The simple signatures of physicians are obviously exceptions.) Simply speaking, a *record* is any object, which, in order to be copied, has to be forged. More precisely, a record is an object or a situation that cannot arise nor disappear by mistake or by chance. Our personal memories, be they images or voices, have the same property; we can usually trust them, because they are so detailed that they cannot have arisen by chance or by uncontrolled processes in our brain.

Can we estimate the probability for a record to appear or disappear by chance? Yes, we can. Every record is made of a characteristic number N of small entities, for example the number of the possible ink dots on paper, the number of iron crystals in a cassette tape, the electrons in a bit of computer memory, the silver iodide grains in a photographic negative, etc. The chance disturbances in any memory are due to internal fluctuations, also called *noise*. Noise makes the record unreadable; it can be dirt on a signature, thermal magnetization changes in iron crystals, electromagnetic noise inside a solid state memory, etc. Noise is found in all classifiers, since it is inherent in all interactions and thus in all information processing.

It is a general property that internal fluctuations due to noise decrease when the size, i.e., the number of components of the record is increased. In fact, the probability p_{mis} for a misreading or miswriting of a record changes as

Challenge 1203 ny

$$p_{\text{mis}} \sim 1/N \,, \tag{500}$$

where N is the number of particles or subsystems used for storing it. This relation appears because, for large numbers, the so-called *normal distribution* is a good approximation of almost any process; the width of the normal distribution, which determines the probability of record errors, grows less rapidly than its integral when the number of entities is increased. (Are you able to confirm this?)

Challenge 1204 ny

We conclude that any good record must be made from a *large* number of entities. The larger the number, the less sensitive the memory is to fluctuations. Now, a system of large size with small fluctuations is called a *(physical) bath*. Only baths make memories possible. In other words, every record contains a bath. We conclude that any *observation* of a system is the interaction of that system with a bath. This connection will be used several times in the following, in particular in quantum theory. When a record is produced by a machine, the 'observation' is usually called a *(generalized) measurement*. Are you able to specify the bath in the case of a person looking at a landscape?

Challenge 1205 s

From the preceding discussion we can deduce a powerful conclusion: since we have such a good memory at our disposition, we can deduce that we are made of many small parts. And since records exist, the world must also be made of a large number of small parts. No microscope of any kind is needed to confirm the existence of molecules or similar small entities; such a tool is only needed to determine the *sizes* of these particles. Their existence can be deduced simply from the observation that we have memory. (Of course, another argument proving that matter is made of small parts is the ubiquity of noise.)

Page 256

A second conclusion was popularized in the late 1920s by Leo Szilard. Writing a memory does not produce entropy; it is possible to store information into a memory without increasing entropy. However, entropy is produced in every case that the memory is *erased*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1206 ny It turns out that the (minimum) entropy created by erasing one bit is given by

$$S_{\text{per erased bit}} = k \ln 2 \,, \tag{501}$$

and the number $\ln 2 \approx 0.69$ is the natural logarithm of 2. Erasing thus on one hand reduces the disorder of the data – the local entropy–, but on the other hand increases the total entropy. As is well known, energy is needed to reduce the entropy of a local system. In short, any system that erases memory requires energy. For example, a logical AND gate effectively erases one bit per operation. Logical thinking thus requires energy. It is also known that *dreaming* is connected with the erasing and reorganization of information. Could that be the reason that, when we are very tired, without any energy left, we do not dream as much as usual? Challenge 1207 s

Entropy is thus necessarily created when we forget. This is evident when we remind ourselves that forgetting is similar to the deterioration of an ancient manuscript. Entropy Ref. 715 increases when the manuscript is not readable any more, since the process is irreversible and dissipative.* Another way to see this is to recognize that to clear a memory, e.g. a magnetic tape, we have to put energy into it, and thus increase its entropy. Conversely, *writing* into a memory can often *reduce* entropy; we remember that signals, the entities that write memories, carry negative entropy. For example, the writing of magnetic tapes usually reduces their entropy.

The capacity of the brain

> “Computers are boring. They can give only answers.”
>
> (Wrongly) attributed to Pablo Picasso

The human brain is built in such a way that its fluctuations cannot destroy its contents. The brain is well protected by the skull for exactly this reason. In addition, the brain literally grows connections, called *synapses*, between its various *neurons*, which are the cells doing the signal processing. The neuron is the basic processing element of the brain, performing the basic classification. It can only do two things: to fire and not to fire. (It is possible that the time at which a neuron fires also carries information; this question is Ref. 718, Ref. 719 not yet settled.) The neuron fires depending on its input, which comes via the synapses from hundreds of other neurons. A neuron is thus an element that can distinguish the inputs it receives into two cases: those leading to firing and those that do not. Neurons are thus classifiers of the simplest type, able only to distinguish between two situations.

Every time we store something in our long term memory, such as a phone number, new synapses are grown or the connection strength of existing synapses is changed. The connections between the neurons are much stronger than the fluctuations in the brain.

Ref. 716 * As Wojciech Zurek clearly explains, the entropy created inside the memory is the main reason that even Maxwell's demon cannot reduce the entropy of two volumes of gases by opening a door between them in such a way that fast molecules accumulate on one side and slow molecules accumulate on the other. (Maxwell had introduced the 'demon' in 1871, to clarify the limits posed by nature to the gods.) This is just another way to rephrase the old result of Leo Szilard, who showed that the measurements by the demon Ref. 717 create more entropy than they can save. And every measurement apparatus contains a memory.

To play being Maxwell's demon, click on the www.wolfenet.com/~zeppelin/maxwell.htm website.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Only strong disturbances, such as a blocked blood vessel or a brain lesion, can destroy neurons and lead to loss of memory.

As a whole, the brain provides an extremely efficient memory. Despite intense efforts, engineers have not yet been able to build a memory with the capacity of the brain in the same volume. Let us estimated this memory capacity. By multiplying the number of neurons, about 10^{11},* by the average number of synapses per neuron, about 100, and also by the estimated number of bits stored in every synapse, about 10, we arrive at a storage capacity for the brain of about

$$M_{\text{rewritable}} \approx 10^{14}\,\text{bit} \approx 10^{4}\,\text{GB}\,. \tag{502}$$

(One *byte*, abbreviated B, is the usual name for eight bits of information.) Note that evolution has managed to put as many neurons in the brain as there are stars in the galaxy, and that if we add all the synapse lengths, we get a total length of about 10^{11} m, which corresponds to the distance to from the Earth to the Sun. Our brain truly is *astronomically* complex.

In practice, the capacity of the brain seems almost without limit, since the brain frees memory every time it needs some new space, by *forgetting* older data, e.g. during sleep. Note that this standard estimate of 10^{14} bits is not really correct! It assumes that the only component storing information in the brain is the synapse strength. Therefore it only measures the *erasable* storage capacity of the brain. In fact, information is also stored in the structure of the brain, i.e., in the exact configuration in which every cell is connected to other cells. Most of this structure is fixed at the age of about two years, but it continues to develop at a lower level for the rest of human life. Assuming that for each of the N cells with n connections there are $f\,n$ connection possibilities, this *write once* capacity of the brain can be estimated as roughly $N\sqrt{f\,n}\,f\,n\log f\,n$ bits. For $N = 10^{11}$, $n = 10^{2}$, $f = 6$, this gives

Challenge 1208 ny

$$M_{\text{writeonce}} \approx 10^{16}\,\text{bit} \approx 10^{6}\,\text{GB}\,. \tag{503}$$

Ref. 720 Recent measurements confirmed that bilingual persons, especially early bilinguals, have a higher density of grey mass in the small parietal cortex on the left hemisphere of the brain. This is a region mainly concerned with language processing. The brain thus makes also use of structural changes for optimized storage and processing.

Incidentally, even though the brains of sperm whales and of elephants can be five to six times as heavy as those of humans, the number of neurons and connections, and thus the capacity, is lower than for humans.

Sometimes it is claimed that people use only between 5% or 10% of their brain capacity. This myth, which goes back to the nineteenth century, would imply that it is possible to measure the actual data stored in the brain and compare it with its capacity to an impossible accuracy. Alternatively, the myth implies that the processing capacity can be measured. It also implies that nature would develop and maintain an organ with 90 % overcapacity, wasting all the energy and material to build, repair and maintain it. The myth is wrong.

* The number of neurons seems to be constant, and fixed at birth. The growth of interconnections is highest between age one and three, when it is said to reach up to 10^{7} new connections per second.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The large storage capacity of the brain also shows that human memory is filled by the environment and is not inborn: one human ovule plus one sperm have a mass of about 1 mg, which corresponds to about $3 \cdot 10^{16}$ atoms. Obviously, fluctuations make it impossible to store 10^{16} bits in it. In fact, nature stores only about $3 \cdot 10^9$ bits in the genes of an ovule, using 10^7 atoms per bit. In contrast, a typical brain has a mass of 1.5 to 2 kg, containing about 5 to $7 \cdot 10^{25}$ atoms, which makes it as efficient as the ovule. The difference between the number of bits in human DNA and those in the brain nicely shows that almost all information stored in the brain is taken from the environment; it cannot be of genetic origin, even allowing for smart decompression of stored information.

In total, all these tricks used by nature result in the most powerful classifier yet known.* Are there any limits to the brain's capacity to memorize and to classify? With the tools that humans have developed to expand the possibilities of the brain, such as paper, writing and printing to help memory, and the numerous tools available to simplify and to abbreviate classifications explored by mathematicians, brain classification is only limited by the time spent practising it. Without tools, there are strict limits, of course. Ref. 721 The two-millimetre thick cerebral cortex of humans has a surface of about four sheets of A4 paper, a chimpanzee's yields one sheet and a monkey's is the size of a postcard. It is estimated that the total intellectually accessible memory is of the order of

$$M_{\text{intellectual}} \approx 1\,\text{GB}\,, \tag{504}$$

though with a large experimental error.

The brain is also unparalleled in its processing capacity. This is most clearly demonstrated by the most important consequence deriving from memory and classification: thought and language. Indeed, the many types of thinking or language we use, such as comparing, distinguishing, remembering, recognizing, connecting, describing, deducing, explaining, imagining, etc., all describe different ways to classify memories or perceptions. In the end, every type of thinking or talking directly or indirectly classifies observations. But how far are computers from achieving this! The first attempt, in 1966, was a programming joke by Joseph Weizenbaum: the famous chatterbot program Eliza (try it at www.manifestation.com/neurotoys/eliza.php3) is a parody of a psychoanalyst. Even today, over 40 years later, conversation with a computer program, such as Friendbot (found at www.friendbot.co.uk), is still a disappointing experience. We need to understand the reasons for this slow development.

Curiosities about the brain

The brain plays strange games on the people that carry it. Modern research has shown that students can be distinguished into five separate groups.

1. Strong students
2. Uninterested students
3. Students that overestimate themselves (often, but not always, boys)
4. Students that underestimate themselves (often, but not always, girls)
5. Weak students

* Also the power consumption of the brain is important: even though it contains only about 2% of the body's mass, is uses 25% of the energy taken in by food.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This has to be kept in mind when teaching classes. To which group do/did you belong?

* *

Teachers should all be brain experts. The brain learns best when it has an *aim*. How many teachers state the aim of their class at its beginning? Students need different *motivations*: potential applications, curiosity, competition, activation of already acquired knowledge, impressing the opposite sex, or exploring the unknown. And they need it on different levels of difficulty. Which teacher provides this mix? Students have different ways to *create concepts*: using words, sounds, images, emotions, body sensations, etc. Which teacher addresses them all in his lessons?

Chapter 31

THOUGHT AND LANGUAGE

What is language?

> Reserve your right to think, for even to think wrongly is better than not to think at all.
>
> Hypatia of Alexandria

> Ein Satz kann nur sagen, *wie* ein Ding ist, nicht *was* es ist.*
>
> Ludwig Wittgenstein, *Tractatus*, 3.221

Language possibly is the most wonderful gift of human nature. Using the ability to produce sounds and to put ink on paper, people attach certain *symbols*,** also called *words* or *terms* in this context, to the many partitions they specify with the help of their thinking. Such a categorization is then said to define a *concept* or *notion*, and is set in *italic typeface* in this text. A standard set of concepts forms a language.*** In other words, a *(human) language* is a standard way of symbolic interaction between people.**** There are human languages based on facial expressions, on gestures, on spoken words, on whistles, on written words, and more. The use of *spoken* language is considerably younger than the human species; it seems that it appeared only about two hundred thousand years ago. Written language is even younger, namely only about six thousand years old. But the set of concepts used, the *vocabulary*, is still expanding. For humans, the understanding of language begins soon after birth (perhaps even before), the active use begins at around a year of age, the ability to read can start as early as two, and personal vocabulary continues to grow as long as curiosity is alive.

---

* 'A proposition can only say *how* a thing is, not *what* it is.'

** A symbol is a type of *sign*, i.e., an entity associated by some convention to the object it refers. Following Charles Peirce (1839–1914) – see www.peirce.org – the most original philosopher born in the United States, a symbol differs from an *icon* (or *image*) and from an *index*, which are also attached to objects by convention, in that it does not resemble the object, as does an icon, and in that it has no contact with the object, as is the case for an index.

*** The recognition that language is based on a partition of ideas, using the various differences between them to distinguish them from each other, goes back to the Swiss thinker Ferdinand de Saussure (1857–1913), who is regarded as the founder of linguistics. His textbook *Cours de linguistique générale*, Editions Payot, 1985, has been the reference work of the field for over half a century. Note that Saussure, in contrast to Peirce, prefers the term 'sign' to 'symbol', and that his definition of the term 'sign' includes also the object to which it refers.

**** For slightly different definitions and a wealth of other interesting information about language, see the beautiful book by David Crystal, *The Cambridge Encyclopedia of Language*, Cambridge University Press, 1987.

German phonemes	40
Italian phonemes	30
Words of the English language (more than most languages, with the possible exception of German)	*c.* 350 000
Number of languages on Earth in the year 2000	*c.* 8000

Physics being a lazy way to chat about motion, it needs language as an essential tool. Of the many aspects of language, from literature to poetry, from jokes to military orders, from expressions of encouragement, dreams, love and emotions, physics uses only a small and rather special segment. This segment is defined by the inherent restriction to talk about motion. Since motion is an observation, i.e., an interaction with the environment that several people experience in the same way, this choice puts a number of restrictions on the contents – the vocabulary – and on the form – the grammar – of such discussions.

For example, from the definition that observations are shared by others, we get the requirement that the statements describing them must be translatable into all languages. But when can a statement be translated? On this question two extreme points of view are possible: the first maintains that *all* statements can be translated, since it follows from the properties of human languages that each of them can express every possible statement. In this view, only sign systems that allow one to express the complete spectrum of human messages form a *human language*. This property distinguishes spoken and sign language from animal languages, such as the signs used by apes, birds or honey bees, and also from computer languages, such as Pascal or C. With this meaning of language, all statements can be translated by definition.

It is more challenging for a discussion to follow the opposing view, namely that precise translation is possible only for those statements which use terms, word types and grammatical structures found in *all* languages. Linguistic research has invested considerable effort in the distillation of phonological, grammatical and semantic *universals*, as they are called, from the 6000 or so languages thought to exist today.*

The investigations into the *phonological* aspect, which showed for example that every

* A professional database by the linguist Merritt Ruhlen with 5700 languages and many details on each language can be found at ehl.santafe.edu/intro1.htm. A long but unprofessional list with 6 900 languages (and with 39 000 language and dialect names) can be found on the website www.ethnologue.com. Beware, it is edited by a fringe religious group that aims to increase the number of languages as much as possible.

It is estimated that 15 000 ± 5 000 languages have existed in the past.

Nevertheless, in today's world, and surely in the sciences, it is often sufficient to know one's own language plus English. Since English is the language with the largest number of words, learning it well is a greater challenge than learning most other languages. Ref. 722

when, where, after (before), under (above)	[time and place]
kind of, part of	[taxonomy, partonomy]
like	[hedge/prototype]

language has at least two consonants and two vowels, does not provide any material for the discussion of translation.* Studying the *grammatical* (or *syntactic*) aspect, one finds that all languages use smallest elements, called 'words', which they group into sentences. They all have pronouns for the first and second person, 'I' and 'you', and always contain nouns and verbs. All languages use *subjects* and *predicates* or, as one usually says, the three entities *subject*, *verb* and *object*, though not always in this order. Just check the languages you know. Challenge 1209 e

On the *semantic* aspect, the long list of lexical universals, i.e., words that appear in all languages, such as 'mother' or 'Sun', has recently been given a structure. The linguist Anna Wierzbicka performed a search for the building blocks from which all concepts can be built. She looked for the definition of every concept with the help of simpler ones, and continued doing so until a fundamental level was reached that cannot be further reduced. The set of concepts that are left over are the primitives. By repeating this exercise in many languages, Wierzbicka found that the list is the same in all cases. She thus had discovered *universal semantic primitives*. In November 1992, the list contained the terms given in Table 75.

Following the life-long research of Anna Wierzbicka and her research school, all these concepts exist in all languages of the world studied so far.** They have defined the meaning of each primitive in detail, performed consistency checks and eliminated alternative approaches. They have checked this list in languages from all language groups, in languages from all continents, thus showing that the result is valid everywhere. In every language all other concepts can be defined with the help of the semantic primitives. Ref. 723

* Studies explore topics such as the observation that in many languages the word for 'little' contains an 'i' (or high pitched 'e') sound: petit, piccolo, klein, tiny, pequeño, chiisai; exceptions are: small, parvus.

** It is easy to imagine that this research steps on the toes of many people. A list that maintains that 'true', 'good', 'creation', 'life', 'mother' or 'god' are composite will elicit violent reactions, despite the correctness of the statements. Indeed, some of these terms were added in the 1996 list, which is somewhat longer. In addition, a list that maintains that we only have about thirty basic concepts in our heads is taken by many to be offensive.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Simply stated, learning to speak means learning these basic terms, learning how to combine them and learning the names of these composites. The definition of language given above, namely as a means of communication that allows one to express everything one wants to say, can thus be refined: a *human language* is any set of concepts that includes the universal semantic primitives.

For physicists – who aim to talk in as few words as possible – the list of semantic primitives has three facets. First, the approach is appealing, as it is similar to physics' own aim: the idea of primitives gives a structured summary of everything that can be said, just as the atomic elements structure all objects that can be observed. Second, the list of primitives can be structured. In fact, the list of primitives can be divided into two groups: one group contains all terms describing motion (do, happen, when, where, feel, small, etc. – probably a term from the semantic field around light or colour should be added) and the other group contains all terms necessary to talk about abstract sets and relations (this, all, kind of, no, if, etc.). Even for linguistics, aspects of motion and logical concepts are the basic entities of human experience and human thinking. To bring the issue to a point, the semantic primitives contain the basic elements of physics and the basic elements of mathematics. All humans are thus both physicists and mathematicians. The third point is that the list of primitives is too long. The division of the list into two groups directly suggests shorter lists; we just have to ask physicists and mathematicians for concise summaries of their respective fields. To appreciate this aim, try to define what 'if' means, or what an 'opposite' is – and explore your own ways of reducing the list.

Challenge 1210 d

Reducing the list of primitives is also one of our aims in this adventure. We will explore the mathematical group of primitives in this chapter the physical group will occupy us in the rest of our adventure. However, a shorter list of primitives is not sufficient. Our goal is to arrive at a list consisting of only *one* basic concept. Reaching this goal is not simple, though. First, we need to check whether the set of classical physical concepts that we have discovered so far is complete. Can classical physical concepts describe *all* observations? The upcoming quantum part of our adventure is devoted to this question. The second task is to reduce the list. This task is not straightforward; we have already discovered that physics is based on a circular definition: in Galilean physics, space and time are defined using matter, and matter is defined using space and time. We will need quite some effort to overcome this obstacle. The final part of this text tells the precise story. After numerous adventures we will indeed discover a basic concept on which all other concepts are based.

Page 317

We can summarize all the above-mentioned results of linguistics in the following way. By constructing a statement made only of subject, verb and object, consisting only of nouns and verbs, using only concepts built from the semantic primitives, we are sure that it can be translated into all languages. This explains why physics textbooks are often so boring: the authors are often too afraid to depart from this basic scheme. On the other hand, research has shown that such straightforward statements are not restrictive: with them one can say everything that can be said.

> Every word was once a poem.
> Ralph Waldo Emerson*

* Ralph Waldo Emerson (1803–1882), US-American essayist and philosopher.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

What is a concept?

> Concepts are merely the results, rendered permanent by language, of a previous process of comparison.
>
> William Hamilton

There is a group of people that has taken the strict view on translation and on precision to the extreme. They build all concepts from an even smaller set of primitives, namely only two: 'set' and 'relation', and explore the various possible combinations of these two concepts, studying their classifications. Step by step, this radical group, commonly called *mathematicians*, came to define with full precision concepts such as numbers, points, curves, equations, symmetry groups and more. The construction of these concepts is summarized partly in the following and partly in Appendix B.

However, despite the involved precision, in fact precisely because of it, no mathematical concept talks about nature or about observations.* Therefore the study of motion needs other, more useful concepts. What properties must a useful concept have? For example, what is 'passion' and what is a 'cotton bud'? Obviously, a useful concept implies a list of its parts, its aspects and their internal relations, as well as their relation to the exterior world. Thinkers in various fields, from philosophy to politics, agree that the definition of any *concept* requires:

— explicit and fixed content,
— explicit and fixed limits,
— explicit and fixed domain of application.

The inability to state these properties or keep them fixed is often the easiest way to distinguish *crackpots* from more reliable thinkers. Unclearly defined terms, which thus do not qualify as concepts, regularly appear in myths, e.g. 'dragon' or 'sphinx', or in ideologies, e.g. 'worker' or 'soul'. Even physics is not immune. For example, we will discover later that neither 'universe' nor 'creation' are concepts. Are you able to argue the case?

Challenge 1211 s

But the three defining properties of any concepts are interesting in their own right. Explicit content means that concepts are built one onto another. In particular, the most fundamental concepts appear to be those that have no parts and no external relations, but only internal ones. Can you think of one? Only the last part of this walk will uncover the final word on the topic.

Challenge 1212 s

The requirements of explicit limits and explicit contents also imply that all concepts describing nature are *sets*, since sets obey the same requirements. In addition, explicit domains of application imply that all concepts also are *relations*.** Since mathematics is based on the concepts of 'set' and of 'relation', one follows directly that mathematics can

* Insofar as one can say that mathematics is based on the concepts of 'set' and 'relation', which are based on experience, one can say that mathematics explores a section of reality, and that its concepts are *derived* from experience. This and similar views of mathematics are called *platonism*. More concretely, platonism is the view that the concepts of mathematics exist *independently* of people, and that they are discovered, and not created, by mathematicians.

In short, since mathematics makes use of the brain, which is a physical system, actually *mathematics is applied physics*.

** We see that every physical concept is an example of a (mathematical) *category*, i.e., a combination of objects and mappings. For more details about categories, with a precise definition of the term, see page 826.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

provide the *form* for any concept, especially whenever high precision is required, as in the study of motion. Obviously, the *content* of the description is only provided by the study of nature itself; only then do concepts become useful.

In the case of physics, the search for sufficiently precise concepts can be seen as the single theme structuring the long history of the field. Regularly, new concepts have been proposed, explored in all their properties, and tested. Finally, concepts are rejected or adopted, in the same way that children reject or adopt a new toy. Children do this unconsciously, scientists do it consciously, using language.* For this reason, concepts are universally intelligible.

Note that the concept '*concept*' itself is not definable independently of experience; a concept is something that helps us to act and react to the world in which we live. Moreover, concepts do not live in a world separate from the physical one: every concept requires memory from its user, since the user has to remember the way in which it was formed; therefore every concept needs a material support for its use and application. Thus all thinking and all science is fundamentally based on experience.

In conclusion, all concepts are based on the idea that nature is made of related parts. This idea leads to complementing couples such as 'noun–verb' in linguistics, 'set–relation' or 'definition–theorem' in mathematics, and 'aspect of nature–pattern of nature' in physics. These couples constantly guide human thinking, from childhood onwards, as developmental psychology can testify.

What are sets? What are relations?

> Alles, was wir sehen, könnte auch anders sein. Alles, was wir überhaupt beschreiben können, könnte auch anders sein. Es gibt keine Ordnung der Dinge a priori.**
>
> Ludwig Wittgenstein, *Tractatus*, 5.634

Defining sets and defining relations are the two fundamental acts of our thinking. This can be seen most clearly in any book about mathematics; such a book is usually divided into paragraphs labelled 'definition', 'theorem', 'lemma' and 'corollary'. The first type of paragraph defines concepts, i.e., defines sets, and the other three types of paragraphs express relations, i.e., connections between these sets. *Mathematics* is thus the exploration of the possible symbolic concepts and their relations. Mathematics is the science of symbolic necessities.

Sets and relations are tools of classification; that is why they are also the tools of any bureaucrat. (See Figure 407.) This class of humans is characterized by heavy use of paper clips, files, metal closets, archives – which all define various types of sets – and by the extensive use of numbers, such as reference numbers, customer numbers, passport

* Concepts formed unconsciously in our early youth are the most difficult to define precisely, i.e., with language. Some who were unable to define them, such as the Prussian philosopher Immanuel Kant (1724–1804) used to call them 'a priori' concepts (such as 'space' and 'time') to contrast them with the more clearly defined 'a posteriori' concepts. Today, this distinction has been shown to be unfounded both by the study of child psychology (see the footnote on page 807) and by physics itself, so that these qualifiers are therefore not used in our walk.

** 'Everything we see could also be otherwise. Everything we describe at all could also be otherwise. There is no order of things a priori.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 407 Devices for the definition of sets (left) and of relations (right)

TABLE 76 The defining properties of a set – the ZFC axioms

The axioms of Zermelo–Fraenkel–C set theory
– Two sets are equal if and only if they have the same elements. (Axiom of extensionality)
– The empty set is a set. (Axiom of the null set)
– If x and y are sets, then the unordered pair $\{x, y\}$ is a set. (Axiom of unordered pairs)
– If x is a set of sets, the union of all its members is a set. (Union or sum set axiom)
– The entity $\{\varnothing, \{\varnothing\}, \{\{\varnothing\}\}, \{\{\{\varnothing\}\}\}, \ldots\}$ is a set [a] – in other words, infinite collections, such as the natural numbers, are sets. (Axiom of infinity)
– An entity defined by all elements having a given property is a set, provided this property is reasonable; some important technicalities defining 'reasonable' are necessary. (Axiom of separation)
– If the domain of a function is a set, so is its range. (Axiom of replacement)
– The entity y of all subsets of x is also a set, called the power set. (Axiom of the power set)
– A set is not an element of itself – plus some technicalities. (Axiom of regularity)
– The product of a family of non-empty sets is non-empty. Equivalently, picking elements from a list of sets allows one to construct a new set – plus technicalities. (Axiom of choice)

a. The more common formulation (though equivalent to the above) is: The entity $\{\varnothing, \{\varnothing\}, \{\varnothing, \{\varnothing\}\}, \{\varnothing, \{\varnothing\}, \{\varnothing, \{\varnothing\}\}\}, \ldots\}$ is a set.

numbers, account numbers, law article numbers – which define various types of relations between the items, i.e., between the elements of the sets.

Both the concepts of set and of relation express, in different ways, the fact that nature can be *described*, i.e., that it can be classified into parts that form a whole. The act of grouping together aspects of experience, i.e., the act of classifying them, is expressed in formal language by saying that a set is defined. In other words, a *set* is a collection of *elements* of our thinking. Every set distinguishes the elements from each other and from the set itself. This definition of 'set' is called the *naive* definition. For physics, the definition is sufficient, but you won't find many who will admit this. In fact, mathematicians have refined the definition of the concept 'set' several times, because the naive definition does not work well for infinite sets. A famous example is the story about sets which do not contain themselves. Obviously, any set is of two sorts: either it contains itself or it does not. If we take the set of all sets that do *not* contain themselves, to which sort does it belong?

Challenge 1213 s

To avoid problems with the concept of 'set', mathematics requires a precise definition. The first such definition was given by the German mathematician Ernst Zermelo (b. 1871 Berlin, d. 1951 Freiburg i.B.) and the German–Israeli mathematician Adolf/Abraham Fraenkel (b. 1891 München, d. 1965 Jerusalem). Later, the so-called *axiom of choice* was

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

added, in order to make it possible to manipulate a wider class of infinite sets. The result of these efforts is called the *ZFC* definition.* From this basic definition we can construct all mathematical concepts used in physics. From a practical point of view, it is sufficient to keep in mind that for the whole of physics, the naive definition of a set is equivalent to the precise ZFC definition, actually even to the simpler ZF definition. Subtleties appear only for some special types of infinite sets, but these are not used in physics. In short, from the basic, naive set definition we can construct all concepts used in physics.

Ref. 725 The naive set definition is far from boring. To satisfy two people when dividing a cake, we follow the rule: I cut, you choose. The method has two properties: it is *just*, as everybody thinks that they have the share that they deserve, and it is *fully satisfying*, as everybody has the feeling that they have at least as much as the other. What rule is needed Challenge 1215 d for three people? And for four?

Apart from defining sets, every child and every brain creates links between the different aspects of experience. For example, when it hears a voice, it automatically makes the connection that a human is present. In formal language, connections of this type are called *relations*. Relations connect and differentiate elements along other lines than sets: the two form a complementing couple. Defining a set unifies many objects and at the same time divides them into two: those belonging to the set and those that do not; defining a (binary) relation unifies elements two by two and divides them into many, namely into the many couples it defines.

Sets and relations are closely interrelated concepts. Indeed, one can define (mathematical) relations with the help of sets. A *(binary) relation* between two sets X and Y is a subset of the product set, where the *product set* or *Cartesian product* $X \times Y$ is the set of all ordered pairs (x, y) with $x \in X$ and $y \in Y$. An *ordered pair* (x, y) can easily be defined Challenge 1216 s with the help of sets. Can you find out how? For example, in the case of the relation 'is wife of', the set X is the set of all women and the set Y that of all men; the relation is given by the list all the appropriate ordered pairs, which is much smaller than the product set, i.e., the set of all possible woman–man combinations.

It should be noted that the definition of relation just given is not really complete, since every construction of the concept 'set' already contains certain relations, such as the relation 'is element of.' It does not seem to be possible to reduce either one of the concepts 'set' or 'relation' completely to the other one. This situation is reflected in the physical cases of sets and relations, such as space (as a set of points) and distance, which also seem impossible to separate completely from each other. In other words, even though mathematics does not pertain to nature, its two basic concepts, sets and relations, are taken from nature. In addition, the two concepts, like those of space-time and particles, are each defined with the other.

* A global overview of axiomatic set theory is given by Paul J. Cohen & Reuben Hersch, Non-Cantorian set theory, *Scientific American* **217**, pp. 104–116, 1967. Those were the times when *Scientific American* was a quality magazine.

Ref. 724 Other types of entities, more general than standard sets, obeying other properties, can also be defined, and are also subject of (comparatively little) mathematical research. To find an example, see the section Page 825 on cardinals later on. Such more general entities are called classes whenever they contain at least one set. Challenge 1214 s Can you give an example? In the final part of our mountain ascent we will meet physical concepts that are described neither by sets nor by classes, containing no set at all. That is where the real fun starts.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Infinity

Mathematicians soon discovered that the concept of 'set' is only useful if one can also call collections such as $\{0, 1, 2, 3\ldots\}$, i.e., of the number 0 and all its successors, a 'set'. To achieve this, one property in the Zermelo–Fraenkel list defining the term 'set' explicitly specifies that this collection can be called a set. (In fact, also the axiom of replacement states that sets may be infinite.) Infinity is thus put into mathematics and into the tools of our thought right at the very beginning, in the definition of the term 'set'. When describing nature, with or without mathematics, we should never forget this fact. A few additional points about infinity should be of general knowledge to any expert on motion.

Only *sets* can be infinite. And sets have parts, namely their elements. When a thing or a concept is called 'infinite' one can *always* ask and specify what its parts are: for space the parts are the points, for time the instants, for the set of integers the integers, etc. An indivisible or a finitely divisible entity cannot be called infinite.*

A set is infinite if there is a function from it into itself that is *injective* (i.e., different elements map to different results) but not *onto* (i.e., some elements do not appear as images of the map); e.g. the map $n \mapsto 2n$ shows that the set of integers is infinite. Infinity also can be checked in another way: a set is infinite if it remains so also after removing one element, even repeatedly. We just need to remember that the empty set is *finite*.

There are *many types* of infinities, all of different sizes.** This important result was discovered by the Danish-Russian-German mathematician Georg Cantor (1845–1918). He showed that from the countable set of natural numbers one can construct other infinite sets which are not countable. He did this by showing that the *power set* $P(\omega)$, namely the set of all subsets, of a countably infinite set is infinite, but *not* countably infinite. Sloppily speaking, the power set is 'more infinite' than the original set. The real numbers $\mathbb{R}$, to be defined shortly, are an example of an uncountably infinite set; there are many more of them than there are natural numbers. (Can you show this?) However, *any* type of infinite set contains at least one subset which is countably infinite.

Challenge 1217 s

Even for an infinite set one can define size as the number of its elements. Cantor called this the *cardinality* of a set. The cardinality of a finite set is simply given by the number of its elements. The cardinality of a power set is 2 exponentiated by the cardinality of the set. The cardinality of the set of integers is called $\aleph_0$, pronounced 'aleph zero', after the first letter of the Hebrew alphabet. The smallest *uncountable* cardinal is called $\aleph_1$. The next cardinal is called $\aleph_2$ etc. A whole branch of mathematics is concerned with the manipulation of these infinite 'numbers'; addition, multiplication, exponentiation are easily defined. For some of them, even logarithms and other functions make sense.***

Page 323

The cardinals defined in this way, including $\aleph_n$, $\aleph_\omega$, $\aleph_{\aleph_\aleph}$ are called accessible, because since Cantor, people have defined even larger types of infinities, called *inaccessible*. These numbers (inaccessible cardinals, measurable cardinals, supercompact cardinals,

* Therefore, most gods, being concepts and thus sets, are either finite or, in the case where they are infinite, they are divisible. It seems that only polytheistic world views are not disturbed by this conclusion.

** In fact, there is such a huge number of types of infinities that none of these infinities itself actually describes this number. Technically speaking, there are as many infinities as there are ordinals.

*** Many results are summarized in the excellent and delightful paperback by Rudy Rucker, *Infinity and the Mind – the Science and Philosophy of the Infinite*, Bantam, Toronto, 1983.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

etc.) need additional set axioms, extending the ZFC system. Like the ordinals and the cardinals, they form examples of what are called *transfinite* numbers.

The real numbers have the cardinality of the power set of the integers, namely $2^{\aleph_0}$. Challenge 1218 s Can you show this? The result leads to the famous question: Is $\aleph_1 = 2^{\aleph_0}$ or not? The statement that this be so is called the *continuum hypothesis* and was unproven for several generations. The surprising answer came in 1963: the usual definition of the concept of Ref. 726 set is not specific enough to fix the answer. By specifying the concept of set in more detail, with additional axioms – remember that axioms are defining properties – you can make the continuum hypothesis come out either right or wrong, as you prefer.

Another result of research into transfinites is important: for every definition of a type of infinite cardinal, it seems to be possible to find a larger one. In everyday life, the idea of infinity is often used to stop discussions about size: 'My big brother is stronger than yours.' 'But mine is infinitely stronger than yours!' Mathematics has shown that questions on size do continue afterwards: 'The strength of my brother is the power set of that of Ref. 727 yours!' Rucker reports that mathematicians conjecture that there is no possible nor any conceivable end to these discussions.

For physicists, a simple question appears directly. Do infinite quantities exist in nature? Or better, is it necessary to use infinite quantities to describe nature? You might Challenge 1219 e want to clarify your own opinion on the issue. It will be settled during the rest of our adventure.

Functions and structures

Which relations are useful to describe patterns in nature? A typical example is 'larger stones are heavier'. Such a relation is of a specific type: it relates one specific value of an observable 'volume' to one specific value of the observable 'weight'. Such a one-to-one relation is called a *(mathematical) function* or *mapping*. Functions are the most specific types of relations; thus they convey a maximum of information. In the same way as numbers are used for observables, functions allow easy and precise communication of relations between observations. All physical rules and 'laws' are therefore expressed with the help of functions and, since physical 'laws' are about measurements, functions of numbers are their main building blocks.

A *function* f, or *mapping*, is a thus binary relation, i.e., a set $f = \{(x, y)\}$ of ordered pairs, where for every value of the first element x, called the *argument*, there is only *one* pair (x, y). The second element y is called the *value* of the function at the argument x. The set X of all arguments x is called the *domain of definition* and the set Y of all second arguments y is called the *range* of the function. Instead of $f = \{(x, y)\}$ one writes

$$f : X \to Y \quad \text{and} \quad f : x \mapsto y \quad \text{or} \quad y = f(x)\,, \tag{505}$$

where the type of arrow – with initial bar or not – shows whether we are speaking about sets or about elements.

We note that it is also possible to use the couple 'set' and 'mapping' to define all mathematical concepts; in this case a relation is defined with the help of mappings. A modern school of mathematical thought formalized this approach by the use of (mathematical) *categories*, a concept that includes both sets and mappings on an equal footing in its def-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

inition.*

To think and talk more clearly about nature, we need to define more specialized concepts than sets, relations and functions, because these basic terms are too general. The most important concepts derived from them are operations, algebraic structures and numbers.

A *(binary) operation* is a function that maps the Cartesian product of two copies of a set X into itself. In other words, an operation w takes an ordered couple of arguments $x \in X$ and assigns to it a value $y \in X$:

$$w : X \times X \to X \quad \text{and} \quad w : (x, x) \mapsto y \,. \tag{506}$$

Challenge 1220 s Is division of numbers an operation in the sense just defined?

Now we are ready to define the first of three basic concepts of mathematics. An *algebraic structure*, also called an *algebraic system*, is (in the most restricted sense) a set together with certain operations. The most important algebraic structures appearing in
Page 886 physics are groups, vector spaces, and algebras.

In addition to algebraic structures, mathematics is based on *order structures* and on *topological structures*. Order structures are building blocks of numbers and necessary to define comparisons of any sort. Topological structures are built, via subsets, on the concept of neighbourhood. They are necessary to define continuity, limits, dimensionality,
Page 895 topological spaces and manifolds.

Obviously, most mathematical structures are combinations of various examples of these three basic structure types. For example, the *system* of real numbers is given by the *set* of real numbers with the *operations* of addition and multiplication, the *order relation* 'is larger than' and a *continuity* property. They are thus built by combining an algebraic
Ref. 728 structure, an order structure and a topological structure. Let us delve a bit into the details.

Numbers

> "Which numbers are multiplied by six when their last digit is taken away and transferred to the front?"

Challenge 1221 s

Numbers are the oldest mathematical concept and are found in all cultures. The notion of number, in Greek ἀριθμός, has been changed several times. Each time the aim was to include wider classes of objects, but always retaining the general idea that numbers are entities that can be added, subtracted, multiplied and divided.

The modern way to write numbers, as e.g. in $12\,345\,679 \cdot 54 = 666\,666\,666$, is essential

* A *category* is defined as a collection of objects and a collection of 'morphisms', or mappings. Morphisms can be composed; the composition is associative and there is an identity morphism. The strange world of category theory, sometimes called the abstraction of all abstractions, is presented in William Lawvere & Stephen H. Schanuel, *Conceptual Mathematics: a First Introduction to Categories*, Cambridge University Press, 1997.

Note that every category contains a set; since it is unclear whether nature contains sets, as we will discuss on page 860, it is questionable whether categories will be useful in the unification of physics, despite their intense and abstract charm.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

for science.* It can be argued that the lack of a good system for writing down and for calculating with numbers delayed the progress of science by several centuries. (By the way, the same can be said for the affordable mass reproduction of written texts.)

The simplest numbers, 0, 1, 2, 3, 4, ..., are usually seen as being taken directly from experience. However, they can also be constructed from the notions of 'relation' and 'set'. Challenge 1222 s One of the many possible ways to do this (can you find another?) is by identifying a natural number with the set of its predecessors. With the relation 'successor of', abbreviated S, this definition can be written as

$$0 := \varnothing \quad , \quad 1 := S\,0 = \{0\} = \{\varnothing\} \quad ,$$
$$2 := S\,1 = \{0,1\} = \{\varnothing, \{\varnothing\}\} \quad \text{and} \quad n+1 := S\,n = \{0, \ldots, n\} \,. \tag{507}$$

This set, together with the binary operations 'addition' and 'multiplication,' constitutes the algebraic system $N = (N, +, \cdot, 1)$ of the *natural numbers*. For all number systems the algebraic system and the set are often sloppily designated by the same symbol. The Page 875 algebraic system N is a so-called semi-ring, as explained in Appendix B. (Some authors prefer not to count the number zero as a natural number.) Natural numbers are fairly useful.

TABLE 77 Some large numbers

Number	Example in nature
Around us	
1	number of angels that can be in one place at the same time, following Thomas Aquinas Ref. 729
8	number of times a newspaper can be folded in alternate perpendicular directions
12	largest number of times a paper strip has been folded in the same direction Ref. 730
20	number of digits in precision measurements that will probably never be achieved
34, 55, 89	petals of common types of daisy and sunflower Ref. 731
57	faces of a diamond with brilliant cut
2000	stars visible in the night sky
15 000	average number of objects in a European household
10^5	leaves of a tree (10 m beech)
6 to 7 $\cdot 10^9$	humans in the year 2000
10^{17}	ants in the world
c. 10^{20}	number of snowflakes falling on the Earth per year
c. 10^{24}	grains of sand in the Sahara desert
10^{22}	stars in the universe
10^{25}	cells on Earth

* However, there is no need for written numbers for doing mathematics, as shown by Marcia Ascher, *Ethnomathematics – A Multicultural View of Mathematical Ideas*, Brooks/Cole, 1991.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Number	Example in nature
$1.1 \cdot 10^{50}$	atoms making up the Earth ($6370^3\,\mathrm{km}^3 \cdot 4 \cdot 3.14/3 \cdot 5500\,\mathrm{kg/m}^3 \cdot 30\,\mathrm{mol/kg} \cdot 6 \cdot 10^{23}\,/\mathrm{mol}$)
10^{81}	atoms in the visible universe
10^{90}	photons in the visible universe
10^{169}	number of atoms fitting in the visible universe
10^{244}	number of space-time points inside the visible universe
Information	
51	record number of languages spoken by one person
c. 5000	words spoken on an average day by a man
c. 7000	words spoken on an average day by a woman
c. 2 000 000	number of scientists on Earth around the year 2000
$3 \cdot 10^8$	words spoken during a lifetime (2/3 time awake, 30 words per minute)
$4 \cdot 10^9$	pulses exchanged between both brain halves every second
10^9	words heard and read during a lifetime
10^{17}	image pixels seen in a lifetime ($3 \cdot 10^9\,\mathrm{s} \cdot (1/15\,\mathrm{ms}) \cdot 2/3$ (awake) $\cdot 10^6$ (nerves to the brain) Ref. 732
10^{19}	bits of information processed in a lifetime (the above times 32)
c. $5 \cdot 10^{12}$	printed words available in (different) books around the world (*c.* $100 \cdot 10^6$ books consisting of 50 000 words)
$2^{10} \cdot 3^7 \cdot 8! \cdot 12!$ $= 4.3 \cdot 10^{19}$	possible positions of the $3 \times 3 \times 3$ Rubik's Cube Ref. 733
$5.8 \cdot 10^{78}$	possible positions of the $4 \times 4 \times 4$ Rubik-like cube
$5.6 \cdot 10^{117}$	possible positions of the $5 \times 5 \times 5$ Rubik-like cube
c. 10^{200}	possible games of chess
c. 10^{800}	possible games of go
c. 10^{10^7}	possible states in a personal computer
Parts of us	
600	numbers of muscles in the human body, of which about half are in the face
150 000 ± 50 000	hairs on a healthy head
900 000	neurons in the brain of a grasshopper
$126 \cdot 10^6$	light sensitive cells per retina (120 million rods and 6 million cones)
10^{10} to 10^{11}	neurons in the human brain
$> 10^{16}$	memory bits in the human brain
$500 \cdot 10^6$	blinks of the eye during a lifetime (about once every four seconds when awake)
$300 \cdot 10^6$	breaths taken during human life
$3 \cdot 10^9$	heart beats during a human life
$3 \cdot 10^9$	letters (base pairs) in haploid human DNA
$6.1 \cdot 10^9$	bits in a compact disc
$1 \cdot 10^{11}$	humans who have ever lived
$10^{15\pm1}$	cells in the human body

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Number	Example in nature
$10^{16\pm1}$	bacteria carried in the human body

The system of *integers* $Z = (\ldots, -2, -1, 0, 1, 2, \ldots, +, \cdot, 0, 1)$ is the minimal ring that is an extension of the natural numbers. The system of *rational numbers* $Q = (Q, +, \cdot, 0, 1)$ is the minimal field that is an extension of the ring of the integers. (The terms 'ring' and 'field' are explained in Appendix B.) The system of *real numbers* $R = (R, +, \cdot, 0, 1, >)$ is the minimal extension of the rationals that is continuous and totally ordered. (For the definition of continuity, see page 896 and 876.) Equivalently, the reals are the minimal extension of the rationals forming a complete, totally strictly-Archimedean ordered field. This is the historical construction – or definition – of the integer, rational and real numbers from the natural numbers. However, it is not the only one construction possible. The most beautiful definition of all these types of numbers is the one discovered in 1969 by John Conway, and popularized by him, Donald Knuth and Martin Kruskal.

Page 875

Ref. 734

— A number is a sequence of bits. The two bits are usually called 'up' and 'down'. Examples of numbers and the way to write them are given in Figure 408.
— The empty sequence is zero.
— A finite sequence of n ups is the integer number n, and a finite sequence of n downs is the integer $-n$. Finite sequences of mixed ups and downs give the *dyadic rational numbers*. Examples are 1, 2, 3, −7, 19/4, 37/256, etc. They all have denominators with a power of 2. The other *rational numbers* are those that end in an infinitely repeating string of ups and downs, such as the *reals*, the *infinitesimals* and simple infinite numbers. Longer countably infinite series give even more crazy numbers. The complete class is called the class of *surreal* numbers.*

There is a second way to write surreal numbers. The first is the just mentioned sequence of bits. But in order to define addition and multiplication, another notation is usually used, deduced from Figure 408. A surreal α is defined as the earliest number of all those between two series of earlier surreals, the left and the right series:

$$\alpha = \{a, b, c, \ldots | A, B, C, \ldots\} \quad \text{with} \quad a, b, c, < \alpha < A, B, C \,. \tag{508}$$

For example, we have

$$\begin{aligned} &\{0|\} = 1\,,\ \{0,1|\} = 2\,,\ \{|0\} = -1\,,\ \{|-1,0\} = -2\,,\ \{0|1\} = 1/2\,, \\ &\{0|1/2, 1/4\} = 1\,,\ \{0, 1, 3/2, 25/16\,|\,41/16, 13/8, 7/4, 2\} = 1 + 37/64\,, \end{aligned} \tag{509}$$

showing that the finite surreals are the *dyadic numbers* $m/2^n$ (n and m being integers). Given two surreals $\alpha = \{\ldots, a, \ldots | \ldots, A, \ldots\}$ with $a < \alpha < A$ and $\beta = \{\ldots, b, \ldots | \ldots, B, \ldots\}$ with $b < \beta < B$, addition is defined recursively, using earlier, already defined numbers, as

$$\alpha + \beta = \{\ldots, a + \beta, \ldots, \alpha + b, \ldots | \ldots, A + \beta, \ldots, \alpha + B, \ldots\}\,. \tag{510}$$

* The surreal numbers do *not* form a set since they contain all *ordinal numbers*, which themselves do not form a set, even though they of course *contain* sets. In short, ordinals and surreals are classes which are *larger* than sets.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

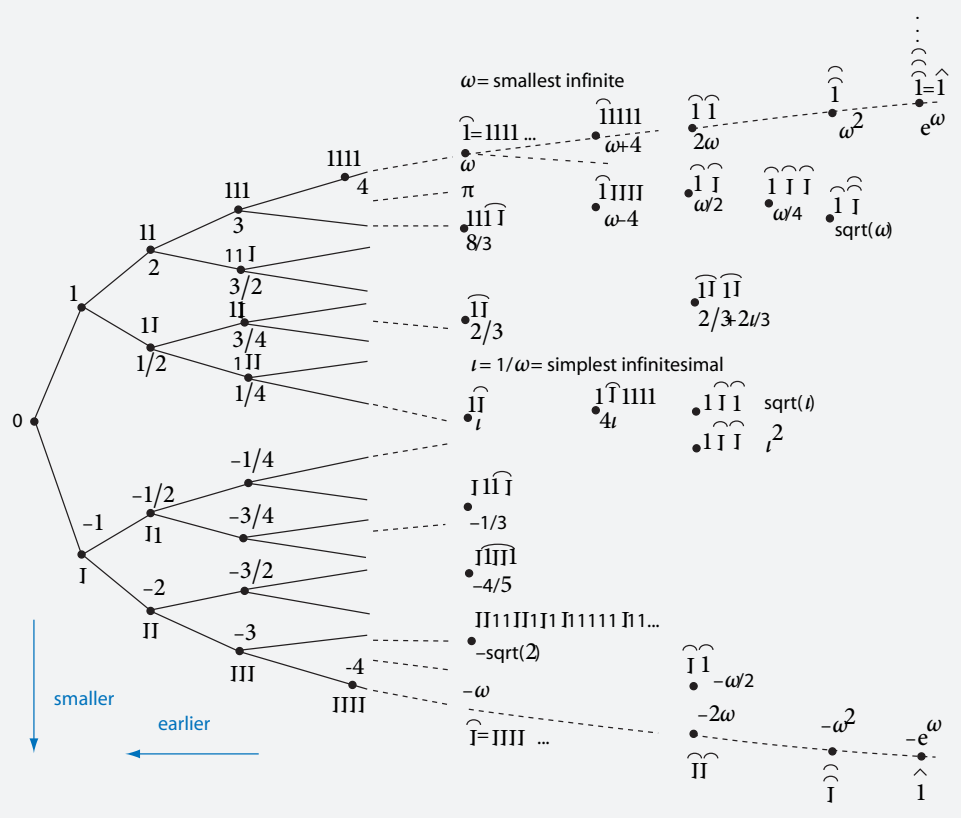

FIGURE 408 The surreal numbers in conventional and in bit notation

This definition is used simply because it gives the same results as usual addition for integers and reals. Can you confirm this? By the way, addition is not always commutative. Are you able to find the exceptions, and to find the definition for subtraction? Multiplication is also defined recursively, namely by the expression

Challenge 1223 s

$$\alpha\beta = \{\dots, a\beta + \alpha b - ab, \dots, A\beta + \alpha B - AB, \dots | \dots, a\beta + \alpha B - aB, \dots, A\beta + \alpha b - Ab, \dots\} \,. \tag{511}$$

These definitions allow one to write $\iota = 1/\omega$, and to talk about numbers such as $\sqrt{\omega}$, the square root of infinity, about $\omega + 4$, $\omega - 1$, 2ω, e^{ω} and about other strange numbers shown in Figure 408. However, the surreal numbers are not commonly used. More common is one of their subsets.

Ref. 734

The *real numbers* are those surreals whose length is not larger than infinity and that do not have periodic endings with a period of length 1. In other words, the surreals distinguish the number 0.999999... from the number 1, whereas the reals do not. However, this is only the case if the nines form a *simple* infinite sequence. In that case, between the two numbers there are infinitely many surreal numbers. Can you name a few?

Challenge 1224 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Reals are more useful for describing nature than surreals, first because they form a set – which the surreals do not – and secondly because they allow the definition of integration. Other numbers defined with the help of reals, e.g. the complex numbers $\mathbb{C}$and the quaternions $\mathbb{H}$, are presented in Appendix B. A few more elaborate number systems are also presented there.

Appendix B

To conclude, in physics it is usual to call *numbers* the elements of any set that is a semi-ring (e.g. $\mathbb{N}$), a ring (e.g. $\mathbb{Z}$) or a field ($\mathbb{Q}$, $\mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$). All these concepts are defined in Appendix B. Since numbers allow one to compare magnitudes and thus to measure, they play a central role in the description of observations.

Ref. 735

> A series of equal balls is packed in such a way that the area of needed wrapping paper is minimal. For small numbers of balls the linear package, with all balls in one row, is the most efficient. For which number of balls is the linear package no longer a minimum?

Challenge 1225 s

Why use mathematics?

> Die Forderung der Möglichkeit der einfachen Zeichen ist die Forderung der Bestimmtheit des Sinnes.*
>
> Ludwig Wittgenstein, *Tractatus*, 3.23

Several well-known physicists have repeatedly asked why mathematics is so important. For example, Niels Bohr is quoted as having said: 'We do not know why the language of mathematics has been so effective in formulating those laws in their most succinct form.' Eugene Wigner wrote an often cited paper entitled *The unreasonable effectiveness of mathematics*. At the start of science, many centuries earlier, Pythagoras and his contemporaries were so overwhelmed by the usefulness of numbers in describing nature, that Pythagoras was able to organize a sect based on this connection. The members of the inner circle of this sect were called 'learned people,' in Greek '*mathematicians*', from the Greek μάθημα 'teaching'. This sect title then became the name of the modern profession.

Ref. 736

Ref. 737

These men forgot that numbers, as well as a large part of mathematics, are concepts developed precisely with the aim of describing nature. Numbers and mathematical concepts were developed right from the start to provide as succinct a description as possible. That is one consequence of mathematics being the science of symbolic necessities.

Perhaps we are being too dismissive. Perhaps these thinkers mainly wanted to express their feeling of wonder when experiencing that language works, that thinking and our brain works, and that life and nature are so beautiful. This would put the title question nearer to the well-known statement by Albert Einstein: 'The most incomprehensible fact about the universe is that it is comprehensible.' Comprehension is another word for description, i.e., for classification. Obviously, any separable system is comprehensible, and there is nothing strange about it. But is the universe separable? As long as is it described as being made of particles and vacuum, this is the case.

We will find in the last part of this adventure that the basic assumption made at our start is built on sand. The assumption that observations in nature can be *counted*, and

* 'The requirement that simple signs be possible is the requirement that sense be determinate.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

thus that nature is separable, is an approximation. The quoted 'incomprehensibility' becomes amazement at the precision of this approximation. Nevertheless, Pythagoras' sect, which was based on the thought that 'everything in nature is numbers', was wrong. Like so many beliefs, observation will show that it was wrong.

> Die Physik ist für Physiker viel zu schwer.*
> David Hilbert

Is mathematics a language?

> Die Sätze der Mathematik sind Gleichungen, also Scheinsätze. Der Satz der Mathematik drückt keinen Gedanken aus.**
> Ludwig Wittgenstein, *Tractatus*, 6.2, 6.21

Surely, mathematics is a *vocabulary* that helps us to talk with precision. Mathematics can be seen as the exploration of *all* possible concepts that can be constructed from the two fundamental bricks 'set' and 'relation' (or some alternative, but equivalent pair). *Mathematics* is the science of symbolic necessities. Rephrased again, mathematics is the exploration of all possible types of classifications. This explains its usefulness in all situations where complex, yet precise classifications of observations are necessary, such as in physics.

However, mathematics cannot express everything that humans want to communicate, such as wishes, ideas or feelings. Just try to express the fun of swimming using mathematics. Indeed, *mathematics is the science of symbolic necessities*; thus mathematics is not a language, nor does it contain one. Mathematical concepts, being based on *abstract* sets and relations, do not pertain to nature. Despite its beauty, mathematics does not allow us to talk about nature or the observation of motion. Mathematics does not tell *what* to say about nature; it does tell us *how* to say it.

In his famous 1900 lecture in Paris, the German mathematician David Hilbert*** gave a list of 23 great challenges facing mathematics. The sixth of Hilbert's problems was to find a mathematical treatment of the axioms of physics. Our adventure so far has shown that physics started with *circular* definitions that has not yet been eliminated after 2500 years of investigations: space-time is defined with the help of objects and objects are de-
Page 317
fined with the help of space and time. Being based on a circular definition, physics is thus *not* modelled after mathematics, even if many physicists and mathematicians, including
Ref. 738
Hilbert, would like it to be so. Physicists have to live with logical problems and have to

* Physics is much too difficult for physicists.

** 'The propositions of mathematics are equations, and therefore pseudo-propositions. A proposition of mathematics does not express a thought.'

*** David Hilbert (1862 Königsberg–1943 Göttingen), professor of mathematics in Göttingen and greatest mathematician of his time. He was a central figure to many parts of mathematics, and also played an important role both in the birth of general relativity and of quantum theory. His textbooks are still in print. His famous personal credo was: 'Wir müssen wissen, wir werden wissen.' (We must know, we will know.) His famous Paris lecture is published e.g. in *Die Hilbertschen Probleme*, Akademische Verlagsgesellschaft Geest & Portig, 1983. The lecture galvanized all of mathematics. (Despite efforts and promises of similar fame, *nobody* in the world had a similar overview of mathematics that allowed him or her to repeat the feat in the year 2000.) In his last decade he suffered the persecution of the Nazi regime; the persecution eliminated Göttingen from the list of important science universities, without recovering its place up to this day.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

walk on unsure ground in order to achieve progress. In fact, they have done so for 2500 years. If physics were an axiomatic system, it would not contain contradictions; on the other hand, it would cease to be a language and would cease to describe nature. We will Page 1442 return to this issue later.

Curiosities and fun challenges about mathematics

Challenge 1226 s What is the largest number that can be written with four digits of 2 and no other sign? And with four 4s?

* *

Pythagorean triplets are integers that obey $a^2 + b^2 = c^2$. Give at least ten examples. Then Challenge 1227 e show the following three properties: at least one number in a triplet is a multiple of 3; at least one number in a triplet is a multiple of 4; at least one number in a triplet is a multiple of 5.

* *

A mother is 21 years older than her child, and in 6 years the child will be 5 times younger Challenge 1228 s than the mother. Where is the father? This is the *young mother puzzle*.

* *

The number $1/n$, when written in decimal notation, has a periodic sequence of digits. The period is at most $n - 1$ digits long, as for $1/7 = 0.142857\,142857\,1428\ldots$. Which other Challenge 1229 d numbers $1/n$ have periods of length $n - 1$?

* *

Felix Klein was a famous professor of mathematics at Göttingen University. There were two types of mathematicians in his department: those who did research on whatever they wanted and those for which Klein provided the topic of research. To which type did Klein Challenge 1230 s belong?

Obviously, this is a variation of another famous puzzle. A barber shaves all those Challenge 1231 s people who do not shave themselves. Does the barber shave himself?

* *

Everybody knows what a *magic square* is: a square array of numbers, in the simplest case from 1 to 9, that are distributed in such a way that the sum of all rows, columns (and possibly all diagonals) give the same sum. Can you write down the simplest $3 \times 3 \times 3$ Challenge 1232 s *magic cube*?

* *

The digits 0 to 9 are found on keyboards in two different ways. Calculators and keyboards have the 7 at the top left, whereas telephones and automatic teller machines have the digit 1 at the top left. The two standards, respectively by the International Standards Organization (ISO) and by the International Telecommunication Union (ITU, formerly CCITT), Ref. 739 evolved separately and have never managed to merge.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

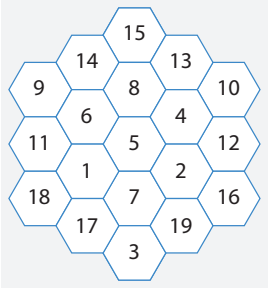

FIGURE 409 The only magic hexagon starting with the number 1 (up to reflections and rotations)

* *

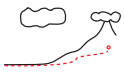
Leonhard Euler in his notebooks sometimes wrote down equations like

$$1 + 2^2 + 2^4 + 2^6 + 2^8 + \ldots = -\frac{1}{3} \,. \tag{512}$$

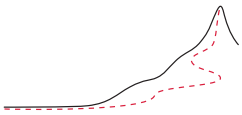
Challenge 1233 d Can this make sense?

* *

In the history of recreational mathematics, several people have independently found the well-known magic hexagon shown in Figure 409. The first discoverer was, in 1887, Ernst von Hasselberg. The hexagon is called magic because all lines add up to the same number, 38. Hasselberg also proved the almost incredible result that no other magic hexagon exists.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 32

CONCEPTS, LIES AND PATTERNS OF NATURE

> Die Grenzen meiner Sprache bedeuten die Grenzen meiner Welt.*
>
> Ludwig Wittgenstein, *Tractatus*, 5.6

> Der Satz ist ein Bild der Wirklichkeit. Der Satz ist ein Modell der Wirklichkeit, so wie wir sie uns denken.**
>
> Ludwig Wittgenstein, *Tractatus*, 4.01

Ref. 740 In contrast to mathematics, physics does aim at being a language. Through the description of motion it aims to express *everything* observed and, in particular, all examples and possibilities of change.*** Like any language, physics consists of concepts and sentences. In order to be able to express everything, it must aim to use few words for a lot of facts.**** Physicists are essentially *lazy* people: they try to minimize the effort in everything they do. The concepts in use today have been optimized by the combined effort of many people to be as practical, i.e., as powerful as possible. A concept is called *powerful* when it allows one to express in a compact way a large amount of information, meaning that it can rapidly convey a large number of details about observations.

General statements about many examples of motion are called *rules* or *patterns*. In the past, it was often said that 'laws govern nature', using an old and inappropriate ideology. A physical 'law' is only a way of saying as much as possible with as few words as possible. When saying 'laws govern nature' we actually mean to say 'being lazy, we describe obser-

* 'The limits of my language are the limits of my world.'

** 'A proposition is a picture of reality. A proposition is a model of reality as we imagine it.'

*** All observations are about change or variation. The various types of change are studied by the various sciences; they are usually grouped in the three categories of *human sciences*, *formal sciences* and *natural sciences*. Among the latter, the oldest are astronomy and metallurgy. Then, with the increase of curiosity in early antiquity, came the natural science concerned with the topic of motion: *physics*. In the course of our walk it will become clear that this seemingly restrictive definition indeed covers the whole set of topics studied in physics. In particular it includes the more common definition of physics as the study of matter, its properties, its components and their interactions.

**** A particular, specific observation, i.e., a specific example of input shared by others, is called a *fact*, or in other contexts, an *event*. A striking and regularly observed fact is called a *phenomenon*, and a general observation made in many different situations is called a *(physical) principle*. (Often, when a concept is introduced that is used with other meaning in other fields, in this walk it is preceded by the qualifier 'physical' or 'mathematical' in parentheses.) Actions performed towards the aim of collecting observations are called *experiments*. The concept of experiment became established in the sixteenth century; in the evolution of a child, it can best be compared to that activity that has the same aim of collecting experiences: *play*.

vations with patterns'. Laws are the epitome of laziness. Formulating laws is pure sloth. In fact, the correct expression is *patterns describe nature*.

Physicists have defined the laziness necessary for their field in much detail. In order to become a master of laziness, we need to distinguish lazy patterns from those which are not, such as lies, beliefs, statements that are not about observations, and statements that are not about motion. We do this below.

Page 840

The principle of extreme laziness is the origin, among others, of the use of numbers in physics. Observables are often best described with the help of numbers, because numbers allow easy and precise communication and classification. Length, velocity, angles, temperature, voltage or field strength are of this type. The notion of 'number', used in every measurement, is constructed, often unconsciously, from the notions of 'set' and 'relation', as shown above. Apart from the notion of number, other concepts are regularly defined to allow fast and compact communication of the 'laws' of nature; all are 'abbreviation tools.' In this sense, the statement 'the level of the Kac–Moody algebra of the Lagrangian of the heterotic superstring model is equal to one' contains precise information, explainable to everybody; however, it would take dozens of pages to express it using only the terms 'set' and 'relation.' In short, the *precision* common in physics results from its *quest for laziness*.

> Es ist besser, daß die Leute nicht wissen, wie Gesetze und Wurst zustande kommen. Sonst könnten sie nachts nicht ruhig schlafen.*
>
> Otto von Bismarck

Are physical concepts discovered or created?

> Das logische Bild der Tatsachen ist der Gedanke.**
>
> Ludwig Wittgenstein, *Tractatus*, 3

The title question is often rephrased as: are physical concepts free of beliefs, taste or personal choices? The question has been discussed so much that it even appears in Hollywood films. We give a short summary that can help you to distinguish honest from dishonest teachers.

Creation of concepts, in contrast to their discovery, would imply free choice between many alternative possibilities. The chosen alternative would then be due to the beliefs or tastes used. In physics (in obvious contrast to other, more ideological fields of enquiry), we know that different physical descriptions of observations are either equivalent or, in the opposite case, imprecise or even wrong. A description of observations is thus essentially unique: any choices of concepts are only apparent. There is no real freedom in the definition of physical concepts. In this property, physics is in strong contrast to artistic activity.

If two different concepts can be used to describe the same aspect of observations, they must be equivalent, even if the relation that leads to the equivalence is not immediately clear. In fact, the requirement that people with different standpoints and observing the same event deduce equivalent descriptions lies at the very basis of physics. It expresses

* 'It is better that people do not know how laws and sausages are made. Otherwise they would not sleep well at night.' Otto von Bismarck (1815–1898), Prussian Chancellor.

** 'A logical picture of facts is a thought.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the requirement that observations are observer independent. In short, the strong requirement of viewpoint independence makes the free choice of concepts a logical impossibility.

The conclusion that concepts describing observations are discovered rather than created is also reached independently in the field of linguistics by the above-mentioned research on semantic primitives,* in the field of psychology by the observations on the formation of the concepts in the development of young children, and in the field of ethology by the observations of animal development, especially in the case of mammals. In all three fields detailed observations have been made of how the interactions between an individual and its environment lead to concepts, of which the most basic ones, such as space, time, object or interaction, are common across the sexes, cultures, races and across many animal species populating the world. Curiosity and the way that nature works leads to the same concepts for all people and even the animals; the world offers only one possibility, without room for imagination. Imagining that physical concepts can be created at your leisure is a belief – or a useful exercise, but never successful.

Physical concepts are classifications of observations. The activity of classification itself follows the patterns of nature; it is a mechanical process that machines can also perform. This means that any distinction, i.e., any statement that A is different from B, is a theory-free statement. No belief system is necessary to distinguish different entities in nature. Cats and pigs can also do so. Physicists *can* be replaced by animals, even by machines. Our mountain ascent will repeatedly confirm this point.

As already mentioned, the most popular physical concepts allow to describe observations as succinctly and as accurately as possible. They are formed with the aim of having the largest possible amount of understanding with the smallest possible amount of effort. Both Occam's razor – the requirement not to introduce unnecessary concepts – and the drive for unification automatically reduce the number and the type of concepts used in physics. In other words, the progress of physical science was and is based on a programme that reduces the possible choice of concepts as drastically as possible.

Page 1501

In summary, we found that physical concepts are the same for everybody and are free of beliefs and personal choices: they are first of all *boring*. Moreover, as they could stem from machines instead of people, they are *born of laziness*. Despite these human analogies – not meant to be taken too seriously – physical concepts are *not* created; they are discovered. If a teacher tells you the opposite, he is lying.

Having handled the case of physical concepts, let us now turn to physical statements. The situation is somewhat similar: physical statements must be lazy, arrogant and boring. Let us see why.

> Wo der Glaube anfängt, hört die Wissenschaft auf.**
>
> Ernst Haeckel, *Natürliche Schöpfungsgeschichte*, 1879.

* Anna Wierzbicka concludes that her research clearly indicates that semantic primitives are *discovered*, in particular that they are deduced from the fundamentals of human experience, and not invented.

> Und grün des Lebens goldner Baum.*
>
> J.W. v. Goethe, *Faust*.

> Physics is usually presented as an objective science, but I notice that physics changes and the world stays the same, so there must be something subjective about physics.
>
> Richard Bandler

Progressing through the study of motion reflects a young child's attitude towards life. The progress follows the simple programme on the left of Table 78.

Adult scientists do not have much more to add, except the more fashionable terms on the right, plus several specialized professions to make money from them. The experts of step 7 are variously called lobbyists or fund raisers; instead of calling this program 'curiosity', they call it the 'scientific method.' They mostly talk. Physics being the talk about motion,** and motion being a vast topic, many people specialize in this step.

The experts of step 6 are called *experimental physicists* or simply *experimentalists*, a term derived from the Latin 'experiri', meaning 'to try out'. Most of them are part of the category 'graduate students'. The experts of steps 5 and 4 are called *theoretical physicists*

* 'Grey, dear friend, is all theory, and green the golden tree of life.' Johann Wolfgang von Goethe (1749–1832), the influential German poet.

** Several sciences have the term 'talk' as part of their name, namely all those whose name finishes in '-logy', such as e.g. biology. The ending stems from ancient Greek and is deduced from λήγειν meaning 'to say, to talk'. Physics as the science of motion could thus be called 'kinesiology' from κίνησις, meaning 'motion'; but for historical reasons this term has a different meaning, namely the study of human muscular activity. The term 'physics' is either derived from the Greek φύσικη (τέχνη is understood) meaning '(the art of) nature', or from the title of Aristotle' works τά φυσικά meaning 'natural things'. Both expressions are derived from φύσις, meaning 'nature'.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

or simply *theoreticians*.* This is a rather modern term; for example, the first professors of theoretical physics were appointed around the start of the twentieth century. The term is derived from the Greek θεωρία meaning 'observation, contemplation'. Finally, there are the people who focus on steps 1 to 3, and who induce others to work on steps 4 to 6; they are called *geniuses*.

Obviously an important point is hidden in step 6: how do all these people know whether their checks fail? How do they recognize truth?

> All professions are conspiracies against laymen.
> George Bernard Shaw

What is a lie?

> Get your facts straight, and then you can distort them at your leisure.
> Mark Twain

> The pure truth is always a lie.
> Bert Hellinger

Lies are useful statements, as everybody learns during their youth. One reason that they are useful is because we can draw any imaginable conclusion from them. A well-known discussion between two Cambridge professors early in the twentieth century makes the point. McTaggart asked: 'If 2 + 2 = 5, how can you prove that I am the pope?' Godfrey Hardy: 'If 2 + 2 = 5, then 4 = 5; subtract 3; then 1 = 2; but McTaggart and the pope are two; therefore McTaggart and the pope are one.' As noted long ago, *ex falso quodlibet*; from what is wrong, anything imaginable can be deduced. It is true that in our mountain ascent we need to build on previously deduced results and that our trip could not be completed if we had a false statement somewhere in our chain of arguments. But lying is such an important activity that one should learn to perform it well.

There are various stages in the art of lying. Many animals have been shown to de-
Ref. 704 ceive their kin. Children start lying just before their third birthday, by hiding experiences. Adults cheat on taxes. And many intellectuals or politicians even claim that truth does not exist.

However, in most countries, everybody must know what 'truth' is, since in a law court for example, telling an untruth can lead to a prison sentence. The courts are full of experts in lie detection. If you lie in court, you better do it well; experience shows that you might get away with many criminal activities. In court, a *lie* is a statement that knowingly contrasts with observations.** The truth of a statement is thus checked by observation. The check itself is sometimes called the *proof* of the statement. For law courts, as for physics, *truth* is thus the correspondence with facts, and *facts* are shared observations. A 'good' lie is thus a lie whose contrast with shared observations is hard to discover.

* If you like theoretical physics, have a look at the refreshingly candid web page by Nobel Prize winner Gerard 't Hooft with the title *How to become a good theoretical physicist*. It can be found at www.phys.uu.nl/~thooft/theorist.html.

** Statements not yet checked are variously called *speculations*, *conjectures*, *hypotheses*, or – wrongly – simply *theses*. Statements that are in correspondence with observations are called *correct* or *true*; statements that contrast with observations are called *wrong* or *false*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The first way of lying is to put an emphasis on the sharedness only. Populists and polemics do this regularly. ('Every foreigner is a danger for the values of our country.') Since almost any imaginable opinion, however weird, is held by some group – and thus shared – one can always claim it as true.* Unfortunately, it is no secret that ideas also get shared because they are fashionable, imposed or opposed to somebody who is generally disliked. Often a sibling in a family has this role – remember Cassandra.** For a good lie we thus need more than sharedness, more than *intersubjectivity* alone.

A good lie should be, like a true statement, really independent of the listener and the observer and, in particular, independent of their age, their sex, their education, their civilization or the group to which they belong. For example, it is especially hard – but not impossible – to lie with mathematics. The reason is that the basic concepts of mathematics, be they 'set', 'relation' or 'number', are taken from observation and are intersubjective, so that statements about them are easily checked. Usually, lies thus avoid mathematics.***

Secondly, a 'good' lie should avoid statements about observations and use *interpretations* instead. For example, some people like to talk about other universes, which implies talking about fantasies, not about observations. A good lie has to avoid, however, to fall in the opposite extreme, namely to make statements which are meaningless; the most destructive comment that can be made about a statement is the one used by the great
Page 1035 Austrian physicist Wolfgang Pauli: 'That is not even wrong.'

Thirdly, a good lie doesn't care about observations, only about imagination. Only truth needs to be *empirical*, to distinguish it from *speculative* statements. If you want to lie 'well' even with empirical statements, you need to pay attention. There are two types of empirical statements: *specific* statements and *universal* statements. For example, 'On the 31st of August 1960 I saw a green swan swimming on the northern shore of the lake of Varese' is specific, whereas 'All ravens are black' is universal, since it contains the term 'all'. There is a well-known difference between the two, which is important for lying well: specific statements cannot be falsified, they are only verifiable, and universal statements
Ref. 741 cannot be verified, they are only falsifiable. Why is this so?

Universal statements such as 'the speed of light is constant' cannot be tested for *all* possible cases. (Note that if they could, they would not be universal statements, but just a list of specific ones.) However, they can be reversed by a counter-example. Another example of the universal type is: 'Apples fall upwards.' Since it is falsified by an observation conducted by Newton several centuries ago, or by everyday experience, it qualifies as an (easily detectable) lie. In general therefore, lying by stating the opposite of a theory is usually unsuccessful. If somebody insists on doing so, the lie becomes a *superstition*, a *belief*, a *prejudice* or a *doctrine*. These are the low points in the art of lying. A famous

* The work of the French sociologist Gabriel Tarde (1843–1903), especially his concepts of *imitation* and group mind, already connects to this fact.

** The implications of birth order on creativity in science and on acceptance of new ideas has been studied in the fascinating book by Frank J. Sulloway, *Born to Rebel – Birth Order, Family Dynamics and Creative Lives*, Panthon Books, 1996. This exceptional book tells the result of a life-long study correlating the personal situations in the families of thousands of people and their receptivity to about twenty revolutions in the recent history. The book also includes a test in which the reader can deduce their own propensity to rebel, on a scale from 0 to 100 %. Darwin scores 96 % on this scale.

*** In mathematics, 'true' is usually specified as 'deducible' or 'provable'; this is in fact a special case of the usual definition of truth, namely 'correspondence with facts', if one remembers that mathematics studies the properties of classifications.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

case of insistence on a lie is that of the colleagues of Galileo, who are said to have refused to look through his telescope to be convinced that Jupiter has moons, an observation that would have shaken their belief that everything turns around the Earth. Obviously these astronomers were amateurs in the art of lying. A good universal lie is one whose counter-example is not so easily spotted.

There should be no insistence on lies in physics. Unfortunately, classical physics is full of lies. We will dispel them during the rest of our walk.

Lying by giving specific instead of universal statements is much easier. ('I can't remember.') Even a specific statement such as 'yesterday the Moon was green, cubic and smelled of cheese' can never be completely falsified: there is no way to show with absolute certainty that this is wrong. The only thing that we can do is to check whether the statement is compatible with other observations, such as whether the different shape affected the tides as expected, whether the smell can be found in air collected that day, etc. A good specific lie is thus not in contrast with other observations.*

Incidentally, universal and specific statements are connected: the *opposite* of a universal statement is always a specific statement, and vice versa. For example, the opposite of the general statement 'apples fall upwards', namely 'some apples fall downwards', is specific. Similarly, the the specific statement 'the Moon is made of green cheese' is in opposition to the universal statement 'the Moon is solid since millions of years and has almost no smell or atmosphere.'

In other words, law courts and philosophers disagree. Law courts have no problem with calling theories true, and specific statements lies. Many philosophers avoid this. For example, the statement 'ill-tempered gaseous vertebrates do not exist' is a statement of the universal type. If a universal statement is in agreement with observations, and if it is falsifiable, law courts call it *true*. The opposite, namely the statement: 'ill-tempered gaseous vertebrates do exist', is of the *specific* type, since it means 'Person X has observed an ill-tempered gaseous vertebrate in some place Y at some time Z'. To verify this, we need a record of the event. If such a record, for example a photographs or testimony does not exist, and if the statement *can* be falsified by other observations, law courts call the specific statement a *lie*. Even though these are the rules for everyday life and for the law, there is no agreement among philosophers and scientists that this is acceptable. Why? Intellectuals are a careful lot, because many of them have lost their lives as a result of exposing lies too openly.

In short, specific lies, like all specific statements, can never be falsified with certainty. This is what makes them so popular. Children learn specific lies first. ('I haven't eaten

* It is often difficult or tedious to verify statements concerning the past, and the difficulty increases with the distance in time. That is why people can insist on the occurrence of events which are supposed to be exceptions to the patterns of nature ('miracles'). Since the advent of rapid means of communication these checks are becoming increasingly easy, and no miracles are left over. This can be seen in Lourdes in France, where even though today the number of visitors is much higher than in the past, no miracles have been seen in decades.

In fact, all modern 'miracles' are kept alive only by consciously eschewing checks, such as the supposed yearly liquefaction of blood in Napoli, the milk supposedly drunk by statues in temples, the supposed healers in television evangelism, etc. Most miracles only remain because many organizations make money out of the difficulty of falsifying specific statements. For example, when the British princess Diana died in a car crash in 1997, even though the events were investigated in extreme detail, the scandal press could go on almost without end about the 'mysteries' of the accident.

Ref. 742

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the jam.') General lies, like all general statements, can always be corroborated by examples. This is the reason for the success of ideologies. But the criteria for recognizing lies, even general lies, have become so commonplace that beliefs and lies try to keep up with them. It became fashionable to use expressions such as 'scientific fact' – there are no non-scientific facts –, or 'scientifically proven' – observations cannot be proven otherwise – and similar empty phrases. These are not 'good' lies; whenever we encounter sentences beginning with 'science says ...' or 'science and religion do ...', replacing 'science' by 'knowledge' or 'experience' is an efficient way of checking whether such statements are to be taken seriously or not.*

Lies differ from true statements in their emotional aspect. Specific statements are usually boring and fragile, whereas specific lies are often sensational and violent. In contrast, general statements are often daring and fragile whereas general lies are usually boring and violent. The truth is fragile. True statements require the author to stick his neck out to criticism. Researchers know that if one doesn't stick the neck out, it can't be an observation or a theory. (A *theory* is another name for one or several connected, not yet falsified universal statements about observations.)** Telling the truth does make vulnerable. For this reason, theories are often *daring*, *arrogant* or *provoking*; at the same time they have to be *fragile* and *vulnerable*. For men, theories thus resemble what they think about women. Darwin's *The origin of the species*, which developed daring theories, illustrates the stark contrast between the numerous boring and solid facts that Darwin collected and the daring theory that he deduced. Boredom of facts is a sign of truth.

In contrast, the witch-hunters propagating 'creationism' or so-called 'intelligent design' are examples of liars. The specific lies they propagate, such as 'the world was created in October 4004 BCE', are sensational, whereas the general lies they propagate, such as 'there have not been big changes in the past', are boring. This is in full contrast with common sense. Moreover, lies, in contrast to true statements, make people violent. The worse the lie, the more violent the people. This connection can be observed regularly in the news. In other words, 'creationism' and 'intelligent design' are not only lies, they are bad lies. A 'good' *general lie*, like a good physical theory, seems crazy and seems vulnerable, such as 'people have free will'. A 'good' *specific lie* is boring, such as 'this looks like bread, but for the next ten minutes it is not'. Good lies do not induce violence. Feelings can thus be a criterion to judge the quality of lies, if we pay careful attention to the type of statement. A number of common lies are discussed later in this chapter.

* To clarify the vocabulary usage of this text: *religion* is spirituality plus a varying degree of power abuse. The mixture depends on each person's history, background and environment. *Spirituality* is the open participation in the whole of nature. Most, maybe all, people with a passion for physics are spiritual. Most are not religious.

** In other words, a set of not yet falsified patterns of observations on the same topic is called a *(physical) theory*. The term 'theory' will always be used in this sense in this walk, i.e., with the meaning 'set of correct general statements'. This use results from its Greek origin: 'theoria' means 'observation'; its original meaning, 'passionate and emphatic contemplation', summarizes the whole of physics in a single word. ('Theory', like 'theatre', is formed from the root θέ, meaning 'the act of contemplating'.) Sometimes, however, the term 'theory' is used – being confused with 'hypothesis' – with the meaning of 'conjecture', as in 'your theory is wrong', sometimes with the meaning of 'model', as in 'Chern–Simons' theory and sometimes with the meaning of 'standard procedure', as in 'perturbation theory'. These incorrect uses are avoided here. To bring the issue to a point: the *theory of evolution* is not a conjecture, but a set of correct statements based on observation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

An important aspect of any 'good' lie is to make as few *public* statements as possible, so that critics can check as little as possible. (For anybody sending corrections of mistakes in this text, the author provides a small reward.) To detect lies, public scrutiny is important, though not always reliable. Sometimes, even scientists make statements which are not based on observations. However, a 'good' lie is always well prepared and told on purpose; accidental lies are frowned upon by experts. Examples of good lies in science are 'aether', 'UFOs', 'creation science', or 'cold fusion'. Sometimes it took many decades to detect the lies in these domains.

To sum up, the central point of the art of lying without being caught is simple: do not divulge details. Be *vague*. All the methods used to verify a statement ask for details, for *precision*. For any statement, its degree of precision allows one to gauge the degree to which the author is sticking his neck out. The more precision that is demanded, the weaker a statement becomes, and the more likely a fault will be found, if there is one. This is the main reason that we chose an increase in precision as a guide for our mountain ascent. By the way, the same method is used in criminal trials. To discover the truth, investigators typically ask all the witnesses a large number of questions, allowing as many *details* as possible come to light. When sufficient details are collected, and the precision is high enough, the situation becomes clear. Telling 'good' lies is much more difficult than telling the truth; it requires an excellent imagination.

Is this statement true? – A bit about nonsense

> Truth is a rhetorical concept.
>
> Paul Feyerabend

> There are three types of people: those who believe in Father Christmas, those who do not believe in Father Christmas, and those who are Father Christmas.

Not all statements can be categorized as true or false. There is a third option: statements can simply make no sense. There are even such statements in mathematics, where they are called *undecidable*. An example is the continuum hypothesis. This hypothesis is undecidable because it makes a statement that depends on the precise meaning of the term 'set'; in standard mathematical usage the term is not defined sufficiently precisely so that a truth value can be assigned to the continuum hypothesis. In short, statements can be undecidable because the concepts contained in them are not sharply defined.

Statements can also be undecidable for other reasons. Phrases such as 'This statement

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

is not true' illustrate the situation. Kurt Gödel* has even devised a general way of constructing such statements in the domain of logic and mathematics. The different variations of these *self-referential* statements, especially popular both in the field of logic and computer science, have captured a large public.** Similarly undecidable statements can be constructed with terms such as 'calculable', 'provable' and 'deducible'. Ref. 745

In fact, self-referential statements are undecidable because they are meaningless. If the usual definition of 'true', namely corresponding to facts, is substituted into the sentence 'This statement is not true', we quickly see that it has no meaningful content. The most famous meaningless sentence of them all was constructed by the linguist Noam Chomsky:

Colorless green ideas sleep furiously.

It is often used as an example for the language processing properties of the brain, but nobody sensible elevates it to the status of a paradox and writes philosophical discussions about it. To do that with the title of this section is a similar waste of energy. Ref. 711

The main reason for the popular success of self-reference is the difficulty in perceiving the lack of meaning.*** A good example is the statement:

This statement is false or you are an angel.

We can actually deduce from it that 'you are an angel.' Can you see how? If you want, you can change the second half and get even more interesting statements. Such examples show that statements referring to themselves have to be treated with great care when under investigation. In short, whenever you meet somebody who tries to use the self-referential construction by Kurt Gödel to deduce another statement, take a step back, or better, a few more. Self-reference, especially the type defined by Gödel, is a hard but common path – especially amongst wannabe-intellectuals – to think, tell and write *nonsense*. Nothing useful can be deduced from nonsense. Well, not entirely; it does help to meet psychiatrists on a regular basis. Challenge 1235 s

In physics, in the other natural sciences, and in legal trials these problems do not emerge, because self-referential statements are not used.**** In fact, the work of logicians confirms, often rather spectacularly, that there is no way to extend the term 'truth' beyond the definition of 'correspondence with facts.'

---

* Kurt Gödel (1906–1978), famous Austrian logician.

** A general introduction is given in the beautiful books by RAYMOND SMULLYAN: *Satan, Cantor and Infinity and Other Mind-boggling Puzzles*, Knopf, 1992; *What is the Name of This Book? The Riddle of Dracula and Other Logical Puzzles*, Touchstone, 1986, and *The Lady or the Tiger? And Other Puzzles*, Times Books, 1982. Also definitions can have no content, such as David Hilbert's 'smallest number that has not been mentioned this century' or 'the smallest sequence of numbers that is described by more signs than this sentence'.

*** A well-known victim of this difficulty is Paulus of Tarsus. The paradox of the Cretan poet *Epimenedes* (6th century BCE) who said 'All Cretans lie' is too difficult for the notoriously humour-impaired Paulus, who in his letter to Titus (chapter 1, verses 12 and 13, in the christian bible) calls Epimenedes a 'prophet', adds some racist comments, and states that this 'testimony' is true. But wait! There is a final twist to this story. The statement 'All Cretans lie' is *not* a paradox at all; a truth value can actually be ascribed to it, because the statement is not really self-referential. Can you confirm this? The only *genuine* paradox is 'I am lying', to which it is indeed impossible to ascribe a truth value. Ref. 746 Challenge 1234 s

**** Why are circular statements, like those of Galilean physics, not self-referential? Challenge 1236 ny

* *

Challenge 1253 e 'I can generate energy from the vacuum.' Show that this is a lie.

* *

Challenge 1254 e 'Not everything that exists can be measured.' Show that this is a lie.

* *

'Not everything is known.' This statement is quite interesting: modern physics indeed claims the opposite in many domains. For example, all forms of energy are known; so are all forms of moving entities. In short, even though this statement is correct – indeed, not everything is known – it is often used by liars. Be careful when you hear it.

* *

Here is a lie that uses mathematics, from a journalist: 'Your university exams treat women applicants worse than men; your statistics show that only 41 % of all female, but 57% of all male applicants are admitted.' The university is small and has only two faculties; so it checks its numbers.

Faculty 1 admitted 60% of all males (60 of 100 applicants) and 65% of all applicant females (13 of 20 applicants). Faculty 2 admitted 30% of all males (3 of 10 applicants) and 32% of all females (16 of 50 applicants).

In total, the university thus admitted 63 of 110 male applicants (or 57%) and 29 of 70 female applicants (or 41%). In other words, even though in each faculties the percentage of admitted females was *higher*, the *total* admission percentage for females was *lower*.

Challenge 1255 e Why? In fact, this is a true story; in this version, the numbers are simplified, to make the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

situation as clear as possible. But a large university once got in trouble with journalists in this way, despite preferring women in each of its departments. Some journalists are excellent liars.

OBSERVATIONS

> Knowledge is a sophisticated statement of ignorance.
>
> Attributed to Karl Popper

The collection of a large number of true statements about a type of observations, i.e., of a large number of facts, is called *knowledge*. Where the domain of observations is sufficiently extended, one speaks of a *science*. A *scientist* is thus somebody who collects knowledge.* We found above that an observation is classified input into the memory of several people. Since there is motion all around, to describe all these observations is a mammoth task. As for every large task, to a large extent the use of appropriate tools determines the degree of success that can be achieved. These tools, in physics and in all other sciences, fall in three groups: tools for the collection of observations, tools to communicate observations and tools to communicate relations between observations. The latter group has been already discussed in the section on language and on mathematics. We just touch on the other two.

Ref. 747

Have enough observations been recorded?

> Every generation is inclined to define 'the end of physics' as coincident with the end of their scientific contributions.
>
> Julian Schwinger**

Physics is an experimental science; it rests on the collection of observations. To realize this task effectively, all sorts of *instruments*, i.e., tools that facilitate observations, have been developed and built. Microscopes, telescopes, oscilloscopes, as well as thermometers, hygrometers, manometers, pyrometers, spectrometers amongst others are familiar examples. The precision of many of these tools is being continuously improved even today; their production is a sizeable part of modern industrial activity, examples being electrical measuring apparatus and diagnostic tools for medicine, chemistry and biology.

* The term 'scientist' is a misnomer peculiar to the English language. Properly speaking, a 'scientist' is a follower of *scientism*, an extremist philosophical school that tried to resolve all problems through science. For this reason, some religious sects have the term in their name. Since the English language did not have a shorter term to designate 'scientific persons', as they used to be called, the term 'scientist' started to appear in the United States, from the eighteenth century onwards. Nowadays the term is used in all English-speaking countries – but not outside them, fortunately.

** Julian Seymour Schwinger (1918–1994), US-American infant prodigy. He was famous for his clear thinking and his excellent lectures. He worked on waveguides and synchroton radiation, made contributions to nuclear physics and developed quantum electrodynamics. For the latter he received the 1965 Nobel Prize in Physics together with Tomonaga and Feynman. He was a thesis advisor to many famous physicists and wrote several excellent and influential textbooks. Nevertheless, at the end of his life, he became strangely interested in a hoax turned sour: cold fusion.

Ref. 748

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Instruments can be as small as a tip of a few tungsten atoms to produce an electron beam of a few volts, and as large as 27 km in circumference, producing an electron beam with more than 100 GV effective accelerating voltage. Instruments have been built that contain and measure the coldest known matter in the universe. Other instruments can measure length variations of much less than a proton diameter over kilometre long distances. Instruments have been put deep inside the Earth, on the Moon, on several planets, and have been sent outside the Solar system.

In this walk, instruments are not described; many good textbooks on this topic are available. Most observations collected by instruments are not mentioned here. The most important results in physics are recorded in standard publications, such as the Landolt–Börnstein series and the physics journals (Appendix E gives a general overview of information sources).

Ref. 749, Ref. 750

Ref. 751

Will there be significant new future observations in the domain of the fundamentals of motion? At present, *in this specific domain*, even though the number of physicists and publications is at an all-time high, the number of new experimental discoveries has been steadily diminishing for many years and is now fairly small. The sophistication and investment necessary to obtain new results has become extremely high. In many cases, measuring instruments have reached the limits of technology, of budgets or even those of nature. The number of new experiments that produce results showing no deviation from theoretical predictions is increasing steadily. The number of historical papers that try to enliven dull or stalled fields of enquiry are increasing. Claims of new effects which turn out to be false, due to measurement errors, self-deceit or even fraud have become so frequent that scepticism has become a common response. Although in many domains of science, including physics, discoveries are still expected, on the fundamentals of motion the arguments just presented seem to show that new observations are only a remote possibility. The task of collecting observations on the foundations of motion (though not on other topics of physics) seems to be *complete*. Indeed, most observations described here were obtained before the end of the twentieth century. We are not too early with our walk.

> “Measure what is measurable; make measurable what is not.”
>
> Wrongly attributed to Galileo.

Ref. 752

Are all physical observables known?

> “Scientists have odious manners, except when you prop up their theory; then you can borrow money from them.”
>
> Mark Twain

The most practical way to communicate observations was developed a long time ago: by measurements. A measurement allows effective communication of an observation to other times and places. This is not always as trivial as it sounds; for example, in the Middle Ages people were unable to compare precisely the ‘coldness’ of the winters of two different years! The invention of the thermometer provided a reliable solution to this requirement. A *measurement* is thus the classification of an observation into a standard set of observations; to put it simply, a measurement is a *comparison with a standard*. This definition of a measurement is precise and practical, and has therefore been universally

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

adopted. For example, when the length of a house is measured, this aspect of the house is classified into a certain set of standard lengths, namely the set of lengths defined by multiples of a unit. A *unit* is the abstract name of the standard for a certain observable. Numbers and units allow the most precise and most effective communication of measurement results.

For all measurable quantities, practical standard units and measurement methods have been defined; the main ones are listed and defined in Appendix C. All units are derived from a few fundamental ones; this is ultimately due to our limited number of senses: length, time and mass are related to sight, hearing and touch. Our limited number of senses is, in turn, due to the small number of observables of nature.

We call *observables* the different measurable aspects of a system. Most observables, such as size, speed, position, etc. can be described by numbers, and in this case they are *quantities*, i.e., multiples of some standard unit. Observables are usually abbreviated by *(mathematical) symbols*, usually letters from some alphabet. For example, the symbol c commonly specifies the velocity of light. For most observables, standard symbols have been defined by international bodies.* The symbols for the observables that describe the state of an object are also called *variables*. Variables on which other observables depend are often called *parameters*. (Remember: a parameter is a variable constant.) For example, the speed of light is a constant, the position a variable, the temperature is often a parameter, on which the length of an object, for example, can depend. Note that not all observables are quantities; in particular, parities are not multiples of any unit.

Today the task of defining tools for the communication of observations can be considered *complete*. (For quantities, this is surely correct; for parity-type observables there could be a few examples to be discovered.) This is a simple and strong statement. Even the BIPM, the Bureau International des Poids et Mesures, has stopped adding new units.**

As a note, the greatness of a physicist can be ranked by the number of observables he has introduced. Even a great scientist such as Einstein, who discovered many 'laws' of nature, only introduced one new observable, namely the metric tensor for the description of gravity. Following this criterion – as well as several others – Maxwell is the most important physicist, having introduced electric and magnetic fields, the vector potential, and several other material dependent observables. For Heisenberg, Dirac and Schrödinger, the wave function describing electron motion could be counted as half an observable (as it is a quantity necessary to calculate measurement results, but not itself an observable). Incidentally, even the introduction of *any* term that is taken up by others is a rare event; 'gas', 'entropy' and only a few others are such examples. It has always been much more difficult to discover an observable than to discover a 'law'; usually, observables are developed by many people cooperating together. Indeed, many 'laws' bear people's names, but almost no observables.

* All mathematical symbols used in this walk, together with the alphabets from which they are taken, are listed in Appendix A on notation. They follow international standards whenever they are defined. The standard symbols of the physical quantities, as defined by the International Standards Organization (ISO), the International Union of Pure and Applied Physics (IUPAP) and the International Union of Pure and Applied Chemistry (IUPAC), can be found for example in the *bible*, i.e., the *CRC Handbook of Chemistry and Physics*, CRC Press, Boca Raton, 1992.

** The last, the katal or mol/s, was introduced in 1999. Physical units are presented in Appendix C.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

If the list of observables necessary to describe nature is complete, does this mean that all the patterns or rules of nature are known? No; in the history of physics, observables were usually defined and measured long *before* the precise rules connecting them were found. For example, all observables used in the description of motion itself, such as time, position and its derivatives, momentum, energy and all the thermodynamic quantities, were defined before or during the nineteenth century, whereas the most precise versions of the patterns or 'laws' of nature connecting them, special relativity and non-equilibrium thermodynamics, have been found only in the twentieth century. The same is true for all observables connected to electromagnetic interaction. The corresponding patterns of nature, quantum electrodynamics, was discovered long after the corresponding observables. The observables that were discovered last were the fields of the strong and the weak nuclear interactions. Also, in this case, the patterns of nature were formulated much later.*

Do observations take time?

An observation is an interaction with some part of nature leading to the production of a record, such as a memory in the brain, data on a tape, ink on paper, or any other fixed pattern applied to a support. The necessary irreversible interaction process is often called *writing* the record. Obviously, writing takes a certain amount of time; zero interaction time would give no record at all. Therefore any recording device, including our brain, always records some *time average* of the observation, however short it may be.

What we call a fixed image, be it a mental image or a photograph, is always the time average of a moving situation. Without time averaging, we would have no fixed memories. On the other hand, any time averaging introduces a blur that hides certain details; and in our quest for precision, at a certain moment, these details are bound to become important. The discovery of these details will begin in the upcoming part of the walk, the one centred on quantum theory. In the final part of our mountain ascent we will discover that there is a shortest possible averaging time. Observations of that short duration show so many details that even the distinction between particles and empty space is lost. In contrast, our concepts of everyday life appear only after relatively long time averages. The search for an average-free description of nature is one of the big challenges of our adventure.

Is induction a problem in physics?

> Nur *gesetzmäßige* Zusammenhänge sind *denkbar*.**
>
> Ludwig Wittgenstein, *Tractatus*, 6.361

* Is it possible to talk about observations at all? It is many a philosopher's hobby to discuss whether there actually is an example for an 'Elementarsatz' – an atomic fact – mentioned by Wittgenstein in his *Tractatus*. There seems to be at least one that fits: *Differences exist*. It is a simple sentence; in the final part of our walk, it will play a central role.

** 'Only connexions that are *subject to law* are *thinkable*.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

> There is a tradition of opposition between adherents of induction and of deduction. In my view it would be just as sensible for the two ends of a worm to quarrel.
>
> Alfred North Whitehead

Induction is the usual term used for the act of making, from a small and finite number of experiments, general conclusions about the outcome of *all* possible experiments performed in other places, or at other times. In a sense, it is the technical term for sticking out one's neck, which is necessary in every scientific statement. Induction has been a major topic of discussion for science commentators. Frequently one finds the remark that knowledge in general, and physics in particular, relies on induction for its statements. According to some, induction is a type of hidden belief that underlies all sciences but at the same time contrasts with them.

To avoid wasting energy, we make only a few remarks. The first can be deduced from a simple experiment. Try to convince a critic of induction to put their hand into a fire. Nobody who honestly calls induction a belief should conclude from a few unfortunate experiences in the past that such an act would also be dangerous in the future... In short, somehow induction works.

A second point is that physical universal statements are always openly stated; they are never hidden. The refusal to put one's hand into a fire is a consequence of the invariance of observations under time and space translations. Indeed, general statements of this type form the very basis of physics. However, no physical statement is a belief only because it is universal; it always remains open to experimental checks. Physical induction is not a hidden method of argumentation, it is an explicit part of experimental statements. In fact, the complete list of 'inductive' statements used in physics is given in the table on page 220. These statements are so important that they have been given a special name: they are called *symmetries*. The table lists all known symmetries of nature; in other words, it lists all inductive statements used in physics.

Perhaps the best argument for the use of induction is that there is no way to avoid it when one is thinking. There is no way to think, to talk or to remember without using concepts, i.e., without assuming that most objects or entities have the same properties over time. There is also no way to communicate with others without assuming that the observations made from the other's viewpoint are similar to one's own. There is no way to think without symmetry and induction. Indeed, the concepts related to symmetry and induction, such as space and time, belong to the fundamental concepts of language. The only sentences which do not use induction, the sentences of logic, do not have any content (*Tractatus*, 6.11). Indeed, without induction, we cannot classify observations at all! Evolution has given us memory and a brain because induction works. To criticize induction is not to criticize natural sciences, it is to criticize the use of thought in general. We should never take too seriously people who themselves do what they criticize in others; sporadically pointing out the ridicule of this endeavour is just the right amount of attention they deserve.

Page 819
Ref. 747
Challenge 1256 s

The topic could be concluded here, were it not for some interesting developments in modern physics that put two additional nails in the coffin of arguments against induction. First, in physics whenever we make statements about all experiments, all times or all velocities, such statements are actually about a *finite number* of cases. We know today that

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

infinities, both in size and in number, do not occur in nature. The infinite number of cases appearing in statements in classical physics and in quantum mechanics are apparent, not real, and due to human simplifications and approximations. Statements that a certain experiment gives the same result 'everywhere' or that a given equation is correct for 'all times', always encompass only a *finite* number of examples. A great deal of otherwise often instinctive repulsion to such statements is avoided in this way. In the sciences, as well as in this book, 'all' *never* means an infinite number of cases.

Finally, it is well known that extrapolating from a few cases to many is false when the few cases are independent of each other. However, this conclusion is correct if the cases are interdependent. From the fact that somebody found a penny on the street on two subsequent months, cannot follow that he will find one the coming month. Induction is only correct if we know that all cases have similar behaviour, e.g. because they follow from the same origin. For example, if a neighbour with a hole in his pocket carries his salary across that street once a month, and the hole always opens at that point because of the beginning of stairs, then the conclusion would be correct. It turns out that the results of modern physics encountered in the final part of our walk show that all situations in nature are indeed interdependent, and thus we prove in detail that what is called 'induction' is in fact a logically correct conclusion.

> In the progress of physics, the exception usually turned out to be the general case.

THE QUEST FOR PRECISION AND ITS IMPLICATIONS

> Der Zweck der Philosophie ist die logische Klärung der Gedanken.*
>
> Ludwig Wittgenstein, *Tractatus*, 4.112

To talk well about motion means to talk precisely. Precision requires avoiding three common mistakes in the description of nature.

First, concepts should never have a contradiction built into their definition. For example, any phenomenon occurring in nature evidently is a 'natural' phenomenon; therefore, to talk about either 'supernatural' phenomena or 'unnatural' phenomena is a mistake that nobody interested in motion should let go unchallenged; such terms contain a logical contradiction. Naturally, *all* observations are natural. Incidentally, there is a reward of more than a million dollars for anybody proving the opposite. In over twenty years, nobody has yet been able to collect it.

Ref. 753

Second, concepts should not have unclear or constantly changing definitions. Their content and their limits must be kept constant and explicit. The opposite of this is often encountered in crackpots or populist politicians; it distinguishes them from more reliable thinkers. Physicists can also fall into the trap; for example, there is, of course, only one *single* (physical) universe, as even the name says. To talk about more than one universe is an increasingly frequent error.

Ref. 754

Third, concepts should not be used outside their domain of application. It is easy to succumb to the temptation to transfer results from physics to philosophy without check-

* 'The object of philosophy is the logical clarification of thoughts.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ing the content. An example is the question: 'Why do particles follow the laws of nature?' The flaw in the question is due to a misunderstanding of the term 'laws of nature' and to a confusion with the laws of the state. If nature were governed by 'laws', they could be changed by parliament. Remembering that 'laws of nature' simply means 'pattern', 'property' or 'description of behaviour', and rephrasing the question correctly as 'Why do particles behave in the way we describe their behaviour?' one can recognize its senselessness.

In the course of our walk, we will often be tempted by these three mistakes. A few such situations follow, with the ways of avoiding them.

> Consistency is the last refuge of the unimaginative.
>
> Oscar Wilde

What are interactions? – No emergence

> The whole is always more than the sum of its parts.
>
> Aristotle, *Metaphysica*, 10f–1045a.

In the physical description of nature, the whole is always *more* than the sum of its parts. Actually, the difference between the whole and the sum of its parts is so important that it has a special name: the *interaction* between the parts. For example, the energy of the whole minus the sum of the energies of its parts is called the energy of interaction. In fact, the study of interactions is the main topic of physics. In other words, physics is concerned *primarily* with the difference between the parts and the whole, contrary to what is often suggested by bad journalists or other sloppy thinkers.

Note that the term 'interaction' is based on the general observation that anything that affects anything else is, in turn, affected by it; interactions are *reciprocal*. For example, if one body changes the momentum of another, then the second changes the momentum of the first by the same (negative) amount. The reciprocity of interactions is a result of conservation 'laws'. The reciprocity is also the reason that somebody who uses the term 'interaction' is considered a heretic by monotheistic religions, as theologians regularly point out. They repeatedly stress that such a reciprocity implicitly denies the immutability of the deity. (Are they correct?)

Challenge 1257 s

The application of the definition of interaction also settles the frequently heard question of whether in nature there are 'emergent' properties, i.e., properties of systems that cannot be deduced from the properties of their parts and interactions. By definition, there are no emergent properties. 'Emergent' properties can only appear if interactions are approximated or neglected. The idea of 'emergent' properties is a product of minds with restricted horizons, unable to see or admit the richness of consequences that general principles can produce. In defending the idea of emergence, one belittles the importance of interactions, working, in a seemingly innocuous, maybe unconscious, but in fact sneaky way, against the use of reason in the study of nature. 'Emergence' is a belief.

Page 309

Ref. 755

The simple definition of interaction given above sounds elementary, but it leads to surprising conclusions. Take the atomic idea of Democritus in its modern form: nature is made of vacuum and of particles. The first consequence is the *paradox of incomplete description*: experiments show that there are interactions between vacuum and particles. However, interactions are differences between parts and the whole, in this case between

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

vacuum and particles on the one hand, and the whole on the other. We thus have deduced that nature is not made of vacuum and particles alone.

The second consequence is the *paradox of overcomplete description*: experiments also show that interactions happen through exchange of particles. However, we have counted particles already as basic building blocks. Does this mean that the description of nature by vacuum and particles is an overdescription, counting things twice?

Challenge 1258 s

Page 1418

We will resolve both paradoxes in the last part of our mountain ascent.

What is existence?

> You know what I like most?
> Rhetorical questions.

Ref. 756

Assume a friend tells you 'I have seen a *grampus* today!' You would naturally ask what it looks like. What answer do we expect? We expect something like 'It's an animal with a certain number of heads similar to a X, attached to a body like a Y, with wings like a Z, it make noises like a U and it felt like a V' – the letters denoting some other animal or object. Generally speaking, in the case of an object, this scene from Darwin's voyage to South America shows that in order to talk to each other, we first need certain basic, common concepts ('animal', 'head', 'wing', etc.). In addition, for the definition of a new entity we need a characterization of its parts ('size', 'colour'), of the way these parts relate to each other, and of the way that the whole interacts with the outside world ('feel', 'sound'). In other words, for an object to exist, we must be able to give a list of relations with the outside world. An object exists if we can interact with it. (Is observation sufficient to determine existence?)

Challenge 1259 s

For an abstract concept, such as 'time' or 'superstring', the definition of existence has to be refined only marginally: *(physical) existence is the effectiveness to describe interactions accurately*. This definition applies to trees, time, virtual particles, imaginary numbers, entropy and so on. It is thus pointless to discuss whether a physical concept 'exists' or whether it is 'only' an abstraction used as a tool for descriptions of observations. The two possibilities coincide. The point of dispute can only be whether the description provided by a concept is or is not *precise*.

For mathematical concepts, existence has a somewhat different meaning: a mathematical concept is said to exist if it has no built-in contradictions. This is a much weaker requirement than physical existence. It is thus incorrect to deduce physical existence from mathematical existence. This is a frequent error; from Pythagoras' times onwards it was often stated that since mathematical concepts exist, they must therefore also exist in nature. Historically, this error occurred in the statements that planet orbits 'must' be circles, that planet shapes 'must' be spheres or that physical space 'must' be Euclidean. Today this is still happening with the statements that space and time 'must' be continuous and that nature 'must' be described by sets. In all these cases, the reasoning is wrong. In fact, the continuous attempts to deduce physical existence from mathematical existence hide that the opposite is correct: a short reflection shows that mathematical existence is a special case of physical existence.

Challenge 1260 s

We note that there is also a different type of existence, namely *psychological existence*. A concept can be said to exist psychologically if it describes human internal experience.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Thus a concept can exist psychologically even if it does not exist physically. It is easy to
Challenge 1261 s find examples from the religions or from systems that describe inner experiences. Also myths, legends and comic strips define concepts that only exist psychologically, not physically. In our walk, whenever we talk about existence, we mean physical existence only.

Do things exist?

> Wer Wissenschaft und Kunst besitzt,
> Hat auch Religion;
> Wer jene beiden nicht besitzt,
> Der habe Religion.*
>
> Johann Wolfgang von Goethe, *Zahme Xenien, IX*

Using the above definition of existence, the question becomes either trivial or imprecise. It is trivial in the sense that things necessarily exist if they describe observations, since they were defined that way. But perhaps the questioner meant to ask: Does reality exist independently of the observer?

Using the above, this question can be rephrased: 'Do the things we observe exist independently of observation?' After thousands of years of extensive discussion by professional philosophers, logicians, sophists and amateurs the answer is the same: it is 'Yes', because the world did not change after great-grandmother died. The disappearance of observers does not seem to change the universe. These experimental findings can be corroborated by inserting the definition of 'existence' into the question, which then becomes: 'Do the things we observe interact with other aspects of nature when they do not interact with people?' The answer is evident. Recent popular books on quantum mechanics fantasize about the importance of the 'mind' of observers – whatever this term may mean; they provide pretty examples of authors who see themselves as irreplaceable, seemingly having lost the ability to see themselves as part of a larger entity.

Of course there are other opinions about the existence of things. The most famous is that of the Irishman George Berkeley (1685–1753) who rightly understood that thoughts based on observation alone, if spread, would undermine the basis of the religious organization of which he was one of the top managers. To counteract this tendency, in 1710 he published *A Treatise Concerning the Principles of Human Knowledge*, a book denying the existence of the material world. This reactionary book became widely known in like-minded circles (it was a time when few books were written) even though it is based on a fundamentally flawed idea: it assumes that the concept of 'existence' and that of 'world'
Challenge 1262 e can be defined independently. (You may be curious to try the feat.)

Berkeley had two aims when he wrote his book. First, he tried to deny the capacity of people to arrive at judgements on nature or on any other matter *from their own experience*. Second, he also tried to deny the *ontological reach* of science, i.e., the conclusions one can draw from experience on the questions about human existence. Even though Berkeley is generally despised nowadays, he actually achieved his main aim: he was the originator of the statement that science and religion do not contradict, but *complement* each other. By religion, Berkeley did not mean either morality or spirituality; every scientist is a friend of both of these. By religion, Berkeley meant that the standard set of beliefs for which he

* He who possesses science and art, also has religion; he who does not possess the two, better have religion.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

stood is above the deductions of reason. This widely cited statement, itself a belief, is still held dearly by many even to this day. However, when searching for the origin of motion, all beliefs stand in the way, including this one. Carrying beliefs is like carrying oversized baggage: it prevents one from reaching the top of Motion Mountain.

Does the void exist?

> Teacher: 'What is found between the nucleus and the electrons?'
> Student: 'Nothing, only air.'
>
> Natura abhorret vacuum.
>
> Antiquity

In philosophical discussions '*void*' is usually defined as 'non-existence'. It then becomes a game of words to ask for a yes or no answer to the question 'Does the void exist?' The expression 'the existence of non-existence' is either a contradiction of terms or is at least unclearly defined; the topic would not seem to be of great interest. However, similar questions do appear in physics, and a physicist should be prepared to notice the difference of this from the previous one. Does a vacuum exist? Does empty space exist? Or is the world 'full' everywhere, as the more conservative biologist Aristotle maintained? In the past, people have been killed for giving an answer that was unacceptable to authorities.

It is not obvious, but it is nevertheless important, that the modern physical concepts of 'vacuum' and 'empty space' are not the same as the philosophical concept of 'void'. 'Vacuum' is not defined as 'non-existence'; on the contrary, it is defined as the absence of matter and radiation. Vacuum is an entity with specific observable properties, such as its number of dimensions, its electromagnetic constants, its curvature, its vanishing mass, its interaction with matter through curvature and through its influence on decay, etc. (A table of the properties of a physical vacuum is given on page 757.) Historically, it took a long time to clarify the distinction between a physical vacuum and a philosophical void. People confused the two concepts and debated the existence of the vacuum for more than two thousand years. The first to state that it existed, with the courage to try to look through the logical contradiction at the underlying physical reality, were Leucippus and Democritus, the most daring thinkers of antiquity. Their speculations in turn elicited the reactionary response of Aristotle, who rejected the concept of vacuum. Aristotle and his disciples propagated the belief about nature's *horror of the vacuum*.

The discussion changed completely in the seventeenth century, when the first experimental method to realize a vacuum was devised by Torricelli.* Using mercury in a glass tube, he produced the first laboratory vacuum. Can you guess how? Arguments against the existence of the vacuum again appeared around 1900, when it was argued that light needed 'aether' for its propagation, using almost the same arguments that had been used two hundred years earlier, but in different words. However, experiments failed to detect any of the supposed properties of this unclearly defined concept. Experiments in the field of general relativity showed that a vacuum can move – though in a completely different way from the way in which the aether was expected to move – that the vacuum can be

Challenge 1263 s

* Evangelista Torricelli (b. 1608 Faenza, d. 1647 Florence), Italian physicist, pupil and successor to Galileo. The (non-SI) pressure unit 'torr' is named after him.

bent, but it then tends to return to its shape. Then, in the late twentieth century, quantum field theory again argued against the existence of a true vacuum and in favour of a space full of virtual particle–antiparticle pairs, culminating in the discussions around the cosmological constant.

Page 1396

The question 'Does the void exist?' is settled conclusively only in the last part of this walk, in a rather surprising way.

Page 1420

Is nature infinite?

> It is certain and evident to our senses, that in the world some things are in motion. Now whatever is moved is moved by another... If that by which it is moved be itself moved, then this also needs to be to be moved by another, and that by another again. But this cannot go on to infinity, because then there would be no first mover and consequently, no other mover, seeing that subsequent movers move only inasmuch as they are moved by the first mover, as the staff moves only because it is moved by the hand. Therefore it is necessary to arrive at a first mover, moved by no other; and this everyone understands to be god.
>
> Thomas Aquinas (*c.* 1225–1274) *Summa Theologiae*, I, q. 2.

Most of the modern discussions about set theory centre on ways to defining the term 'set' for various types of infinite collections. For the description of motion this leads to two questions: Is the universe infinite? Is it a set? We begin with the first one. Illuminating the question from various viewpoints, we will quickly discover that it is both simple and imprecise.

Do we need infinite quantities to describe nature? Certainly, in classical and quantum physics we do, e.g. in the case of space-time. Is this necessary? We can say already a few things.

Any set can be finite in one aspect and infinite in another. For example, it is possible to proceed along a finite mathematical distance in an infinite amount of time. It is also possible to travel along any distance whatsoever in a given amount of mathematical time, making infinite speed an option, even if relativity is taken into account, as was explained earlier.

Page 425

Despite the use of infinities, scientists are still limited. We saw above that many types of infinities exist. However, no infinity larger than the cardinality of the real numbers plays a role in physics. No space of functions or phase space in classical physics and no Hilbert space in quantum theory has higher cardinality. Despite the ability of mathematicians to define much larger kinds of infinities, the description of nature does not need them. Even the most elaborate descriptions of motion use only the infinity of the real numbers.

Page 825

Ref. 743

But is it possible at all to say *of nature* or of one of its aspects that it is indeed *infinite*? Can such a statement be compatible with observations? No. It is evident that every statement that claims that something in nature is infinite is a belief, and is not backed by

Challenge 1264 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

observations. We shall patiently eliminate this belief in the following.

The possibility of introducing false infinities make any discussion on whether humanity is near the 'end of science' rather difficult. The amount of knowledge and the time required to discover it are unrelated. Depending on the speed with which one advances through it, the end of science can be near or unreachable. In practice, scientists have thus the power to *make* science infinite or not, e.g. by reducing the speed of progress. As scientists need funding for their work, one can guess the stand that they usually take.

Ref. 744

In short, the universe cannot be proven to be infinite. But can it be *finite*? At first sight, this would be the only possibility left. (It is not, as we shall see.) But even though many have tried to describe the universe as finite in all its aspects, no one has yet been successful. In order to understand the problems that they encountered, we continue with the other question mentioned above:

Is the universe a set?

A simple observation leads us to question whether the universe is a set. For 2500 years it has been said that the universe is made of vacuum and particles. This implies that the universe is made of a certain *number* of particles. Perhaps the only person to have taken this conclusion to the limit was the English astrophysicist Arthur Eddington (1882–1944), who wrote:

Ref. 757

> Ref. 758 I believe there are 15,747,724,136,275,002,577,605,653,961,181,555,468,044,717,914, 527,116,709,366,231,425,076,185,631,031,296 protons in the universe and the same number of electrons.

Eddington was ridiculed over and over again for this statement and for his beliefs that lead up to it. His arguments were indeed based on his personal preferences for certain pet numbers. However, we should not laugh too loudly. In fact, for 2500 years almost all scientists have thought along the same line, the only difference being that they have left the precise number unspecified! In fact, *any other number* put into the above sentence would be equally ridiculous. Avoiding specifying it is just a cowards' way of avoiding looking at this foggy aspect of the particle description of nature.

Is there a particle number at all in nature? If you smiled at Eddington's statement, or if you shook your head over it, it may mean that you instinctively believe that nature is not a set. Is this so? Whenever we define the universe as the totality of events, or as the totality of all space-time points and objects, we imply that space-time points can be distinguished, that objects can be distinguished and that both can be distinguished from each other. We thus assume that nature is separable and a set. But is this correct? The question is important. The ability to distinguish space-time points and particles from each other is often called *locality*. Thus the universe is separable or is a set if and only if our description of it is local.* And in everyday life, locality is observed without exception.

In daily life we also observe that nature is separable and a whole at the same time. It is a 'many that can be thought as one': in daily life nature is a set. Indeed, the basic

* In quantum mechanics also other, more detailed definitions of locality are used. We will mention them in the quantum part of this text. The issue mentioned here is a different, more fundamental one, and not connected with that of quantum theory.

Page 1082

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

characteristic of nature is its diversity. In the world around us we observe changes and differences; we observe that nature is separable. Furthermore, all aspects of nature belong together: there are relations between these aspects, often called 'laws,' stating that the different aspects of nature form a whole, usually called the universe.

In other words, the possibility of describing observations with the help of 'laws' follows from our experience of the separability of nature. The more precisely the separability is specified, the more precisely the 'laws' can be formulated. Indeed, if nature were not separable or were not a unity, we could not explain why stones fall downwards. Thus we are led to speculate that we should be able to deduce all 'laws' from the fact that nature is separable.

In addition, only the separability allows us to describe nature at all. A description is a classification, that is, a mapping between certain aspects of nature and certain concepts. All concepts are sets and relations. Since the universe is separable, it can be described with the help of sets and relations. Both are separable entities with distinguishable parts. A precise description is commonly called an understanding. In short, the universe is comprehensible only because it is separable.

Moreover, only the separability of the universe makes our brain such a good instrument. The brain is built from a large number of connected components, and only the brain's separability allows it to function. In other words, thinking is only possible because nature is separable.

Finally, only the separability of the universe allows us to distinguish reference frames, and thus to define all symmetries at the basis of physical descriptions. And in the same way that separability is thus necessary for *covariant* descriptions, the unity of nature is necessary for *invariant* descriptions. In other words, the so-called 'laws' of nature are based on the experience that nature is both separable and unifiable – that it is a set.

These arguments seem overwhelmingly to prove that the universe is a set. However, these arguments apply only to everyday experience, everyday dimensions and everyday energies. Is nature a set also *outside* the domains of daily life? Are objects different at all energies, even when they are looked at with the highest precision possible? We have three open issues left: the issue of the number of particles in the universe; the circular definition of space, time and matter; and the issue as to whether describing nature as made of particles and void is an overdescription, an underdescription, or neither. These three issues make us doubt whether objects are countable at all energies. We will discover in the final part of our mountain ascent that this is not the case in nature. The consequences will be extensive and fascinating. As an example, try to answer the following: if the universe is not a set, what does that mean for space and time?

Page 1440

Challenge 1265 s

Does the universe exist?

> Each progressive spirit is opposed by a
> thousand men appointed to guard the past.
> Maurice Maeterlink

Following the definition above, existence of a concept means its usefulness to describe interactions. There are two common definitions of the concept of 'universe'. The first is the totality of all matter, energy and space-time. But this usage results in a strange consequence: since nothing can interact with this totality, we cannot claim that the universe

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

exists.

So let us take the more restricted view, namely that the universe is only the totality of all matter and energy. But also in this case it is impossible to interact with the universe. Challenge 1266 s Can you give a few arguments to support this?

In short, we arrive at the conclusion that the universe does not exist. We will indeed Page 1443 confirm this result in more detail later on in our walk. In particular, since the universe does not exist, it does not make sense to even try to answer *why* it exists. The best answer Ref. 711 might be: because of furiously sleeping, colourless green ideas.

What is creation?

> (Gigni) De nihilo nihilum, in nihilum nil posse reverti.*
>
> Ref. 759 Persius, *Satira*, III, v. 83-84.

> Anaxagoras, discovering the ancient theory that nothing comes from nothing, decided to abolish the concept of creation and introduced in its place that of discrimination; he did not hesitate to state, in effect, that all things are mixed to the others and that discrimination produces their growth.
>
> Ref. 760 *Anonymous fragment*, Middle Ages.

The term 'creation' is often heard when talking about nature. It is used in various contexts with different meanings.

One speaks of creation as the characterization of human actions, such as observed in an artist painting or a secretary typing. Obviously, this is one type of change. In the classification of change introduced at the beginning of our walk, the changes cited are movements of objects, such as the electrons in the brain, the molecules in the muscles, the material of the paint, or the electrons inside the computer. This type of creation is thus a special case of motion.

One also speaks of creation in the biological or social sense, such as in 'the creation of life', or 'creation of a business', or 'the creation of civilization'. These events are forms of growth or of self-organization; again, they are special cases of motion.

Physicists one often say that a lamp 'creates' light or that a stone falling into a pond 'creates' water ripples. Similarly, they talk of 'pair creation' of matter and antimatter. It Page 1049 was one of the important discoveries of physics that all these processes are special types Page 1184 of motion, namely excitation of fields.

In popular writing on cosmology, 'creation' is also a term commonly applied, or better misapplied, to the *big bang*. However, the expansion of the universe is a pure example of motion, and contrary to a frequent misunderstanding, the description of the big bang contains only processes that fall into one of the previous three categories, as shown in the Page 591 relevant chapter in general relativity. The big bang is not an example of creation. Quantum cosmology provides more reasons to support the fact that the naive term 'creation' Page 590 is not applicable to the big bang. First, it turns out that the big bang was not an event.

* Nothing (can appear) from nothing, nothing can disappear into nothing.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Second, it was not a beginning. Third, it did not provide a *choice* from a large set of possibilities. The big bang does not have any properties attributed to the term 'creation'.

In summary, we conclude that in all cases, *creation is a type of motion*. (The same applies to the notions of 'disappearance' and 'annihilation'.) No other type of creation is observed in nature. In particular, the naive sense of 'creation', namely 'appearance from nothing' – *ex nihilo* in Latin – is never observed in nature. All observed types of 'creation' require space, time, forces, energy and matter for their realization. Creation requires something to exist already, in order to take place. In addition, precise exploration shows that no physical process and no example of motion has a beginning. Our walk will show us that nature does not allow us to pinpoint beginnings. This property alone is sufficient to show that 'creation' is not a concept applicable to what happens in nature. Worse still, creation is applied only to physical systems; we will discover that nature is not a system and that systems do not exist.

The opposite of creation is *conservation*. The central statements of physics are conservation theorems: for energy, mass, linear momentum, angular momentum, charge, etc. In fact, every conservation 'law' is a detailed and accurate rejection of the concept of creation. The ancient Greek idea of atoms already contains this rejection. Atomists stated that there is no creation and no disappearance, but only motion of atoms. Every transformation of matter is a motion of atoms. In other words, the idea of the atom was a direct consequence of the negation of creation. It took humanity over 2000 years before it stopped locking people in jail for talking about atoms, as had happened to Galileo.

Page 252

However, there is one exception in which the naive concept of creation does apply: it describes what magicians do on stage. When a magician makes a rabbit appear from nowhere, we indeed experience 'creation' from nothing. At its best such magic is a form of entertainment, at its worst, a misuse of gullibility. The idea that the universe results from either of these two does not seem appealing; on second thought though, maybe looking at the universe as the ultimate entertainment could open up a fresh and more productive approach to life.

Voltaire (1694–1778) popularized an argument against creation often used in the past: we do not know whether creation has taken place or not. Today the situation is different: we *do* know that it has *not* taken place, because creation is a type of motion and, as we will see in the concluding part of our mountain ascent, motion did not exist near the big bang.

Have you ever heard the expression 'creation of the laws of nature'? It is one of the most common examples of disinformation. First of all, this expression confuses the 'laws' with nature itself. A description is not the same as the thing itself; everybody knows that giving their beloved a description of a rose is different from giving an actual rose. Second, the expression implies that nature is the way it is because it is somehow 'forced' to follow the 'laws' – a rather childish and, what is more, incorrect view. And third, the expression assumes that it is possible to 'create' descriptions of nature. But a 'law' is a description, and a description by definition cannot be created: so the expression makes no sense at all. The expression 'creation of the laws of nature' is the epitome of confused thinking.

It may well be that calling a great artist 'creative' or 'divine', as was common during the Renaissance, is not blasphemy, but simply an encouragement to the gods to try to do as well. In fact, whenever one uses the term 'creation' to mean anything other than some form of motion, one is discarding both observations and human reason. It is one

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of the last pseudo-concepts of our modern time; no expert on motion should forget this. It is impossible to escalate Motion Mountain without getting rid of 'creation'. This is not easy. We will encounter the next attempt to bring back creation in the study of quantum theory.

Page 1343

> Every act of creation is first of all an act of destruction.
>
> Pablo Picasso

Is nature designed?

> In the beginning the universe was created. This has made a lot of people very angry and has been widely regarded as a bad move.
>
> Douglas Adams

The tendency to infer the creation of an object from its simple existence is widespread. Some people jump to this conclusion every time they see a beautiful landscape. This habit stems from the triple prejudice that a beautiful scene implies a complex description, in turn implying complex building instructions, and therefore pointing to an underlying *design*.

This chain of thought contains several mistakes. First, in general, beauty is not a consequence of complexity. Usually it is the opposite: indeed, the study of chaos and of self-organization demonstrated how beautifully complex shapes and patterns can be generated with extremely simple descriptions. True, for most human artefacts, complex descriptions indeed imply complex building processes; a personal computer is a good example of a complex object with a complex production process. But in nature, this connection does not apply. We have seen above that even the amount of information needed to construct a human body is about a million times smaller than the information stored in the brain alone. Similar results have been found for plant architecture and for many other examples of patterns in nature. The simple descriptions behind the apparent complexities of nature have been and are still being uncovered by the study of self-organization, chaos, turbulence and fractal shapes. In nature, complex structures derive from *simple* processes. Beware of anyone who says that nature has 'infinite complexity': first of all, complexity is not a measurable entity, despite many attempts to quantify it. In addition, all known complex system can be described by (relatively) few parameters and simple equations. Finally, nothing in nature is infinite.

Ref. 761

The second mistake in the argument for design is to link a description with an 'instruction', and maybe even to imagine that some unknown 'intelligence' is somehow pulling the strings of the world's stage. The study of nature has consistently shown that there is no hidden intelligence and no instruction behind the processes of nature. An instruction is a list of orders to an executioner. But there are no orders in nature, and no executioners. There are no 'laws' of nature, only descriptions of processes. Nobody is building a tree; the tree is an outcome of the motion of molecules making it up. The genes in the tree do contain information; but no molecule is given any instructions. What seem to be instructions to us are just natural movements of molecules and energy, described by the same patterns taking place in non-living systems. The whole idea of instruction – like that of 'law' of nature – is an ideology, born from an analogy with monarchy or even

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tyranny, and a typical anthropomorphism.

The third mistake in the argument for design is the suggestion that a complex description for a system implies an underlying design. This is not correct. A complex description only implies that the system has a long evolution behind it. The correct deduction is: something of large complexity exists; therefore it has *grown*, i.e., it has been transformed through input of (moderate) energy over time. This deduction applies to flowers, mountains, stars, life, people, watches, books, personal computers and works of art; in fact it applies to all objects in the universe. The complexity of our environment thus points out the considerable age of our environment and reminds us of the shortness of our own life.

The lack of basic complexity and the lack of instructions in nature confirm a simple result: there is not a single observation in nature that implies or requires design or creation. On the other hand, the variety and intensity of nature's phenomena fills us with deep awe. The wild beauty of nature shows us how *small* a part of nature we actually are, both in space and in time.* We shall explore this experience in detail. We shall find that remaining open to nature's phenomena in all their overwhelming intensity is central to the rest of our adventure.

Page 1343

> There is a separation between state and church,
> but not yet between state and science.
>
> Paul Feyerabend

What is a description?

> In theory, there is no difference between theory
> and practice. In practice, there is.

Following standard vocabulary usage, a description of an observation is a list of the details. The above example of the grampus showed this clearly. In other words, a *description* of an observation is the act of categorizing it, i.e., of comparing, by identifying or distinguishing, the observation with all the other observations already made. A description is a classification. In short, *to describe means to see as an element of a larger set*.

Page 856

A description can be compared to the 'you are here' sign on a city tourist map. Out of a set of possible positions, the 'you are here' sign gives the actual one. Similarly, a description highlights the given situation in comparison with all other possibilities. For example, the formula $a = GM/r^2$ is a description of the observations relating motion to gravity, because it classifies the observed accelerations a according to distance to the central body r and to its mass M; indeed such a description sees each specific case as an example of a general pattern. The habit of generalizing is one reason for the often disturbing dismissiveness of scientists: when they observe something, their professional training usually makes them classify it as a special case of a known phenomenon and thus keeps them from being surprised or from being exited about it.

A description is thus the opposite of a *metaphor*; the latter is an analogy relating an observation with another *special* case; a description relates an observation with a *general* case, such as a physical theory.

* The search for a 'sense' in life or in nature is a complicated (and necessary) way to try to face the smallness of human existence.

> Naturerscheinungen seien.**
> Ludwig Wittgenstein, *Tractatus*, 6.371

— Why are the leaves of most trees green? Because they absorb red and blue light. Why do they absorb those colours? Because they contain chlorophyll. Why is chlorophyll green? Because all chlorophyll types contain magnesium between four pyrrole groups, and this chemical combination gives the green colour, as a result of its quantum mechanical energy levels. Why do plants contain chlorophyll? Because this is what land plants can synthesize. Why only this? Because all land plants originally evolved from the green algae, who are only able to synthesize this compound, and not the compounds found in the blue or in the red algae, which are also found in the sea.
— Why do children climb trees, and why do some people climb mountains? Because of the sensations they experience during their activity: the feelings of achievement, the symbolic act to go upwards, the wish to get a wider view of the world are part of this type of adventure.

The 'why'-questions in the last two paragraphs show the general difference between reasons and purposes (although the details of these two terms are not defined in the same way by everybody). A *purpose* or *intention* is a classification applied to the actions of humans or animals; strictly speaking, it specifies the quest for a feeling, namely for achieving some type of satisfaction after completion of the action. On the other hand, a *reason* is a specific relation of a fact with the rest of the universe, usually its past. What we call a reason always rests outside the observation itself, whereas a purpose is always internal to it.

Reasons and purposes are the two possibilities of explanations, i.e., the two possible answers to questions starting with 'why'. Usually, physics is not concerned with purpose or with people's feeling, mainly because its original aim, to talk about motion with precision, does not seem to be achievable in this domain. Therefore, *physical* explanations of facts are never purposes, but are always reasons. A *physical explanation* of an observation is always the description of its relation with the rest of nature.*** Ref. 762

* 'Happy he who can know the causes of things and who, free of all fears, can lay the inexorable fate and the noise of Acheron to his feet.' *Georgica*, book II, verses 490 ss.) Publius Vergilius Maro (70–19 BCE), the great roman poet, is author of the Aeneid. Acheron was the river crossed by those who had just died and were on their way to the Hades.

** 'The whole modern conception of the world is founded on the illusion that the so-called laws of nature are the explanations of natural phenomena.'

*** It is important to note that purposes are *not* put aside because they pertain to the future, but because they are inadmissible anthropomorphisms. In fact, for deterministic systems, we can equally say that the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This means that – contrary to common opinion – a question starting with 'why' is accessible to physical investigation as long as it asks for a reason and not for a purpose. In particular, questions such as 'why do stones fall downwards and not upwards?' or 'why do electrons have that value of mass, and why do they have mass at all?' or 'why does space have three dimensions and not thirty-six?' can be answered, as these ask for the connection between specific observations and more general ones. Of course, not all demands for explanation have been answered yet, and there are still problems to be solved. Our present trail only leads from a few answers to some of the more fundamental questions about motion.

The most general quest for an explanation derives from the question: why is the universe the way it is? The topic is covered in our mountain ascent using the two usual approaches, namely:

Unification and demarcation

> Tout sujet est un; et, quelque vaste qu'il soit, il peut être renfermé dans un seul discours.*
>
> Buffon, *Discours sur le style.*

Studying the properties of motion, constantly paying attention to increase the accuracy of description, we find that explanations are generally of two types:**

— 'It is like all such cases; also this one is described by ...' The situation is recognized as a *special case* of a general behaviour.
— 'If the situation were different, we would have a conclusion in contrast with observations.' The situation is recognized as the *only possible case*.***

In other words, the first approach is to formulate rules or 'laws' that describe larger and larger numbers of observations, and compare the observation with them. This endeavour is called the *unification* of physics – by those who like it; those who don't like it, call it 'reductionism'. For example, the same rule describes the flight of a tennis ball, the motion of the tides at the sea shore, the timing of ice ages, and the time at which the planet Venus ceases to be the evening star and starts to be the morning star. These processes are all consequences of universal gravitation. Similarly, it is not evident that the same rule describes the origin of the colour of the eyes, the formation of lightning, the digestion of food and the working of the brain. These processes are described by quantum electrodynamics.

Unification has its most impressive successes when it predicts an observation that has not been made before. A famous example is the existence of antimatter, predicted

future is actually a *reason* for the present and the past, a fact often forgotten.

* Every subject is one and, however vast it is, it can be comprised in a single discourse.

Challenge 1267 s ** Are these the only possible ones?

*** These two cases have not to be confused with similar sentences that *seem* to be explanations, but that aren't:

— 'It is like the case of ...' A similarity with another *single* case is *not* an explanation.
— 'If it were different, it would contradict the idea that ...' A contradiction with an *idea* or with a theory is *not* an explanation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

by Dirac when he investigated the solutions of an equation that describes the precise behaviour of common matter.

The second procedure in the search for explanations is the elimination of all other imaginable alternatives in favour of the actually correct one. This endeavour has no commonly accepted name: it could be called the *demarcation* of the 'laws' of physics – by those who like it; others call it 'anthropocentrism', or simply 'arrogance'.

When we discover that light travels in such a way that it takes the shortest possible time to its destination, when we describe motion by a principle of least action, or when we discover that trees are branched in such a way that they achieve the largest effect with the smallest effort, we are using a demarcation viewpoint.

In summary, unification, answering 'why' questions, and demarcation, answering 'why not' questions, are typical for the progress throughout the history of physics. We can say that the dual aspects of unification and demarcation form the composing and the opposing traits of physics. They stand for the desire to *know everything*.

Challenge 1268 s
Challenge 1269 s

However, neither demarcation nor unification can explain the universe. Can you see why? In fact, apart from unification and demarcation, there is a third possibility that merges the two and allows one to say more about the universe. Can you find it? Our walk will automatically lead to it later.

Pigs, apes and the anthropic principle

> Das wichtigste Instrument des Wissenschaftlers ist der Papierkorb.*

The wish to achieve demarcation of the patterns of nature is most interesting when we follow the consequences of different rules of nature until we find them in contradiction with the most striking observation: our own human existence. In this special case the program of demarcation is often called the *anthropic principle* – from the Greek ἄνθρωπος, meaning 'man'.

For example, if the Sun–Earth distance were different from what it is, the resulting temperature change on the Earth would have made impossible the appearance of life, which needs liquid water. Similarly, our brain would not work if the Moon did not circle the Earth. It is also well-known that if there were fewer large planets in the solar system, the evolution of humans would have been impossible. The large planets divert large numbers of comets, preventing them from hitting the Earth. The spectacular collision of comet Shoemaker–Levy-9 with Jupiter, the astronomical event of July 1994, was an example of this diversion of a comet.**

Also the anthropic principle has its most impressive successes when it predicts unknown observations. The most famous example stems from the study of stars. Carbon atoms, like all other atoms except most hydrogen, helium or lithium atoms, are formed in stars through fusion. While studying the mechanisms of fusion in 1953, the well-known British astrophysicist Fred Hoyle*** found that carbon nuclei could not be formed from

* The most important instrument of a scientist is the waste paper basket.

** For a collection of pictures of this event, see e.g. the garbo.uwasa.fi/pc/gifslevy.html website.

*** Fred Hoyle (b. 1915 Bingley, d. 2001), important British astronomer and astrophysicist. He was the first and maybe only physicist who ever made a specific prediction – namely the existence of an excited state of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the alpha particles present inside stars at reasonable temperatures, unless they had an excited state with an increased cross-section. From the fact of our existence, which is based on carbon, Hoyle thus predicted the existence of a previously unknown excited state of the carbon nucleus. And, indeed, the excited state was found a few months later by Willy Fowler.*

Ref. 763

In its *serious* form, the anthropic principle is therefore the quest to deduce the description of nature from the experimental fact of our own existence. In the popular literature, however, the anthropic principle is often changed from a simple experimental method to deduce the patterns of nature, to its *perverted* form, a melting pot of absurd metaphysical ideas in which everybody mixes up their favourite beliefs. Most frequently, the experimental observation of our own existence has been perverted to reintroduce the idea of 'design', i.e., that the universe has been constructed with the aim of producing humans; often it is even suggested that the anthropic principle is an *explanation* – a gross example of disinformation.

Ref. 764

How can we distinguish between the serious and the perverted form? We start with an observation. We would get exactly the same rules and patterns of nature if we used the existence of pigs or monkeys as a starting point. In other words, if we would reach *different* conclusions by using the *porcine principle* or the *simian principle*, we are using the perverted form of the anthropic principle, otherwise we are using the serious form. (The carbon-12 story is thus an example of the serious form.) This test is effective because there is no known pattern or 'law' of nature that is particular to humans but unnecessary for apes or pigs.**

> Er wunderte sich, daß den Katzen genau an den Stellen Löcher in den Pelz geschnitten wären, wo sie Augen hätten.
>
> Georg Christoph Lichtenberg***

> Mark Twain

the carbon nucleus – from the simple fact that humans exist. A permanent maverick, he coined the term 'big bang' even though he did not accept the evidence for it, and proposed another model, the 'steady state'. His most important and well-known research was on the formation of atoms inside stars. He also propagated the belief that life was brought to Earth from extraterrestrial microbes.

* William A. Fowler (1911–1995) shared the 1983 Nobel Prize in Physics with Subramanyan Chandrasekhar for this and related discoveries.

** Though apes do not seem to be good physicists, as described in the text by D. J. Povinelli, *Folk Physics for Apes: the Chimpanzee's Theory of How the World Works*, Oxford University Press, 2000.

*** 'He was amazed that cats had holes cut into their fur precisely in those places where they had eyes.' Georg Christoph Lichtenberg (1742–1799), German physicist and intellectual, professor in Göttingen, still famous today for his extremely numerous and witty aphorisms and satires. Among others of his time, Lichtenberg made fun of all those who maintained that the universe was made exactly to the measure of man, a frequently encountered idea in the foggy world of the anthropic principle.

> No matter how cruel and nasty and evil you may be, every time you take a breath you make a flower happy.
>
> Mort Sahl

Historically, the two terms 'cause' and 'effect' have played an important role in philosophical discussions. In particular, during the birth of modern mechanics, it was important to point out that every effect has a cause, in order to distinguish precise thought from thought based on beliefs, such as 'miracles', 'divine surprises' or 'evolution from nothing'. It was equally essential to stress that effects are different from causes; this distinction avoids pseudo-explanations such as the famous example by Molière where the doctor explains to his patient in elaborate terms that sleeping pills work because they contain a dormitive virtue.

Ref. 765

But in physics, the concepts of cause and effect are not used at all. That miracles do not appear is expressed every time we use symmetries and conservation theorems. The observation that cause and effect differ from each other is inherent in any evolution equation. Moreover, the concepts of cause and effect are not clearly defined; for example, it is especially difficult to define what is meant by one cause as opposed to several of them, and the same for one or several effects. Both terms are impossible to quantify and to measure. In other words, useful as 'cause' and 'effect' may be in personal life for distinction between events that regularly succeed each other, they are not necessary in physics. In physical explanations, they play no special roles.

> Ἀγαθον καὶ ξαξόν · ἔν καὶ ταὐτό.*

> Wenn ein Arzt hinter dem Sarg seines Patienten geht, so folgt manchmal tatsächlich die Ursache der Wirkung.**
>
> Robert Koch

Is consciousness required?

> Variatio delectat.***
>
> Cicero

Ref. 766

A lot of mediocre discussions are going on about this topic, and we will skip them here. What is consciousness? Most simply and concretely, consciousness means the possession of a small part of oneself that is watching what the rest of oneself is perceiving, feeling, thinking and doing. In short, consciousness is the ability to observe oneself, and in particular one's inner mechanisms and motivations. *Consciousness* is the ability of introspection. For this reason, consciousness is *not* a prerequisite for studying motion. Indeed, animals, plants or machines are also able to observe motion. For the same reason, consciousness is not necessary to observe quantum mechanical motion. On the other hand, both the study of motion and that of oneself have a lot in common: the need to observe

* 'Good and bad – one and the same.'
** 'When a doctor walks behind the coffin of his patient, indeed the cause sometimes follows the effect.'
*** 'Change pleases.' Marcus Tullius Cicero (106–43 BCE), important lawyer, orator and politician at the end of the Roman republic.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

carefully, to overcome preconceptions, to overcome fear and the fun of doing so.

For the time being, we have put enough emphasis on the precision of concepts. Talking about motion is also something to be deeply enjoyed. Let us see why.

> Precision and clarity obey the indeterminacy relation: their product is constant.

Curiosity

> Precision is the child of curiosity.

Like the history of every person, also the history of mankind charts a long struggle to avoid the pitfalls of accepting the statements of authorities as truth, without checking the facts. Indeed, whenever curiosity leads us to formulate a question, there are always two general ways to proceed. One is to check the facts personally, the other is to ask somebody. However, the last way is dangerous: it means to give up a part of oneself. Healthy people, children whose curiosity is still alive, as well as scientists, choose the first way. After all, science is adult curiosity.

Curiosity, also called the *exploratory drive*, plays strange games with people. Starting with the original experience of the world as a big 'soup' of interacting parts, curiosity can drive one to find *all* the parts and *all* the interactions. It drives not only people. It has been observed that when rats show curious behaviour, certain brain cells in the hypothalamus get active and secrete hormones that produce positive feelings and emotions. If a rat has the possibility, via some implanted electrodes, to excite these same cells by pressing a switch, it does so voluntarily: rats get *addicted* to the feelings connected with curiosity. Like rats, humans are curious because they enjoy it. They do so in at least four ways: because they are artists, because they are fond of pleasure, because they are adventurers and because they are dreamers. Let us see how.

Ref. 767

Originally, curiosity stems from the desire to interact in a positive way with the environment. Young children provide good examples: curiosity is a natural ingredient of their life, in the same way that it is for other mammals and a few bird species; incidentally, the same taxonomic distribution is found for play behaviour. In short, all animals that play are curious, and vice versa. Curiosity provides the basis for learning, for creativity and thus for every human activity that leaves a legacy, such as art or science. The artist and art theoretician Joseph Beuys (1920–1986) had as his own guiding principle that *every* creative act is a form of art. Humans, and especially children, enjoy curiosity because they feel its importance for creativity, and for growth in general.

Ref. 768

Curiosity regularly leads one to exclaim: 'Oh!', an experience that leads to the second reason to be curious: relishing feelings of wonder and surprise. Epicurus (Epikuros) (341–271 BCE) maintained that this experience, θαυμάζειν, is the origin of philosophy. These feelings, which nowadays are variously called religious, spiritual, numinous, etc., are the same as those to which rats can become addicted. Among these feelings, Rudolf Otto has introduced the now classical distinction into the fascinating and the frightening. He named the corresponding experiences 'mysterium fascinans' and 'mysterium tremen-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

dum'.* Within these distinctions, physicists, scientists, children and connoisseurs take a clear stand: they choose the fascinans as the starting point for their actions and for their approach to the world. Such feelings of fascination induce some children who look at the night sky to dream about becoming astronomers, some who look through a microscope to become biologists or physicists, and so on. (It could also be that genetics plays a role in this pleasure of novelty seeking.) Ref. 769

Perhaps the most beautiful moments in the study of physics are those appearing after new observations have shaken our previously held thinking habits, have forced us to give up a previously held conviction, and have engendered the feeling of being lost. When, in this moment of crisis, we finally discover a more adequate and precise description of the observations, which provide a better insight into the world, we are struck by a feeling usually called illumination. Anyone who has kept alive the memory and the taste for these magic moments knows that in these situations one is pervaded by a feeling of union between oneself and the world.** The pleasure of these moments, the adventures of the change of thought structures connected with them, and the joy of insight following them provides the drive for many scientists. Little talk and lots of pleasure is their common denominator. In this spirit, the well-known Austrian physicist Victor Weisskopf (1908–2002) liked to say jokingly: 'There are two things that make life worth living: Mozart and quantum mechanics.'

The choice of moving away from the tremendum towards the fascinans stems from an innate desire, most obvious in children, to reduce uncertainty and fear. This drive is the father of all adventures. It has a well-known parallel in ancient Greece, where the first men studying observations, such as Epicurus, stated explicitly that their aim was to free people from unnecessary fear by deepening knowledge and transforming people from frightened passive victims into fascinated, active and responsible beings. Those ancient thinkers started to popularize the idea that, like the common events in our life, the rarer events also follow rules. For example, Epicurus underlined that lightning is a natural phenomenon caused by interactions between clouds, and stressed that it was a natural process, i.e., a process that followed rules, in the same way as the falling of a stone or any other familiar process of everyday life.

Investigating the phenomena around them, philosophers and later scientists succeeded in freeing people from most of their fears caused by uncertainty and a lack of knowledge about nature. This liberation played an important role in the history of human culture and still pervades in the personal history of many scientists. The aim to arrive at stable, rock-bottom truths has inspired (but also hindered) many of them; Albert Einstein is a well-known example for this, discovering relativity, helping to start up but then denying quantum mechanics.

* This distinction is the basis of Rudolf Otto, *Das Heilige – Über das Irrationale in der Idee des Göttlichen und sein Verhältnis zum Rationalen*, Beck, München, 1991. This is a new edition of the epoch-making work originally published at the beginning of the twentieth century. Rudolf Otto (1869–1937) was one of the most important theologians of his time.

** Several researchers have studied the situations leading to these magic moments in more detail, notably the Prussian physician and physicist Hermann von Helmholtz (1821–1894) and the French mathematician Henri Poincaré (1854–1912). They distinguish four stages in the conception of an idea at the basis of such a magic moment: saturation, incubation, illumination and verification. Ref. 770

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Interestingly, in the experience and in the development of every human being, curiosity, and therefore the sciences, appears *before* magic and superstition. Magic needs deceit to be effective, and superstition needs indoctrination; curiosity doesn't need either. Conflicts of curiosity with superstitions, ideologies, authorities or the rest of society are thus preprogrammed.

Curiosity is the exploration of limits. For every limit, there are two possibilities: the limit can turn out to be real or apparent. If the limit is real, the most productive attitude is that of acceptance. Approaching the limit then gives strength. If the limit is only apparent and in fact non-existent, the most productive attitude is to re-evaluate the mistaken view, extract the positive role it performed, and then cross the limit. Distinguishing between real and apparent limits is only possible when the limit is investigated with great care, openness and unintentionality. Most of all, exploring limits need courage.

>
> Voltaire

> "Manche suchen Sicherheit, wo Mut gefragt ist, und suchen Freiheit, wo das Richtige keine Wahl läßt.***"
>
> Bert Hellinger

Most of the material in this chapter is necessary in the adventure to get to the top of Ref. 771 Motion Mountain. But we need more. Like any enterprise, curiosity also requires courage, and complete curiosity, as aimed for in our quest, requires complete courage. In fact, it is easy to get discouraged on this trip. The journey is often dismissed by others as useless, uninteresting, childish, confusing, damaging or, most often, evil. For example, between the death of Socrates in 399 BCE and Paul Thierry, Baron d'Holbach, in the eighteenth century, no book was published with the statement 'gods do not exist', because of the threats to the life of anyone who dared to make the point. Even today, this type of attitude still abounds, as the newspapers show.

Through the constant elimination of uncertainty, both curiosity and scientific activity are implicitly opposed to any idea, person or organization that tries to avoid the comparison of statements with observations. These 'avoiders' demand to live with superstitions and beliefs. But superstitions and beliefs produce unnecessary fear. And fear is the basis of all unjust authorities. One gets into a vicious circle: avoiding comparison with observation produces fear – fear keeps unjust authority in place – unjust authority avoids

* 'The unveiled secret takes revenge.'

** 'It is dangerous to be right in matters where established men are wrong.' Voltaire writes this in his *Catalogue pour la plupart des écrivains français qui ont paru dans Le Siècle de Louis XIV, pour servir à l'histoire littéraire de ce temps* (1752).

*** 'Some look for security where courage is required and look for freedom where the right way doesn't leave any choice.' This is from the beautiful booklet by Bert Hellinger, *Verdichtetes*, Carl-Auer Systeme Verlag, 1996.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

comparison with observation – etc.

As a consequence, curiosity and science are fundamentally opposed to unjust authority, a connection that made life difficult for people such as Anaxagoras (500–428 BCE) in ancient Greece, Hypatia in the Christian Roman empire, Galileo Galilei in the church state, Antoine Lavoisier in France and Albert Einstein (and many others) in Germany. In the second half of the twentieth century, victims were Robert Oppenheimer, Melba Phillips and Chandler Davis in the United States and Andrei Sakharov in the Soviet Union. Each of them tell a horrible but instructive story, as have, more recently, Fang Lizhi, Xu Liangying, Liu Gang and Wang Juntao in China, Kim Song-Man in South Korea, Otanazar Aripov in Uzbekistan, Ramadan al-Hadi al-Hush in Libya, Bo Bo Htun in Burma, Sami Kilani and Salman Salman in Palestine, as well as many hundreds of others. In many authoritarian societies the antagonism between curiosity and injustice has hindered or even completely suppressed the development of physics and other sciences, with extremely negative economic, social and cultural consequences.

When embarking on this ascent, we need to be conscious of what we are doing. In fact, external obstacles can be avoided or at least largely reduced by keeping the project to oneself. Other difficulties still remain, this time of personal nature. Many have tried to embark on this adventure with some hidden or explicit intention, usually of an ideological nature, and then have got entangled by it before reaching the end. Some have not been prepared to accept the humility required for such an endeavour. Others were not prepared for the openness required, which can shatter deeply held beliefs. Still others were not ready to turn towards the unclear, the dark and the unknown, confronting them at every occasion.

On the other hand, the dangers are worth it. By taking curiosity as a maxim, facing disinformation and fear with all one's courage, one achieves freedom from all beliefs. In exchange, you come to savour the fullest pleasures and the deepest satisfaction that life has to offer.

We thus continue our hike. At this point, the trail towards the top of Motion Mountain is leading us towards the next adventure: discovering the origin of sizes and shapes in nature.

Appendix B

NUMBERS AND SPACES

> A mathematician is a machine that transforms coffee into theorems.
> Paul Erdős (b. 1913 Budapest, d. 1996 Warsaw)

Mathematical concepts can all be expressed in terms of 'sets' and 'relations.' any fundamental concepts were presented in the last chapter. Why does athematics, given this simple basis, grow into a passion for certain people? The following pages present a few more advanced concepts as simply* and vividly as possible, for all those who want to smell the passion for mathematics.

Ref. 772

In particular, in this appendix we shall expand the range of *algebraic* and of *topological* structures; the third basic type of mathematical structures, *order* structures, are not so important in physics.

Mathematicians are concerned not only with the exploration of concepts, but also with their *classification*. Whenever a new mathematical concept is introduced, mathematicians try to classify all the possible cases and types. This has been achieved most spectacularly for the different types of numbers, for finite simple groups, and for many types of spaces and manifolds.

NUMBERS AS MATHEMATICAL STRUCTURES

> A person who can solve $x^2 - 92y^2 = 1$ in less than a year is a mathematician.
> Brahmagupta (b. 598 Sindh, d. 668) (implied: solve in *integers*)

Challenge 1270 ny

We start with a short introduction to the vocabulary. Any mathematical system with the same basic properties as the *natural* numbers is called a *semi-ring*. Any mathematical system with the same basic properties as the *integers* is called a *ring*. (The term is due to David Hilbert. Both structures can also be finite rather than infinite.) More precisely, a *ring* $(R, +, \cdot)$ is a set R of elements with two binary operations, called *addition* and *multiplication*, usually written + and · (the latter may simply be understood without notation), for which the following properties hold for all elements $a, b, c \in R$:

* The opposite approach can have the same effect: it is taken in the delightful text by Carl E. Linderholm, *Mathematics Made Difficult*, Wolfe Publishing, 1971.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— R is a commutative group with respect to addition, i.e.
$a+b \in R,\ a+b=b+a,\ a+0=a,\ a+(-a)=a-a=0$ and $a+(b+c)=(a+b)+c$;
— R is closed under multiplication, i.e., $ab \in R$;
— multiplication is associative, i.e., $a(bc)=(ab)c$;
— distributivity holds, i.e., $a(b+c)=ab+ac$ and $(b+c)a=ba+ca$.

Defining properties such as these are called *axioms*. Note that axioms are *not* basic beliefs, as is often stated; axioms are the basic properties used in the definition of a concept: in this case, of a ring.

A *semi-ring* is a set satisfying all the axioms of a ring, except that the existence of neutral and negative elements for addition is replaced by the weaker requirement that if $a+c=b+c$ then $a=b$.

To incorporate division and define the rational numbers, we need another concept. A *field* K is a ring with

— an identity 1, such that all elements a obey $1a=a$;
— at least one element different from zero; and most importantly
— a (multiplicative) inverse a^{-1} for every element $a \neq 0$.

A ring or field is said to be *commutative* if the multiplication is commutative. A non-commutative field is also called a *skew field*. Fields can be finite or infinite. (A field or a ring is characterized by its *characteristic* p. This is the smallest number of times one has to add 1 to itself to give zero. If there is no such number the characteristic is set to 0. p is always a prime number or zero.) All finite fields are commutative. In a field, all equations of the type $cx=b$ and $xc=b$ $(c \neq 0)$ have solutions for x; there is a unique solution if $b \neq 0$. To sum up sloppily by focusing on the most important property, a field is a set of elements for which, together with addition, subtraction and multiplication, a *division* (by non-zero elements) is also defined. The *rational numbers* are the simplest field that incorporates the integers.

The system of the *real numbers* is the minimal extension of the rationals which is complete and totally ordered.*

However, the concept of 'number' is not limited to these examples. It can be generalized in several ways. The simplest generalization is achieved by extending the real numbers to manifolds of more than one dimension. Ref. 774

* A set is mathematically *complete* if physicists call it continuous. More precisely, a set of numbers is *complete* if every non-empty subset that is bounded above has a least upper bound.

A set is *totally ordered* if there exists a binary relation $\leqslant$ between pairs of elements such that for all elements a and b

— if $a \leqslant b$ and $b \leqslant c$, then $a \leqslant c$;
— if $a \leqslant b$ and $b \leqslant a$, then $a=b$;
— $a \leqslant b$ or $b \leqslant a$ holds.

In summary, a set is totally ordered if there is a binary relation that allows to say about any two elements which one is the predecessor of the other in a consistent way.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

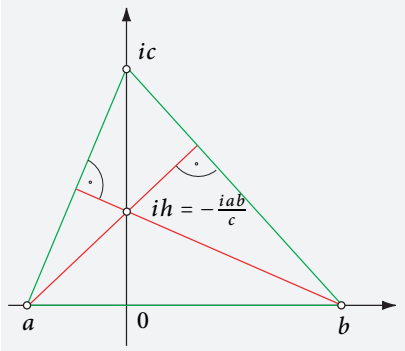

FIGURE 410 A property of triangles easily provable with complex numbers

Complex numbers

A complex number is defined by $z = a + ib$, where a and b are real numbers, and i is a new symbol. Under multiplication, the generators of the complex numbers, 1 and i, obey

·	1	i
1	1	i
i	i	−1

(513)

often summarized as $i = +\sqrt{-1}$.

The *complex conjugate* z^*, also written $\bar{z}$, of a complex number $z = a + ib$ is defined as $z^* = a - ib$. The *absolute value* $|z|$ of a complex number is defined as $|z| = \sqrt{zz^*} = \sqrt{z^*z} = \sqrt{a^2 + b^2}$. It defines a *norm* on the vector space of the complex numbers. From $|wz| = |w|\,|z|$ follows the *two-squares theorem*

$$(a_1^2 + a_2^2)(b_1^2 + b_2^2) = (a_1b_1 - a_2b_2)^2 + (a_1b_2 + a_2b_1)^2 \tag{514}$$

valid for all real numbers a_i, b_i. It was already known, in its version for integers, to Diophantus of Alexandria.

Complex numbers can also be written as ordered pairs (a, A) of real numbers, with their addition defined as $(a, A) + (b, B) = (a + b, A + B)$ and their multiplication defined as $(a, A) \cdot (b, B) = (ab - AB, aB + bA)$. This notation allows us to identify the complex numbers with the *points* on a plane or, if we prefer, to *arrows* in a plane. Translating the definition of multiplication into geometrical language allows us to rapidly prove certain geometrical theorems, such as the one of Figure 410.

Challenge 1271 e

Complex numbers $a + ib$ can also be represented as 2×2 matrices

$$\begin{pmatrix} a & b \\ -b & a \end{pmatrix} \quad \text{with} a, b \in \mathbb{R}\,. \tag{515}$$

Matrix addition and multiplication then correspond to complex addition and multiplication. In this way, complex numbers can be represented by a special type of real matrix.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1272 s What is $|z|$ in matrix language?

The set $\mathbb{C}$ of complex numbers with addition and multiplication as defined above forms both a commutative two-dimensional field and a vector space over $\mathbb{R}$. In the field of complex numbers, quadratic equations $az^2 + bz + c = 0$ for an unknown z always have two solutions (for $a \neq 0$ and counting multiplicity).

Challenge 1273 ny

Complex numbers can be used to describe the points of a plane. A rotation around the origin can be described by multiplication by a complex number of unit length. Other two-dimensional quantities can also be described with complex numbers. Electrical engineers use complex numbers to describe quantities with phases, such as alternating currents or electrical fields in space.

Writing complex numbers of unit length as $\cos\theta + i\sin\theta$ is a useful method for remembering angle addition formulae. Since one has $\cos n\theta + i\sin n\theta = (\cos\theta + i\sin\theta)^n$, one can easily deduce formulae $\cos 2\theta = \cos^2\theta - \sin^2\theta$ and $\sin 2\theta = 2\sin\theta\cos\theta$.

Challenge 1274 e

The complex exponential function is periodic in $2\pi i$; in other words, one has

$$e^1 = e^{1+2\pi i} \,. \tag{516}$$

If one uses this equation twice, one gets

$$e^1 = (e^{1+2\pi i})^{1+2\pi i} = e^{(1+2\pi i)(1+2\pi i)} = e^{1-4\pi^2+4\pi i} = e^{1-4\pi^2} \,. \tag{517}$$

Challenge 1275 e Oops, that would imply $\pi = 0$! What is wrong here?

Challenge 1276 s By the way, there are exactly as many complex numbers as there are real numbers. Can you show this?

Challenge 1277 e The unit complex numbers form the group SO(2)=U(1).

> Love is complex: it has real and imaginary parts.

Quaternions

The positions of the points on a line can be described by real numbers. Complex numbers can be used to describe the positions of the points of a plane. It is natural to try to generalize the idea of a number to higher-dimensional spaces. However, it turns out that no useful number system can be defined for *three*-dimensional space. A new number system, the *quaternions*, can be constructed which corresponds the points of *four*-dimensional space, but only if the commutativity of multiplication is sacrificed. No useful number system can be defined for dimensions other than 1, 2 and 4.

The quaternions were discovered by several mathematicians in the nineteenth century, among them Hamilton,* who studied them for much of his life. In fact, Maxwell's theory of electrodynamics was formulated in terms of quaternions before three-dimensional vectors were used.

Ref. 775

Page 888 Under multiplication, the quaternions $\mathbb{H}$ form a 4-dimensional algebra over the reals

* William Rowan Hamilton (b. 1805 Dublin, d. 1865 Dunsink), Irish child prodigy and famous mathematician, named the quaternions after an expression from the Vulgate (Acts. 12: 4).

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

with a basis 1, i, j, k satisfying

$\cdot$	1	i	j	k
1	1	i	j	k
i	i	-1	k	$-j$
j	j	$-k$	-1	i
k	k	j	$-i$	-1

. (518)

These relations are also often written $i^2 = j^2 = k^2 = -1$, $ij = -ji = k$, $jk = -kj = i$, $ki = -ik = j$. The quaternions 1, i, j, k are also called *basic units* or *generators*. The lack of symmetry across the diagonal of the table shows the non-commutativity of quaternionic multiplication. With the quaternions, the idea of a non-commutative product appeared for the first time in mathematics. However, the multiplication of quaternions *is* associative. As a consequence of non-commutativity, polynomial equations in quaternions have many more solutions than in complex numbers: just search for all solutions of the equation $X^2 + 1 = 0$ to convince yourself of it.

Challenge 1278 ny

Every quaternion X can be written in the form

$$X = x_0 + x_1 i + x_2 j + x_3 k = x_0 + \boldsymbol{v} = (x_0, x_1, x_2, x_3) = (x_0, \boldsymbol{v}) \,, \tag{519}$$

where x_0 is called the *scalar* part and $\boldsymbol{v}$ the *vector* part. The multiplication is thus defined as $(x, \boldsymbol{v})(y, \boldsymbol{w}) = (xy - \boldsymbol{v} \cdot \boldsymbol{w}, x\boldsymbol{w} + y\boldsymbol{v} + \boldsymbol{v} \times \boldsymbol{w})$. The multiplication of two general quaternions can be written as

$$\begin{aligned}(a_1, b_1, c_1, d_1)(a_2, b_2, c_2, d_2) = (&a_1a_2 - b_1b_2 - c_1c_2 - d_1d_2 \,,\; a_1b_2 + b_1a_2 + c_1d_2 - d_1c_2, \\ &a_1c_2 - b_1d_2 + c_1a_2 + d_1b_2, a_1d_2 + b_1c_2 - c_1b_2 + d_1a_2) \,.\end{aligned} \tag{520}$$

The conjugate quaternion $\overline{X}$ is defined as $\overline{X} = x_0 - \boldsymbol{v}$, so that $\overline{XY} = \overline{YX}$. The *norm* $|X|$ of a quaternion X is defined as $|X|^2 = X\overline{X} = \overline{X}X = x_0^2 + x_1^2 + x_2^2 + x_3^2 = x_0^2 + \boldsymbol{v}^2$. The norm is multiplicative, i.e., $|XY| = |X|\,|Y|$.

Unlike complex numbers, every quaternion is related to its complex conjugate by

$$\overline{X} = -\tfrac{1}{2}(X + iXi + jXj + kXk) \,. \tag{521}$$

No relation of this type exists for complex numbers. In the language of physics, a complex number and its conjugate are independent variables; for quaternions, this is not the case. As a result, functions of quaternions are less useful in physics than functions of complex variables.

The relation $|XY| = |X|\,|Y|$ implies the *four-squares theorem*

$$\begin{aligned}&(a_1^2 + a_2^2 + a_3^2 + a_4^2)(b_1^2 + b_2^2 + b_3^2 + b_4^2) \\ &= (a_1b_1 - a_2b_2 - a_3b_3 - a_4b_4)^2 + (a_1b_2 + a_2b_1 + a_3b_4 - a_4b_3)^2 \\ &+(a_1b_3 + a_3b_1 + a_4b_2 - a_2b_4)^2 + (a_1b_4 + a_4b_1 + a_2b_3 - a_3b_2)^2\end{aligned} \tag{522}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

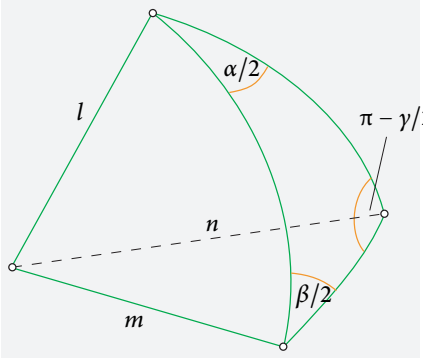

FIGURE 411 Combinations of rotations

valid for all real numbers a_i and b_i, and thus also for any set of eight integers. It was discovered in 1748 by Leonhard Euler (1707–1783) when trying to prove that each integer is the sum of four squares. (That fact was proved only in 1770, by Joseph Lagrange.)

Hamilton thought that a quaternion with zero scalar part, which he simply called a *vector* (a term which he invented), could be identified with an ordinary three-dimensional translation vector; but this is wrong. Such a quaternion is now called a *pure*, or *homogeneous*, or *imaginary* quaternion. The product of two pure quaternions $V = (0, \boldsymbol{v})$ and $W = (0, \boldsymbol{w})$ is given by $VW = (-\boldsymbol{v} \cdot \boldsymbol{w}, \boldsymbol{v} \times \boldsymbol{w})$, where $\cdot$ denotes the scalar product and $\times$ denotes the vector product. Note that any quaternion can be written as the ratio of two pure quaternions.

In reality, a pure quaternion $(0, \boldsymbol{v})$ does not behave like a translation vector under coordinate transformations; in fact, a pure quaternion represents a *rotation* by the angle π or 180° around the axis defined by the direction $\boldsymbol{v} = (v_x, v_y, v_z)$.

Challenge 1279 ny

It turns out that in three-dimensional space, a *general* rotation about the origin can be described by a *unit* quaternion Q, also called a *normed* quaternion, for which $|Q| = 1$. Such a quaternion can be written as $(\cos\theta/2, \boldsymbol{n}\sin\theta/2)$, where $\boldsymbol{n} = (n_x, n_y, n_z)$ is the normed vector describing the direction of the rotation axis and θ is the rotation angle. Such a unit quaternion $Q = (\cos\theta/2, \boldsymbol{n}\sin\theta/2)$ rotates a pure quaternion $V = (0, \boldsymbol{v})$ into another pure quaternion $W = (0, \boldsymbol{w})$ given by

$$W = QVQ^* \,. \tag{523}$$

Thus, if we use pure quaternions such as V or W to describe positions, we can use unit quaternions to describe rotations and to calculate coordinate changes. The concatenation of two rotations is then given by the product of the corresponding unit quaternions. Indeed, a rotation by an angle α about the axis $\boldsymbol{l}$ followed by a rotation by an angle β about the axis $\boldsymbol{m}$ gives a rotation by an angle γ about the axis $\boldsymbol{n}$, with the values determined by

$$(\cos\gamma/2, \sin\gamma/2\boldsymbol{n}) = (\cos\alpha/2, \sin\alpha/2\boldsymbol{l})(\cos\beta/2, \sin\beta/2\boldsymbol{m}) \,. \tag{524}$$

One way to show the result graphically is given in Figure 411. By drawing a triangle on a unit sphere, and taking care to remember the factor 1/2 in the angles, the combination

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

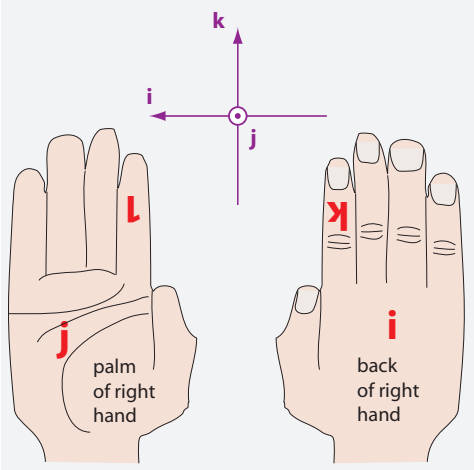

FIGURE 412 The top and back of the right hand, and the quaternions

of two rotations can be simply determined.

The interpretation of quaternions as rotations is also illustrated, in a somewhat different way, in the motion of any hand. To see this, take a green marker and write the letters 1, i, j and k on your hand as shown in Figure 412. Defining the three possible 180° rotation axes as shown in the figure and taking concatenation as multiplication, the motion of the right hand follows the same 'laws' as those of pure unit quaternions. (One still needs to distinguish $+i$ and $-i$, and the same for the other units, by the sense of the arm twist. And the result of a multiplication is that letter that can be read by a person facing you.) You can show that $i^2 = j^2 = k^2 = -1$, that $i^4 = 1$, and all other quaternion relations.) The model also shows that the rotation angle of the arm is half the rotation angle of the corresponding quaternion. In other words, quaternions can be used to describe the belt trick, if the multiplication VW of two quaternions is taken to mean that rotation V is performed *after* rotation W. Quaternions, like human hands, thus behave like a spin 1/2 particle. Quaternions and spinors are isomorphic.

Ref. 773 Challenge 1280 e Challenge 1281 s Page 1066

The reason for the half-angle behaviour of rotations can be specified more precisely using mathematical language. The rotations in three dimensions around a point form the 'special orthogonal group' in three dimensions, which is called SO(3). But the motions of a hand attached to a shoulder via an arm form a different group, isomorphic to the Lie group SU(2). The difference is due to the appearance of half angles in the parametrization of rotations; indeed, the above parametrizations imply that a rotation by 2π corresponds to a multiplication by -1. Only in the twentieth century was it realized that there exist fundamental physical observables that behaves like hands attached to arms: they are called *spinors*. More on spinors can be found in the section on permutation symmetry, where belts are used as an analogy as well as arms. In short, the group SU(2) of the quaternions is the *double cover* of the rotation group SO(3).

Page 901 Page 1066 Ref. 776

The simple representation of rotations and positions with quaternions is used by computer programmes in robotics, in astronomy and in flight simulation. In the software used to create three-dimensional images and animations, visualization software, quaternions are often used to calculate the path taken by repeatedly reflected light rays and thus

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

give surfaces a realistic appearance.

The algebra of the quaternions is the only associative, non-commutative, finite-dimensional normed algebra with an identity over the field of real numbers. Quaternions form a non-commutative field, i.e., a skew field, in which the inverse of a quaternion X is $\overline{X}/|X|$. We can therefore define division of quaternions (while being careful to distinguish XY^{-1} and $Y^{-1}X$). Therefore quaternions are said to form a *division algebra*. In fact, the quaternions $\mathbb{H}$, the complex numbers $\mathbb{C}$ and the reals $\mathbb{R}$ are the only three finite-dimensional associative division algebras. In other words, the skew-field of quaternions is the only finite-dimensional real associative non-commutative algebra without divisors of zero. The *centre* of the quaternions, i.e., the set of quaternions that commute with all other quaternions, is just the set of real numbers.

Quaternions can be represented as matrices of the form

$$\begin{pmatrix} A & B \\ -B^* & A^* \end{pmatrix} \text{with } A, B \in \mathbb{C}, \quad \text{or as} \begin{pmatrix} a & b & c & d \\ -b & a & -d & c \\ -c & d & a & -b \\ -d & -c & b & a \end{pmatrix} \text{with } a, b, c, d \in \mathbb{R}, \tag{525}$$

where $A = a + ib, B = c + id$ and the quaternion X is $X = A + Bj = a + ib + jc + kd$; matrix addition and multiplication then corresponds to quaternionic addition and multiplication.

The generators of the quaternions can be realized as

$$1 : \sigma_0 \quad , \quad i : -i\sigma_1 \quad , \quad j : -i\sigma_2 \quad , \quad k : -i\sigma_3 \tag{526}$$

where the σ_n are the Pauli spin matrices.*

Real 4×4 representations are not unique, as the alternative representation

$$\begin{pmatrix} a & b & -d & -c \\ -b & a & -c & d \\ d & c & a & b \\ c & -d & -b & a \end{pmatrix} \tag{528}$$

Challenge 1282 ny shows; however, no representation by 3×3 matrices is possible.

These matrices contain real and complex elements, which pose no special problems. In contrast, when matrices with quaternionic elements are constructed, care has to be taken, because quaternionic multiplication is not commutative, so that simple relations such as $\mathrm{tr}AB = \mathrm{tr}BA$ are *not* generally valid.

* The *Pauli spin matrices* are the complex Hermitean matrices

$$\sigma_0 = \mathbf{1} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad , \quad \sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \quad , \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} \quad , \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \tag{527}$$

Page 891 all of whose eigenvalues are ± 1; they satisfy the relations $[\sigma_i, \sigma_k]_+ = 2\,\delta_{ik}$ and $[\sigma_i, \sigma_k] = 2i\,\varepsilon_{ikl}\,\sigma_l$. The linear combinations $\sigma_\pm = \frac{1}{2}(\sigma_1 \pm \sigma_2)$ are also frequently used. By the way, another possible representation of the quaternions is $i : i\sigma_3, j : i\sigma_2, k : i\sigma_1$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

What can we learn from quaternions about the description of nature? First of all, we see that binary rotations are similar to positions, and thus to translations: all are represented by 3-vectors. Are rotations the basic operations of nature? Is it possible that translations are only 'shadows' of rotations? The connection between translations and rotations is investigated in the last part of our mountain ascent.

When Maxwell wrote down his equations of electrodynamics, he used quaternion notation. (The now usual 3-vector notation was introduced later by Hertz and Heaviside.) The equations can be written in various ways using quaternions. The simplest is achieved when one keeps a distinction between $\sqrt{-1}$ and the units i, j, k of the quaternions. One then can write all of electrodynamics in a single equation:

Page 706
Ref. 775
Challenge 1283 s

$$\mathrm{d}F = -\frac{Q}{\varepsilon_0} \tag{529}$$

where F is the generalized electromagnetic field and Q the generalized charge. These are defined by

$$\begin{aligned} F &= E + \sqrt{-1}\,cB \\ E &= iE_x + jE_y + kE_z \\ B &= iB_x + jB_y + kB_z \\ \mathrm{d} &= \delta + \sqrt{-1}\,\partial_t/c \\ \delta &= i\partial_x + j\partial_y + k\partial_z \\ Q &= \rho + \sqrt{-1}\,J/c \end{aligned} \tag{530}$$

where the fields E and B and the charge distributions ρ and J have the usual meanings. The content of equation 529 for the electromagnetic field is exactly the same as the usual formulation.

Despite their charm, quaternions do not seem to be ready for the reformulation of special relativity; the main reason for this is the sign in the expression for their norm. Therefore, relativity and space-time are usually described using real numbers.

Octonions

In the same way that quaternions are constructed from complex numbers, *octonions* can be constructed from quaternions. They were first investigated by Arthur Cayley (1821–1895). Under multiplication, *octonions* (or *octaves*) are the elements of an eight-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

dimensional algebra over the reals with the generators 1, i_n with $n = 1 \dots 7$ satisfying

$\cdot$	1	i_1	i_2	i_3	i_4	i_5	i_6	i_7
1	1	i_1	i_2	i_3	i_4	i_5	i_6	i_7
i_1	i_1	-1	i_3	$-i_2$	i_5	$-i_4$	i_7	$-i_6$
i_2	i_2	$-i_3$	-1	i_1	$-i_6$	i_7	i_4	$-i_5$
i_3	i_3	i_2	$-i_1$	-1	i_7	i_6	$-i_5$	$-i_4$
i_4	i_4	$-i_5$	i_6	$-i_7$	-1	i_1	$-i_2$	i_3
i_5	i_5	i_4	$-i_7$	$-i_6$	$-i_1$	-1	i_3	i_2
i_6	i_6	$-i_7$	$-i_4$	i_5	i_2	$-i_3$	-1	i_1
i_7	i_7	i_6	i_5	i_4	$-i_3$	$-i_2$	$-i_1$	-1

(531)

479 other, equivalent multiplication tables are also possible. This algebra is called the *Cayley algebra*; it has an identity and a unique division. The algebra is non-commutative, and also non-associative. It is, however, *alternative*, meaning that for all elements x and y, one has $x(xy) = x^2y$ and $(xy)y = xy^2$: a property somewhat weaker than associativity. It is the only 8-dimensional real alternative algebra without zero divisors. Because it is not associative, the set $\mathbb{O}$ of all octonions does not form a field, nor even a ring, so that the old designation of 'Cayley numbers' has been abandoned. The octonions are the most general hypercomplex 'numbers' whose norm is multiplicative. Its generators obey $(i_n i_m) i_l = \pm i_n (i_m i_l)$, where the minus sign, which shows the non-associativity, is valid for combinations of indices, such as 1-2-4, which are not quaternionic.

Octonions can be represented as matrices of the form

$$\begin{pmatrix} A & B \\ -\bar{B} & \bar{A} \end{pmatrix} \text{where } A, B \in \mathbb{H}\,, \quad \text{or as real } 8 \times 8 \text{ matrices.} \tag{532}$$

Matrix multiplication then gives the same result as octonionic multiplication.

The relation $|wz| = |w|\,|z|$ allows one to deduce the impressive *eight-squares theorem*

$$\begin{aligned}
&(a_1^2 + a_2^2 + a_3^2 + a_4^2 + a_5^2 + a_6^2 + a_7^2 + a_8^2)(b_1^2 + b_2^2 + b_3^2 + b_4^2 + b_5^2 + b_6^2 + b_7^2 + b_8^2) \\
&\quad = (a_1b_1 - a_2b_2 - a_3b_3 - a_4b_4 - a_5b_5 - a_6b_6 - a_7b_7 - a_8b_8)^2 \\
&\quad + (a_1b_2 + a_2b_1 + a_3b_4 - a_4b_3 + a_5b_6 - a_6b_5 + a_7b_8 - a_8b_7)^2 \\
&\quad + (a_1b_3 - a_2b_4 + a_3b_1 + a_4b_2 - a_5b_7 + a_6b_8 + a_7b_5 - a_8b_6)^2 \\
&\quad + (a_1b_4 + a_2b_3 - a_3b_2 + a_4b_1 + a_5b_8 + a_6b_7 - a_7b_6 - a_8b_5)^2 \\
&\quad + (a_1b_5 - a_2b_6 + a_3b_7 - a_4b_8 + a_5b_1 + a_6b_2 - a_7b_3 + a_8b_4)^2 \\
&\quad + (a_1b_6 + a_2b_5 - a_3b_8 - a_4b_7 - a_5b_2 + a_6b_1 + a_7b_4 + a_8b_3)^2 \\
&\quad + (a_1b_7 - a_2b_8 - a_3b_5 + a_4b_6 + a_5b_3 - a_6b_4 + a_7b_1 + a_8b_2)^2 \\
&\quad + (a_1b_8 + a_2b_7 + a_3b_6 + a_4b_5 - a_5b_4 - a_6b_3 - a_7b_2 + a_8b_1)^2
\end{aligned} \tag{533}$$

valid for all real numbers a_i and b_i and thus in particular also for all integers. (There are many variations of this expression, with different possible sign combinations.) The theorem was discovered in 1818 by Carl Ferdinand Degen (1766–1825), and then redis-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

covered in 1844 by John Graves and in 1845 by Arthur Cayley. There is no generalization to higher numbers of squares, a fact proved by Adolf Hurwitz (1859–1919) in 1898.

The octonions can be used to show that a vector product can be defined in more than three dimensions. A *vector product* or *cross product* is an operation × satisfying

$$\begin{aligned} u \times v &= -v \times u \quad \textit{anticommutativity} \\ (u \times v)w &= u(v \times w) \quad \textit{exchange rule.} \end{aligned} \tag{534}$$

Using the definition

$$X \times Y = \frac{1}{2}(XY - YX) \,, \tag{535}$$

the ×-products of imaginary quaternions, i.e., of quaternions of the type $(0, \boldsymbol{u})$, are again imaginary, and correspond to the usual vector product, thus fulfilling (534). Interestingly, it is possible to use definition (535) for *octonions* as well. In that case, the product of imaginary octonions is also imaginary, and (534) is again satisfied. In fact, this is the only other non-trivial example of a vector product. Thus a vector product exists only in three and in seven dimensions.

Ref. 774

Challenge 1284 e

Other types of numbers

The process of constructing new systems of hypercomplex 'numbers' or real algebras by 'doubling' a given one can be continued ad infinitum. However, octonions, *sedenions* and all the following doublings are neither rings nor fields, but only non-associative algebras with unity. Other finite-dimensional algebras with unit element over the reals, once called hypercomplex 'numbers', can also be defined: they include the so-called 'dual numbers', 'double numbers', 'Clifford–Lifshitz numbers' etc. They play no special role in physics.

Mathematicians have also defined number fields which have 'one and a bit' dimensions, such as algebraic number fields. There is also a generalization of the concept of integers to the complex domain: the *Gaussian integers*, defined as $n + im$, where n and m are ordinary integers. Gauss even defined what are now known as *Gaussian primes*. (Can you find out how?) They are not used in the description of nature, but are important in number theory.

Ref. 777

Challenge 1285 s

Physicists used to call quantum-mechanical operators 'q-numbers.' But this term has now fallen out of fashion.

Another way in which the natural numbers can be extended is to include numbers larger infinite numbers. The most important such classes of *transfinite number* are the *ordinals*, the *cardinals* and the *surreals* (which were defined in a previous chapter). The ordinals are essentially an extension of the integers beyond infinity, whereas the surreals are a continuous extension of the reals, also beyond infinity. Loosely speaking, among the transfinites, the ordinals have a similar role as the integers have among the reals; the surreals fill in all the gaps between the ordinals, like the reals do for integers. Interestingly, many series that diverge in $\mathbb{R}$ converge in the surreals. Can you find one example?

Ref. 778

Page 830

Challenge 1286 ny

The surreals include infinitely small numbers, as do the numbers of *nonstandard analysis*, also called *hyperreals*. In both number systems, in contrast to real numbers, the

Ref. 774

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

numbers 1 and 0.999 999 9... (where an infinite, but hyperfinite string of nines is implied) do not coincide, but are separated by infinitely many other numbers.

Page 831

Grassmann numbers

With the discovery of supersymmetry, another system of numbers became important, called the *Grassmann numbers*.* They are in fact a special type of hypercomplex numbers. In supersymmetric Lagrangians, fields depend on two types of coordinates: on the usual real space-time coordinates and additionally on the Grassmann coordinates.

Grassmann numbers, also called *fermionic coordinates*, θ have the defining properties

$$\theta^2 = 0 \quad \text{and} \quad \theta_i\theta_j + \theta_j\theta_i = 0 \,. \tag{536}$$

Challenge 1287 ny You may want to look for a matrix representation of these numbers.

VECTOR SPACES

Vector spaces, also called linear spaces, are mathematical generalizations of certain aspects of the intuitive three-dimensional space. A set of elements any two of which can be added together and any one of which can be multiplied by a number is called a vector space, if the result is again in the set and the usual rules of calculation hold.

More precisely, a *vector space* over a number field K is a set of elements, called *vectors*, for which a vector addition and a *scalar multiplication* is defined, such that for all vectors a, b, c and for all numbers s and r from K one has

$$\begin{aligned}
(a+b)+c = a+(b+c) = a+b+c \quad & \textit{associativity of vector addition} \\
n + a = a \quad & \textit{existence of null vector} \\
(-a) + a = n \quad & \textit{existence of negative vector} \\
1a = a \quad & \textit{regularity of scalar multiplication} \\
(s+r)(a+b) = sa + sb + ra + rb \quad & \textit{complete distributivity of scalar multiplication}
\end{aligned} \tag{537}$$

If the field K, whose elements are called *scalars* in this context, is taken to be the real (or complex, or quaternionic) numbers, one speaks of a real (or complex, or quaternionic) vector space. Vector spaces are also called *linear vector spaces* or simply *linear spaces*.

The complex numbers, the set of all real functions defined on the real line, the set of all polynomials, the set of matrices with a given number of rows and columns, all form vector spaces. In mathematics, a vector is thus a more general concept than in physics.

Challenge 1288 ny (What is the simplest possible mathematical vector space?)

In physics, the term 'vector' is reserved for elements of a more specialized type of vector space, namely normed inner product spaces. To define these, we first need the concept of a metric space.

* Hermann Günther Grassmann (1809–1877), schoolteacher in Stettin, and one of the most profound mathematical thinkers of the nineteenth century.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

A *metric space* is a set with a metric, i.e., a way to define distances between elements. A real function $d(a, b)$ between elements is called a metric if

$$\begin{aligned} d(a,b) &\geqslant 0 && \textit{positivity of metric} \\ d(a,b) + d(b,c) &\geqslant d(a,c) && \textit{triangle inequality} \\ d(a,b) = 0 \quad \text{if and only if} \quad a &= b && \textit{regularity of metric} \end{aligned} \tag{538}$$

A non-trivial example is the following. We define a special distance d between cities. If the two cities lie on a line going through Paris, we use the usual distance. In all other cases, we define the distance d by the shortest distance from one to the other travelling via Paris. This strange method defines a metric between all cities in France.

Challenge 1289 s

A *normed* vector space is a linear space with a norm, or 'length', associated to each a vector. A norm is a non-negative number $||a||$ defined for each vector a with the properties

$$\begin{aligned} ||ra|| &= |r|\,||a|| && \textit{linearity of norm} \\ ||a+b|| &\leqslant ||a|| + ||b|| && \textit{triangle inequality} \\ ||a|| = 0 \quad \text{only if} \quad a &= 0 && \textit{regularity} \end{aligned} \tag{539}$$

Challenge 1290 ny

Usually there are many ways to define a norm for a given space. Note that a norm can always be used to define a metric by setting

$$d(a,b) = ||a-b|| \tag{540}$$

so that all normed spaces are also metric spaces. This is the natural distance definition (in contrast to unnatural ones like that between French cities).

The norm is often defined with the help of an inner product. Indeed, the most special class of linear spaces are the *inner product spaces*. These are vector spaces with an *inner product*, also called *scalar product* $\cdot$ (not to be confused with the scalar multiplication!) which associates a number to each pair of vectors. An inner product space over $\mathbb{R}$ satisfies

$$\begin{aligned} a \cdot b &= b \cdot a && \textit{commutativity of scalar product} \\ (ra)\cdot(sb) &= rs(a\cdot b) && \textit{bilinearity of scalar product} \\ (a+b)\cdot c &= a\cdot c + b\cdot c && \textit{left distributivity of scalar product} \\ a\cdot(b+c) &= a\cdot b + a\cdot c && \textit{right distributivity of scalar product} \\ a\cdot a &\geqslant 0 && \textit{positivity of scalar product} \\ a\cdot a = 0 \quad \text{if and only if} \quad a &= 0 && \textit{regularity of scalar product} \end{aligned} \tag{541}$$

for all vectors a, b, c and all scalars r, s. A *real* inner product space of finite dimension is also called a *Euclidean* vector space. The set of all velocities, the set of all positions, or the set of all possible momenta form such spaces.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

An inner product space over $\mathbb{C}$ satisfies*

$$\begin{aligned}
a \cdot b = \overline{b \cdot a} = \overline{b} \cdot \overline{a} \quad & \textit{Hermitean property} \\
(ra) \cdot (sb) = r\overline{s}(a \cdot b) \quad & \textit{sesquilinearity of scalar product} \\
(a + b) \cdot c = a \cdot c + b \cdot d \quad & \textit{left distributivity of scalar product} \\
a \cdot (b + c) = a \cdot b + a \cdot c \quad & \textit{right distributivity of scalar product} \\
a \cdot a \geqslant 0 \quad & \textit{positivity of scalar product} \\
a \cdot a = 0 \quad \text{if and only if} \quad a = 0 \quad & \textit{regularity of scalar product}
\end{aligned} \tag{542}$$

for all vectors a, b, c and all scalars r, s. A *complex* inner product space (of finite dimension) is also called a *unitary* or *Hermitean* vector space. If the inner product space is *complete*, it is called, especially in the infinite-dimensional complex case, a *Hilbert space*. The space of all possible states of a quantum system forms a Hilbert space.

Page 876

All inner product spaces are also metric spaces, and thus normed spaces, if the metric is defined by

$$d(a, b) = \sqrt{(a - b) \cdot (a - b)} \,. \tag{543}$$

Only in the context of an inner product spaces we can speak about angles (or phase differences) between vectors, as we are used to in physics. Of course, like in normed spaces, inner product spaces also allows us to speak about the length of vectors and to define a *basis*, the mathematical concept necessary to define a coordinate system.

The *dimension* of a vector space is the number of linearly independent basis vectors. Can you define these terms precisely?

Challenge 1291 ny

Which vector spaces are of importance in physics?

Challenge 1292 ny

ALGEBRAS

The term *algebra* is used in mathematics with three different, but loosely related, meanings. First, it denotes a part of mathematics, as in 'I hated algebra at school'. Secondly, it denotes a set of formal rules that are obeyed by abstract objects, as in the expression 'tensor algebra'. Finally – and this is the only meaning used here – an algebra denotes a *specific* type of mathematical structure.

Intuitively, an algebra is a set of vectors with a vector multiplication defined on it. More precisely, an algebra is a vector space (over a field K) that is also a ring. (The concept is due to Benjamin Peirce (1809–1880), father of Charles Sanders Peirce.) A ring is a set for which an addition and a multiplication is defined – like the integers. Thus, in an algebra, there are (often) *three* types of multiplications:

Page 875

— scalar multiplication: the c-fold multiple of a vector x is another vector $y = cx$;
— the (main) algebraic multiplication: the product of two vectors x and y is another vector $z = xy$;

* Two inequivalent forms of the sesquilinearity axiom exist. The other is $(ra) \cdot (sb) = \overline{r}s(a \cdot b)$. The term *sesquilinear* is derived from Latin and means for 'one-and-a-half-linear'.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— if the vector space is a inner product space, the scalar product: the scalar product of two algebra elements (vectors) x and y is a scalar $c = x \cdot y$;

A precise definition of an algebra thus only needs to define properties of the (main) multiplication and to specify the number field K. An *algebra* is defined by the following axioms

$$\begin{aligned} x(y+z) = xy + xz \quad , \quad (x+y)z = xz + yz \quad & \textit{distributivity of multiplication} \\ c(xy) = (cx)y = x(cy) \quad & \textit{bilinearity} \end{aligned} \tag{544}$$

for all vectors x, y, z and all scalars $c \in \mathrm{K}$. To stress their properties, algebras are also called *linear* algebras.

For example, the set of all linear transformations of an n-dimensional linear space (such as the translations on a plane, in space or in time) is a linear algebra, if the composition is taken as multiplication. So is the set of observables of a quantum mechanical system.*

An *associative algebra* is an algebra whose multiplication has the additional property that

$$x(yz) = (xy)z \quad \textit{associativity} \; . \tag{546}$$

Most algebras that arise in physics are associative.** Therefore, in mathematical physics, a linear associative algebra is often simply called an algebra.

The set of multiples of the unit 1 of the algebra is called the *field of scalars* scal(A) of the algebra A. The field of scalars is also a subalgebra of A. The field of scalars and the scalars themselves behave in the same way.

We explore a few examples. The set of all polynomials in one variable (or in several variables) forms an algebra. It is commutative and infinite-dimensional. The constant polynomials form the field of scalars.

Challenge 1294 e

The set of $n \times n$ matrices, with the usual operations, also forms an algebra. It is n^2-dimensional. Those diagonal matrices (matrices with all off-diagonal elements equal to zero) whose diagonal elements all have the same value form the field of scalars. How is

* *Linear transformations* are mappings from the vector space to itself, with the property that sums and scalar multiples of vectors are transformed into the corresponding sums and scalar multiples of the transformed vectors. Can you specify the set of all linear transformations of the plane? And of three-dimensional space? And of Minkowski space?

Challenge 1293 s

All linear transformations transform some special vectors, called *eigenvectors* (from the German word *eigen* meaning 'self') into multiples of themselves. In other words, if T is a transformation, e a vector, and

$$T(e) = \lambda e \tag{545}$$

where λ is a scalar, then the vector e is called an *eigenvector* of T, and λ is associated *eigenvalue*. The set of all eigenvalues of a transformation T is called the *spectrum* of T. Physicists did not pay much attention to these mathematical concepts until they discovered quantum theory. Quantum theory showed that observables are transformations in Hilbert space, because any measurement interacts with a system and thus transforms it. Quantum-mechanical experiments also showed that a measurement result for an observable must be an eigenvalue of the corresponding transformation. The state of the system after the measurement is given by the eigenvector corresponding to the measured eigenvalue. Therefore every expert on motion must know what an eigenvalue is.

Page 1028

Page 1087

** Note that a non-associative algebra does not possess a matrix representation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1295 ny the scalar product of two matrices defined?

The set of all real-valued functions over a set also forms an algebra. Can you specify
Challenge 1296 s the multiplication? The constant functions form the field of scalars.

A *star algebra*, also written $*$-*algebra*, is an algebra over the *complex* numbers for which there is a mapping $* : A \to A,\ x \mapsto x^*$, called an *involution*, with the properties

$$\begin{aligned} (x^*)^* &= x \\ (x+y)^* &= x^* + y^* \\ (cx)^* &= \overline{c}x^* \quad \text{for all} \quad c \in \mathbb{C} \\ (xy)^* &= y^* x^* \end{aligned} \tag{547}$$

valid for all elements x, y of the algebra A. The element x^* is called the *adjoint* of x. Star algebras are the main type of algebra used in quantum mechanics, since quantum-mechanical observables form a $*$-algebra.

A C$*$-*algebra* is a Banach algebra over the complex numbers with an involution $*$ (a function that is its own inverse) such that the norm $\|x\|$ of an element x satisfies

$$\|x\|^2 = x^* x \,. \tag{548}$$

(A Banach algebra is a complete normed algebra; an algebra is *complete* if all Cauchy sequences converge.) In short, C$*$-*algebra* is a nicely behaved algebra whose elements form a continuous set and a complex vector space. The name C comes from 'continuous functions'. Indeed, the *bounded* continuous functions form such an algebra, with a properly
Challenge 1297 s defined norm. Can you find it?

Every C$*$-algebra contains a space of Hermitean elements (which have a real spectrum), a set of normal elements, a multiplicative group of unitary elements and a set of positive elements (with non-negative spectrum).

We should mention one important type of algebra used in mathematics. A *division algebra* is an algebra for which the equations $ax = b$ and $ya = b$ are uniquely solvable in x or y for all b and all $a \neq 0$. Obviously, all type of continuous numbers must be division algebras. Division algebras are thus one way to generalize the concept of a number. One of the important results of modern mathematics states that (finite-dimensional) division algebras can *only* have dimension 1, like the reals, dimension 2, like the complex numbers, dimension 4, like the quaternions, or dimension 8, like the octonions. There is thus no way to generalize the concept of (continuous) 'number' to other dimensions.

And now for some fun. Imagine a ring A which contains a number field K as a subring (or 'field of scalars'). If the ring multiplication is defined in such a way that a general ring element multiplied with an element of K is the same as the scalar multiplication, then A is a vector space, and thus an algebra – *provided* that every element of K commutes with every element of A. (In other words, the subring K must be *central*.)

For example, the quaternions $\mathbb{H}$ are a four-dimensional real division algebra, but although $\mathbb{H}$ is a two-dimensional complex vector space, it is *not* a complex algebra, because i does not commute with j (one has $ij = -ji = k$). In fact, there are no finite-dimensional complex division algebras, and the only finite-dimensional real associative division algebras are $\mathbb{R}$, $\mathbb{C}$ and $\mathbb{H}$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Now, if you are not afraid of getting a headache, think about this remark: every K-algebra is also an algebra over its field of scalars. For this reason, some mathematicians prefer to define an (associative) K-algebra simply as a ring which contains K as a central subfield.

In physics, it is the algebras related to symmetries which play the most important role. We study them next.

Lie algebras

A Lie algebra is special type of algebra (and thus of vector space). Lie algebras are the most important type of non-associative algebras. A vector space L over the field $\mathbb{R}$ (or $\mathbb{C}$) with an additional binary operation $[\ ,\ ]$, called *Lie multiplication* or the *commutator*, is called a real (or complex) *Lie algebra* if this operation satisfies

$$\begin{aligned} [X, Y] &= -[Y, X] && \textit{antisymmetry} \\ [aX + bY, Z] &= a[X, Z] + b[Y, Z] && \textit{(left-)linearity} \\ [X, [Y,Z]] + [Y, [Z, X]] + [Z, [X, Y]] &= 0 && \textit{Jacobi identity} \end{aligned} \tag{549}$$

for all elements $X, Y, Z \in L$ and for all $a, b \in \mathbb{R}$ (or $\mathbb{C}$). (Lie algebras are named after Sophus Lie.) The first two conditions together imply bilinearity. A Lie algebra is called *commutative* if $[X, Y] = 0$ for all elements X and Y. The *dimension* of the Lie algebra is the dimension of the vector space. A subspace N of a Lie algebra L is called an *ideal** if $[L, N] \subset N$; any ideal is also a *subalgebra*. A *maximal ideal* M which satisfies $[L, M] = 0$ is called the *centre* of L.

Challenge 1298 e

A Lie algebra is called a *linear* Lie algebra if its elements are linear transformations of another vector space V (intuitively, if they are 'matrices'). It turns out that every finite-dimensional Lie algebra is isomorphic to a linear Lie algebra. Therefore, there is no loss of generality in picturing the elements of finite-dimensional Lie algebras as matrices.

The name 'Lie algebra' was chosen because the *generators*, i.e., the infinitesimal elements of every Lie group, form a Lie algebra. Since all important symmetries in nature form Lie groups, Lie algebras appear very frequently in physics. In mathematics, Lie algebras arise frequently because from any associative finite-dimensional algebra (in which the symbol $\cdot$ stands for its multiplication) a Lie algebra appears when we define the *commutator* by

Page 902

$$[X, Y] = X \cdot Y - Y \cdot X \ . \tag{550}$$

(This fact gave the commutator its name.) Lie algebras are non-associative in general; but the above definition of the commutator shows how to build one from an associative algebra.

Since Lie algebras are vector spaces, the elements T_i of a *basis* of the Lie algebra always obey a relation of the form:

$$[T_i, T_j] = \sum_k c_{ij}^k T_k \ . \tag{551}$$

Challenge 1299 ny

* Can you explain the notation $[L, N]$? Can you define what a maximal ideal is and prove that there is only one?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The numbers c_{ij}^k are called the *structure constants* of the Lie algebra. They depend on the choice of basis. The structure constants determine the Lie algebra completely. For example, the algebra of the Lie group SU(2), with the three generators defined by $T_a = \sigma^a/2i$, where the σ^a are the Pauli spin matrices, has the structure constants $C_{abc} = \varepsilon_{abc}$.* Page 882

Classification of Lie algebras

Finite-dimensional Lie algebras are classified as follows. Every finite-dimensional Lie algebra is the (semidirect) sum of a semisimple and a solvable Lie algebra.

A Lie algebra is called *solvable* if, well, if it is not semisimple. Solvable Lie algebras have not yet been classified completely. They are not important in physics.

A *semisimple* Lie algebra is a Lie algebra which has no non-zero solvable ideal. Other equivalent definitions are possible, depending on your taste:

— a semisimple Lie algebra does not contain non-zero Abelian ideals;
— its Killing form is non-singular, i.e., non-degenerate;
— it splits into the direct sum of non-Abelian simple ideals (this decomposition is unique);
— every finite-dimensional linear representation is completely reducible;
— the one-dimensional cohomology of g with values in an arbitrary finite-dimensional g-module is trivial.

Finite-dimensional semisimple Lie algebras have been completely classified. They decompose uniquely into a direct sum of *simple* Lie algebras. Simple Lie algebras can be complex or real.

The simple finite-dimensional *complex* Lie algebras all belong to four infinite classes and to five exceptional cases. The infinite classes are also called *classical*, and are: A_n for $n \geqslant 1$, corresponding to the Lie groups $\mathrm{SL}(n+1)$ and their compact 'cousins' $\mathrm{SU}(n+1)$; B_n for $n \geqslant 1$, corresponding to the Lie groups $\mathrm{SO}(2n+1)$; C_n for $n \geqslant 1$, corresponding to the Lie groups $\mathrm{Sp}(2n)$; and D_n for $n \geqslant 4$, corresponding to the Lie groups $\mathrm{SO}(2n)$.

---

* Like groups, Lie algebras can be represented by matrices, i.e., by linear operators. Representations of Lie algebras are important in physics because many continuous symmetry groups are Lie groups.

The *adjoint representation* of a Lie algebra with basis $a_1 \ldots a_n$ is the set of matrices $\mathrm{ad}(a)$ defined for each element a by

$$[a, a_j] = \sum_c \mathrm{ad}(a)_{cj} a_c \,. \tag{552}$$

The definition implies that $\mathrm{ad}(a_i)_{jk} = c_{ij}^k$, where c_{ij}^k are the structure constants of the Lie algebra. For a real Lie algebra, all elements of $\mathrm{ad}(a)$ are real for all $a \in L$.

Note that for any Lie algebra, a scalar product can be defined by setting

$$X \cdot Y = \mathrm{Tr}(\,\mathrm{ad}X \cdot \mathrm{ad}Y\,) \,. \tag{553}$$

This scalar product is symmetric and bilinear. (Can you show that it is independent of the representation?) The corresponding bilinear form is also called the *Killing form*, after the German mathematician Wilhelm Killing (1847–1923), the discoverer of the 'exceptional' Lie groups. The Killing form is invariant under the action of any automorphism of the Lie algebra L. In a given basis, one has

$$X \cdot Y = \mathrm{Tr}(\,(\mathrm{ad}X) \cdot (\mathrm{ad}Y)\,) = c_{lk}^i c_{si}^k x^l y^s = g_{ls} x^l y^s \tag{554}$$

where $g_{ls} = c_{lk}^i c_{si}^k$ is called the *Cartan metric tensor* of L.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Thus A_n is the algebra of all skew-Hermitean matrices; B_n and D_n are the algebras of the symmetric matrices; and C_n is the algebra of the traceless matrices.

The exceptional Lie algebras are G_2, F_4, E_6, E_7, E_8. In all cases, the index gives the number of roots. The dimensions of these algebras are $A_n : n(n+2)$; B_n and $C_n : n(2n+1)$; $D_n : n(2n-1)$; $G_2 : 14$; $F_4 : 32$; $E_6 : 78$; $E_7 : 133$; $E_8 : 248$.

The simple and finite-dimensional *real* Lie algebras are more numerous; their classification follows from that of the complex Lie algebras. Moreover, corresponding to each
Ref. 779 complex Lie group, there is always one compact real one. Real Lie algebras are not so important in fundamental physics.

The so-called superalgebras (see below) play a role in systems with supersymmetry.

Of the large number of *infinite-dimensional* Lie algebras, only few are important in physics: among them are the *Poincaré algebra*, the *Cartan algebra*, the *Virasoro algebra* and a few other Kac–Moody algebras.

Lie superalgebras

Lie superalgebras arise when the concept of Lie algebra is extended to the case of supersymmetry. A Lie superalgebra contains even and odd elements; the even elements correspond to bosons and the odd elements to fermions. Supersymmetry applies to systems with anticommuting coordinates. Lie superalgebras are a natural generalization of Lie algebras to supersymmetry, and simply add a Z_2-grading.

In detail, a *Lie superalgebra* is a Z_2-graded algebra over a field of characteristic 0 – usually $\mathbb{R}$ or $\mathbb{C}$ – with a product $[.,.]$, called the (Lie) *superbracket* or *supercommutator*, that has the properties

$$\begin{aligned} [x, y] &= -(-1)^{|x||y|}[y, x] \\ 0 &= (-1)^{|z||x|}[x, [y, z]] + (-1)^{|x||y|}[y, [z, x]] + (-1)^{|y||z|}[z, [x, y]] \end{aligned} \tag{555}$$

where x, y and z are algebra elements that are 'pure' in the Z_2-grading. The expression $|x|$ denotes the degree of the algebra element x and is either 0 or 1. The second condition is sometimes called the 'super Jacobi identity'. Obviously, the even subalgebra of a Lie superalgebra forms a Lie algebra; in that case the superbracket becomes the usual Lie bracket.

As in the case of Lie algebras, the *simple* Lie superalgebras have been completely classified. They fall into five infinite classes and some special cases, namely

— $A(n, m)$ corresponding to the Lie supergroups $\mathrm{SL}(n+1|m+1)$ and their compact 'cousins' $\mathrm{SU}(N|M)$;
— $B(n, m)$ corresponding to the Lie supergroups $\mathrm{OSp}(2n+1|2m)$;
— $D(n, m)$ corresponding to the Lie supergroups $\mathrm{OSp}(2n|2m)$;
— $P(n)$;
— $Q(n)$;
— the exceptional cases $D_\alpha(2,1)$, $G(3)$, $F(4)$;
— and finally the Cartan superalgebras.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The Virasoro algebra

The *Virasoro algebra* is the infinite algebra of operators L_n satisfying

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12}(m^3 - m)\delta_{m,-n} \tag{556}$$

where the number c, which may be zero, is called the *central charge*, and the factor 1/12 is introduced by historical convention. This rather specific algebra is important in physics because it is the algebra of conformal symmetries in *two* dimensions.* Can you find a representation in terms of infinite square matrices? Mathematically speaking, the Virasoro algebra is a special case of a Kac–Moody algebra.

Challenge 1300 ny

Kac–Moody algebras

In physics, more general symmetries than Lie groups also appear. This happens in particular when general relativity is taken into account. Because of the symmetries of space-time, the number of generators becomes infinite. The concepts of Lie algebra and of superalgebra have to be extended to take space-time symmetry into account. The corresponding algebras are the Kac–Moody algebras. ('Kac' is pronounced like 'Katz'.) *Kac–Moody algebras* are a particular class of infinite-parameter Lie algebras; thus they have an infinite number of generators. They used to be called *associated affine algebras* or *affine Lie algebras*; sometimes they are also called *Z-graded Lie algebras*. They were introduced independently in 1968 by Victor Kac and Robert Moody. We present some specific examples.

Of basic physical importance are those Kac–Moody algebras associated to a symmetry group $G \otimes C[t]$, where t is some continuous parameter. The generators $M_a^{(n)}$ of the corresponding algebra have two indices, one, a, that indexes the generators of the group G and another, n, that indexes the generators of the group of Laurent polynomials $C[t]$. The generators form a Kac–Moody algebra if they obey the relations:

$$[M_a^{(n)}, M_b^{(m)}] = C_{abc} M_c^{(n+m)} \quad \text{for} \quad n, m = 0, 1, 2, \ldots, \infty. \tag{557}$$

For example, if we take G as SU(2) with its generators $T^n = \sigma^a/2i$, σ^a being the Pauli spin matrices, then the objects

$$M_a^{(n)} = T_a \otimes t^n, \quad \text{e.g.} \quad M_3^{(n)} = \frac{1}{2i}\begin{pmatrix} t^n & 0 \\ 0 & -t^n \end{pmatrix} \tag{558}$$

form a Kac–Moody algebra with the structure constants $C_{abc} = \varepsilon_{abc}$ of SU(2).

Page 457 * Note that, in contrast, the conformal symmetry group in *four* dimensions has 15 parameters, and thus its Lie algebra is finite (15) dimensional.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

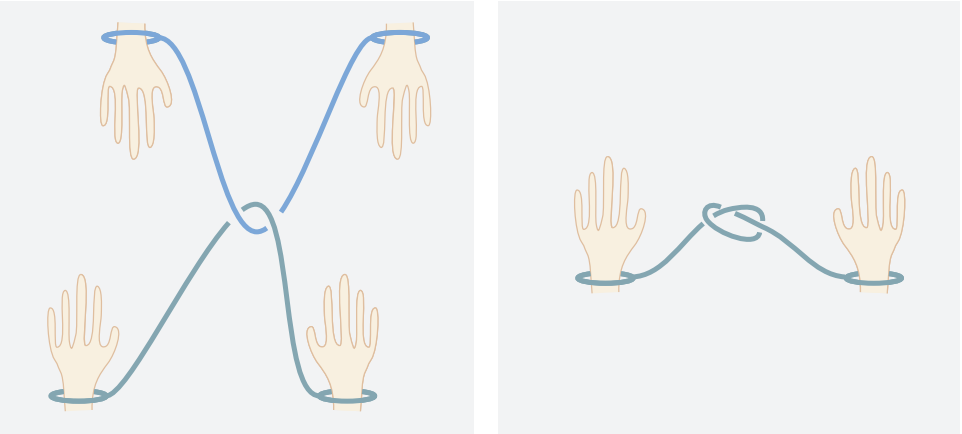

FIGURE 413 Which of the two situations can be untied without cutting?

TOPOLOGY – WHAT SHAPES EXIST?

> Topology is group theory.
> The Erlangen program

In a simplified view of topology that is sufficient for physicists, only one type of entity can possess shape: manifolds. *Manifolds* are generalized examples of pullovers: they are locally flat, can have holes, boundaries and can often be turned inside out.

Pullovers are subtle entities. For example, can you turn your pullover inside out while Challenge 1301 s your hands are tied together? (A friend may help you.) By the way, the same feat is also possible with your trousers, while your feet are tied together. Certain professors like to demonstrate this during topology lectures – of course with a carefully selected pair of underpants.

Another good topological puzzle, the handcuff puzzle, is shown in Figure 413. Which Challenge 1302 s of the two situations can be untied without cutting the ropes?

For a mathematician, pullovers and ropes are everyday examples of manifolds, and the operations that are performed on them are examples of deformations. Let us look at some more precise definitions.

Topological spaces

> En Australie, une mouche qui marche au plafond se trouve dans le même sens qu'une vache chez nous.
> Philippe Geluck, *La marque du chat*.

Ref. 781 The study of shapes requires a good definition of a set made of 'points'. To be able to talk about shape, these sets must be structured in such a way as to admit a useful concept of 'neighbourhood' or 'closeness' between the elements of the set. The search for the most general type of set which allows a useful definition of neighbourhood has led to the concept of topological space. The most pedagogical definition is the following, somewhat

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

different from the usual one.

A *topological space* is a finite or infinite set X of elements, called *points*, together with a neighbourhood for each point. A *neighbourhood* N of a point x is a collection of subsets Y_x of X with the properties that

— x is in N;
— if N and M are neighbourhoods, so is $N \cap M$;
— anything containing a neighbourhood of x is itself a neighbourhood of x.

The choice of the subsets is free. All the subsets Y_x, for all points x, that were chosen in the definition are then called *open sets*. (A neighbourhood and an open set are not necessarily the same; but all open sets are also neighbourhoods.)

One also calls a topological space a 'set with a topology'. In effect, a *topology* specifies the systems of 'neighbourhoods' of every point of the set. 'Topology' is also the name of the branch of mathematics that studies topological spaces.

For example, the real numbers together with the open intervals form the *usual* topology of $\mathbb{R}$. If one takes *all* subsets of $\mathbb{R}$ as open sets, one speaks of the *discrete* topology. If one takes *only* the full set X and the empty set as open sets, one speaks of the *trivial* or *indiscrete* topology.

The concept of topological space allows us to define continuity. A mapping from one topological space X to another topological space Y is *continuous* if the inverse image of every open set in Y is an open set in X. You may verify that this definition is not satisfied by a real function that makes a jump. You may also check that the term 'inverse' is necessary in the definition; otherwise a function with a jump would be continuous, as such a function may still map open sets to open sets.*

Challenge 1303 e

We thus need the concept of topological space, or of neighbourhood, if we want to express the idea that there are no jumps in nature. We also need the concept of topological space in order to be able to define limits.

– CS – more on topological spaces to be added – CS –

Of the many special kinds of topological spaces that have been studied, one type is particularly important. A *Hausdorff space* is a topological space in which for any two points x and y there are disjoint open sets U and V such that x is in U and y is in V. A Hausdorff space is thus a space where, no matter how 'close' two points are, they can always be separated by open sets. This seems like a desirable property; indeed, non-Hausdorff spaces are rather tricky mathematical objects. (At Planck energy, it seems that vacuum appears to behave like a non-Hausdorff space; however, at Planck energy, vacuum is not really a space at all. So non-Hausdorff spaces play no role in physics.) A special case of Hausdorff space is well-known: the manifold.

* The Cauchy-Weierstass definition of continuity says that a real function $f(x)$ is continuous at a point a if (1) f is defined on an open interval containing a, (2) $f(x)$ tends to a limit as x tends to a, and (3) the limit is $f(a)$. In this definition, the continuity of f is defined using the intuitive idea that the real numbers form the basic model of a set that has no gaps. Can you see the connection with the general definition given above?

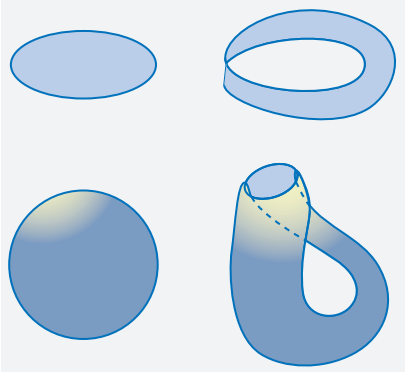

FIGURE 414 Examples of orientable and non-orientable manifolds of two dimensions: a disc, a Möbius strip, a sphere and a Klein bottle

Manifolds

In physics, the most important topological spaces are differential manifolds. Loosely speaking, a *differential manifold* – physicists simply speak of a *manifold* – is a set of points that looks like $\mathbb{R}^n$ under the microscope – at small distances. For example, a sphere and a torus are both two-dimensional differential manifolds, since they look locally like a plane. Not all differential manifolds are that simple, as the examples of Figure 414 show.

A differential manifold is called *connected* if any two points can be joined by a path lying in the manifold. (The term has a more general meaning in topological spaces. But the notions of connectedness and pathwise connectedness coincide for differential manifolds.) We focus on connected manifolds in the following discussion. A manifold is called *simply connected* if every loop lying in the manifold can be contracted to a point. For example, a sphere is simply connected. A connected manifold which is not simply connected is called *multiply connected*. A torus is multiply connected.

Manifolds can be *non-orientable*, as the well-known Möbius strip illustrates. Non-orientable manifolds have only one surface: they do not admit a distinction between front and back. If you want to have fun, cut a paper Möbius strip into two along a centre line. You can also try this with paper strips with different twist values, and investigate the regularities.

Challenge 1305 e

In two dimensions, closed manifolds (or surfaces), i.e., surfaces that are compact and without boundary, are always of one of three types:

— The simplest type are spheres with n attached handles; they are called *n-tori* or *surfaces of genus n*. They are orientable surfaces with Euler characteristic $2 - 2n$.
— The *projective planes* with n handles attached are non-orientable surfaces with Euler characteristic $1 - 2n$.
— The Klein bottles with n attached handles are non-orientable surfaces with Euler characteristic $-2n$.

Therefore Euler characteristic and orientability describe compact surfaces up to homeomorphism (and if surfaces are smooth, then up to diffeomorphism). Homeomorphisms are defined below.

The two-dimensional compact manifolds or surfaces with boundary are found by re-

moving one or more discs from a surface in this list. A compact surface can be embedded in $\mathbb{R}^3$ if it is orientable or if it has non-empty boundary.

In physics, the most important manifolds are space-time and Lie groups of observables. We study Lie groups below. Strangely enough, the topology of space-time is not known. For example, it is unclear whether or not it is simply connected. Obviously, the reason is that it is difficult to observe what happens at large distances form the Earth. However, a similar difficulty appears near Planck scales.

If a manifold is imagined to consist of rubber, connectedness and similar global properties are not changed when the manifold is deformed. This fact is formalized by saying

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

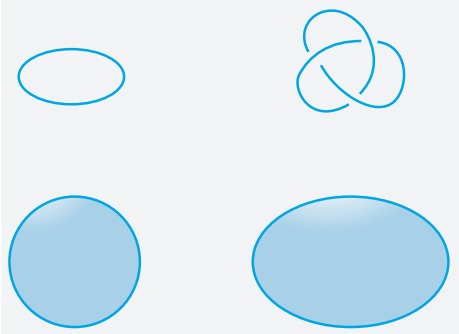

FIGURE 417 Examples of homeomorphic pairs of manifolds

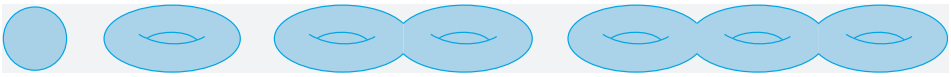

FIGURE 418 The first four two-dimensional compact connected orientable manifolds: 0-, 1-, 2- and 3-tori

that two manifolds are *homeomorphic* (from the Greek words for 'same' and 'shape') if between them there is a continuous, one-to-one and onto mapping with a continuous inverse. The concept of homeomorphism is somewhat more general than that of rubber deformation, as can be seen from Figure 417.

Holes, homotopy and homology

Only 'well-behaved' manifolds play a role in physics: namely those which are orientable and connected. In addition, the manifolds associated with observables, are always compact. The main non-trivial characteristic of connected compact orientable manifolds is that they contain 'holes' (see Figure 418). It turns out that a proper description of the holes of manifolds allows us to distinguish between all different, i.e., non-homeomorphic, types of manifold.

There are three main tools to describe holes of manifolds and the relations among them: homotopy, homology and cohomology. These tools play an important role in the study of gauge groups, because any gauge group defines a manifold.

– CS – more on topology to be added – CS –

In other words, through homotopy and homology theory, mathematicians can *classify* manifolds. Given two manifolds, the properties of the holes in them thus determine whether they can be deformed into each other.

Physicists are now extending these results of standard topology. Deformation is a classical idea which assumes continuous space and time, as well as arbitrarily small action. In nature, however, quantum effects cannot be neglected. It is speculated that quantum effects can transform a physical manifold into one with a *different* topology: for example, a torus into a sphere. Can you find out how this can be achieved? Challenge 1306 d

Topological changes of physical manifolds happen via objects that are generalizations

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of manifolds. An *orbifold* is a space that is locally modelled by $\mathbb{R}^n$ modulo a finite group. Examples are the tear-drop or the half-plane. Orbifolds were introduced by Satake Ichiro in 1956; the name was coined by William Thurston. Orbifolds are heavily studied in string theory.

TYPES AND CLASSIFICATION OF GROUPS

Page 212 We introduced groups early on because groups play an important role in many parts of physics, from the description of solids, molecules, atoms, nuclei, elementary particles and forces up to the study of shapes, cycles and patterns in growth processes.

Group theory is also one of the most important branches of modern mathematics, and is still an active area of research. One of the aims of group theory is the *classification* of all groups. This has been achieved only for a few special types. In general, one distinguishes between finite and infinite groups. Finite groups are better understood.

Every *finite* group is isomorphic to a subgroup of the symmetric group S_N, for some number N. Examples of finite groups are the crystalline groups, used to classify crystal structures, or the groups used to classify wallpaper patterns in terms of their symmetries. The symmetry groups of Platonic and many other regular solids are also finite groups.

Finite groups are a complex family. Roughly speaking, a general (finite) group can be seen as built from some fundamental bricks, which are groups themselves. These fundamental bricks are called *simple* (finite) groups. One of the high points of twentieth-century mathematics was the classification of the finite simple groups. It was a collaborative effort that took around 30 years, roughly from 1950 to 1980. The complete list of Ref. 780 finite simple groups consists of

1) the *cyclic groups* Z_p of prime group order;

2) the *alternating groups* A_n of degree n at least five;

3) the *classical linear groups*, $\mathrm{PSL}(n;q)$, $\mathrm{PSU}(n;q)$, $\mathrm{PSp}(2n;q)$ and $\mathrm{P}\Omega^{\epsilon}(n;q)$;

4) the *exceptional* or *twisted groups* of Lie type ${}^3\mathrm{D}_4(q)$, $\mathrm{E}_6(q)$, ${}^2\mathrm{E}_6(q)$, $\mathrm{E}_7(q)$, $\mathrm{E}_8(q)$, $\mathrm{F}_4(q)$, ${}^2\mathrm{F}_4(2^n)$, $\mathrm{G}_2(q)$, ${}^2\mathrm{G}_2(3^n)$ and ${}^2\mathrm{B}_2(2^n)$;

5) the 26 *sporadic groups*, namely M_{11}, M_{12}, M_{22}, M_{23}, M_{24} (the Mathieu groups), J_1, J_2, J_3, J_4 (the Janko groups), Co_1, Co_2, Co_3 (the Conway groups), HS, Mc, Suz (the Co_1 'babies'), Fi_{22}, Fi_{23}, Fi'_{24} (the Fischer groups), $\mathrm{F}_1 = \mathrm{M}$ (the Monster), F_2, F_3, F_5, He (= F_7) (the Monster 'babies'), Ru, Ly, and ON.

The classification was finished in the 1980s after over 10 000 pages of publications. The proof is so vast that a special series of books has been started to summarize and explain it. The first three families are infinite. The last family, that of the sporadic groups, is the most peculiar; it consists of those finite simple groups which do not fit into the other families. Some of these sporadic groups might have a role in particle physics: possibly even the largest of them all, the so-called *Monster* group. This is still a topic of research. (The Monster group has about $8.1 \cdot 10^{53}$ elements; more precisely, its order is 808 017 424 794 512 875 886 459 904 961 710 757 005 754 368 000 000 000 or $2^{46} \cdot 3^{20} \cdot 5^9 \cdot 7^6 \cdot 11^2 \cdot 13^3 \cdot 17 \cdot 19 \cdot 23 \cdot 29 \cdot 31 \cdot 41 \cdot 47 \cdot 59 \cdot 71$.)

Of the *infinite* groups, only those with some finiteness condition have been studied. It is only such groups that are of interest in the description of nature. Infinite groups are divided into *discrete* groups and *continuous* groups. Discrete groups are an active area of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

mathematical research, having connections with number theory and topology. Continuous groups are divided into *finitely generated* and *infinitely generated* groups. Finitely generated groups can be finite-dimensional or infinite-dimensional.

The most important class of finitely generated continuous groups are the Lie groups.

Lie groups

In nature, the Lagrangians of the fundamental forces are invariant under gauge transformations and under continuous space-time transformations. These symmetry groups are examples of Lie groups, which are a special type of infinite continuous group. They are named after the great Norwegian mathematician Sophus Lie (1849–1899). His name is pronounced like 'Lee'.

A (real) *Lie group* is an infinite symmetry group, i.e., a group with infinitely many elements, which is also an analytic manifold. Roughly speaking, this means that the elements of the group can be seen as points on a smooth (hyper-) surface whose shape can be described by an analytic function, i.e., by a function so smooth that it can be expressed as a power series in the neighbourhood of every point where it is defined. The points of the Lie group can be multiplied according to the group multiplication. Furthermore, the coordinates of the product have to be analytic functions of the coordinates of the factors, and the coordinates of the inverse of an element have to be analytic functions of the coordinates of the element. In fact, this definition is unnecessarily strict: it can be proved that a Lie group is just a topological group whose underlying space is a finite-dimensional, locally Euclidean manifold.

A *complex Lie group* is a group whose manifold is complex and whose group operations are holomorphic (instead of analytical) functions in the coordinates.

In short, a Lie group is a well-behaved manifold in which points can be multiplied (and technicalities). For example, the circle $\boldsymbol{T} = \{z \in \mathbb{C} : |z| = 1\}$, with the usual complex multiplication, is a real Lie group. It is Abelian. This group is also called S^1, as it is the one-dimensional sphere, or U(1), which means 'unitary group of one dimension'. The other one-dimensional Lie groups are the multiplicative group of non-zero real numbers and its subgroup, the multiplicative group of positive real numbers.

So far, in physics, only *linear* Lie groups have played a role – that is, Lie groups which act as linear transformations on some vector space. (The cover of $SL(2,\mathbb{R})$ or the complex compact torus are examples of non-linear Lie groups.) The important linear Lie groups for physics are the Lie subgroups of the general linear group GL(N,K), where K is a number field. This is defined as the set of all non-singular, i.e., invertible, N×N real, complex or quaternionic matrices. All the Lie groups discussed below are of this type.

Every *complex* invertible matrix A can be written in a unique way in terms of a unitary matrix U and a Hermitean matrix H:

$$A = U e^H \,. \tag{559}$$

Challenge 1307 s (H is given by $H = \frac{1}{2} \ln A^\dagger A$, and U is given by $U = A e^{-H}$.)

– CS – more on Lie groups to be added – CS –

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The simple Lie groups U(1) and SO(2,ℝ) and the Lie groups based on the real and complex numbers are Abelian (see Table 79); all others are non-Abelian.

Lie groups are manifolds. Therefore, in a Lie group one can define the distance between two points, the tangent plane (or tangent space) at a point, and the notions of integration and differentiations. Because Lie groups are manifolds, Lie groups have the same kind of structure as the objects of Figures 414, 415 and 416. Lie groups can have any number of dimensions. Like for any manifold, their global structure contains important information; let us explore it.

Connectedness

It is not hard to see that the Lie groups SU(N) are simply connected for all $N = 2, 3 \ldots$; they have the topology of a 2N-dimensional sphere. The Lie group U(1), having the topology of the 1-dimensional sphere, or circle, is multiply connected.

The Lie groups SO(N) are *not* simply connected for any $N = 2, 3 \ldots$. In general, SO(N,K) is connected, and GL(N,ℂ) is connected. All the Lie groups SL(N,K) are connected; and SL(N,ℂ) is simply connected. The Lie groups Sp(N,K) are connected; Sp(2N,ℂ) is simply connected. Generally, all semi-simple Lie groups are connected.

The Lie groups O(N,K), SO(N,M,K) and GL(N,ℝ) are not connected; they contain two connected components.

Note that the Lorentz group is not connected: it consists of four separate pieces. Like the Poincaré group, it is not compact, and neither is any of its four pieces. Broadly speaking, the non-compactness of the group of space-time symmetries is a consequence of the non-compactness of space-time.

Compactness

A Lie group is *compact* if it is closed and bounded when seen as a manifold. For a given parametrization of the group elements, the Lie group is compact if all parameter ranges are closed and finite intervals. Otherwise, the group is called *non-compact*. Both compact and non-compact groups play a role in physics. The distinction between the two cases is important, because representations of compact groups can be constructed in the same simple way as for finite groups, whereas for non-compact groups other methods have to be used. As a result, physical observables, which always belong to a representation of a symmetry group, have different properties in the two cases: if the symmetry group is compact, observables have *discrete* spectra; otherwise they do not.

All groups of internal gauge transformations, such as U(1) and $SU(n)$, form compact groups. In fact, field theory *requires* compact Lie groups for gauge transformations. The only compact Lie groups are T^n, $O(n)$, $U(n)$, $SO(n)$ and $SU(n)$, their double cover $Spin(n)$ and the $Sp(n)$. In contrast, $SL(n,\mathbb{R})$, $GL(n,\mathbb{R})$, $GL(n,\mathbb{C})$ and all others are not compact.

Besides being manifolds, Lie groups are obviously also groups. It turns out that most of their group properties are revealed by the behaviour of the elements which are very close (as points on the manifold) to the identity.

Every element of a compact and connected Lie group has the form $\exp(A)$ for some A. The elements A arising in this way form an algebra, called the *corresponding Lie algebra*. For any linear Lie group, every element of the connected subgroup can be expressed as a

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

finite product of exponentials of elements of the corresponding Lie algebra. In short, Lie algebras express the local properties of Lie groups. That is the reason for their importance in physics.

Page 891

TABLE 79 Properties of the most important real and complex Lie groups

Lie group	Description	Properties[a]	Lie algebra	Description of Lie algebra	Dimension
1. Real groups					real
$\mathbb{R}^n$	Euclidean space with addition	Abelian, simply connected, not compact; $\pi_0 = \pi_1 = 0$	$\mathbb{R}^n$	Abelian, thus Lie bracket is zero; not simple	n
$\mathbb{R}^\times$	non-zero real numbers with multiplication	Abelian, not connected, not compact; $\pi_0 = \mathbb{Z}_2$, no π_1	$\mathbb{R}$	Abelian, thus Lie bracket is zero	1
$\mathbb{R}^{>0}$	positive real numbers with multiplication	Abelian, simply connected, not compact; $\pi_0 = \pi_1 = 0$	$\mathbb{R}$	Abelian, thus Lie bracket is zero	1
$S^1 = \mathbb{R}/\mathbb{Z} = U(1) = T = SO(2) = Spin(2)$	complex numbers of absolute value 1, with multiplication	Abelian, connected, not simply connected, compact; $\pi_0 = 0$, $\pi_1 = \mathbb{Z}$	$\mathbb{R}$	Abelian, thus Lie bracket is zero	1
$\mathbb{H}^\times$	non-zero quaternions with multiplication	simply connected, not compact; $\pi_0 = \pi_1 = 0$	$\mathbb{H}$	quaternions, with Lie bracket the commutator	4
S^3	quaternions of absolute value 1, with multiplication, also known as $Sp(1)$; topologically a 3-sphere	simply connected, compact; isomorphic to $SU(2)$, $Spin(3)$ and to double cover of $SO(3)$; $\pi_0 = \pi_1 = 0$	$Im(\mathbb{H})$	quaternions with zero real part, with Lie bracket the commutator; simple and semi-simple; isomorphic to real 3-vectors, with Lie bracket the cross product; also isomorphic to $su(2)$ and to $so(3)$	3
$GL(n, \mathbb{R})$	general linear group: invertible n-by-n real matrices	not connected, not compact; $\pi_0 = \mathbb{Z}_2$, no π_1	$M(n, \mathbb{R})$	n-by-n matrices, with Lie bracket the commutator	n^2

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Lie group	Description	Properties[a]	Lie algebra	Description of Lie algebra	Dimension
$GL^+(n,\mathbb{R})$	n-by-n real matrices with positive determinant	simply connected, not compact; $\pi_0 = 0$, for $n = 2$: $\pi_1 = \mathbb{Z}$, for $n \geq 2$: $\pi_1 = \mathbb{Z}_2$; $GL^+(1,\mathbb{R})$ isomorphic to $\mathbb{R}^{>0}$	$M(n,\mathbb{R})$	n-by-n matrices, with Lie bracket the commutator	n^2
$SL(n,\mathbb{R})$	special linear group: real matrices with determinant 1	simply connected, not compact if $n > 1$; $\pi_0 = 0$, for $n = 2$: $\pi_1 = \mathbb{Z}$, for $n \geq 2$: $\pi_1 = \mathbb{Z}_2$; $SL(1,\mathbb{R})$ is a single point, $SL(2,\mathbb{R})$ is isomorphic to $SU(1,1)$ and $Sp(2,\mathbb{R})$	$sl(n,\mathbb{R})$ $= A_{n-1}$	n-by-n matrices with trace 0, with Lie bracket the commutator	$n^2 - 1$
$O(n,\mathbb{R})$ $= O(n)$	orthogonal group: real orthogonal matrices; symmetry of hypersphere	not connected, compact; $\pi_0 = \mathbb{Z}_2$, no π_1	$so(n,\mathbb{R})$	skew-symmetric n-by-n real matrices, with Lie bracket the commutator; $so(3,\mathbb{R})$ is isomorphic to $su(2)$ and to $\mathbb{R}^3$ with the cross product	$n(n-1)/2$
$SO(n,\mathbb{R})$ $= SO(n)$	special orthogonal group: real orthogonal matrices with determinant 1	connected, compact; for $n \geqslant 2$ not simply connected; $\pi_0 = 0$, for $n = 2$: $\pi_1 = \mathbb{Z}$, for $n \geq 2$: $\pi_1 = \mathbb{Z}_2$	$so(n,\mathbb{R})$ $= B_{\frac{n-1}{2}}$ or $D_{\frac{n}{2}}$	skew-symmetric n-by-n real matrices, with Lie bracket the commutator; for $n = 3$ and $n \geqslant 5$ simple and semisimple; SO(4) is semisimple but not simple	$n(n-1)/2$
$Spin(n)$	spin group; double cover of $SO(n)$; Spin(1) is isomorphic to $\mathbb{Q}_2$, Spin(2) to S^1	simply connected for $n \geqslant 3$, compact; for $n = 3$ and $n \geqslant 5$ simple and semisimple; for $n > 1$: $\pi_0 = 0$, for $n > 2$: $\pi_1 = 0$	$so(n,\mathbb{R})$	skew-symmetric n-by-n real matrices, with Lie bracket the commutator	$n(n-1)/2$
$Sp(2n,\mathbb{R})$	symplectic group: real symplectic matrices	not compact; $\pi_0 = 0$, $\pi_1 = \mathbb{Z}$	$sp(2n,\mathbb{R})$ $= C_n$	real matrices A that satisfy $JA + A^T J = 0$ where J is the standard skew-symmetric matrix;[b] simple and semisimple	$n(2n+1)$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Lie group	Description	Properties[a]	Lie algebra	Description of Lie algebra	Dimension
$\mathrm{Sp}(n)$ for $n \geqslant 3$	compact symplectic group: quaternionic $n \times n$ unitary matrices	compact, simply connected; $\pi_0 = \pi_1 = 0$	$\mathrm{sp}(n)$	n-by-n quaternionic matrices A satisfying $A = -A^*$, with Lie bracket the commutator; simple and semisimple	$n(2n+1)$
$\mathrm{U}(n)$	unitary group: complex $n \times n$ unitary matrices	not simply connected, compact; it is *not* a complex Lie group/algebra; $\pi_0 = 0$, $\pi_1 = \mathbb{Z}$; isomorphic to S^1 for $n = 1$	$\mathrm{u}(n)$	n-by-n complex matrices A satisfying $A = -A^*$, with Lie bracket the commutator	n^2
$\mathrm{SU}(n)$	special unitary group: complex $n \times n$ unitary matrices with determinant 1	simply connected, compact; it is *not* a complex Lie group/algebra; $\pi_0 = \pi_1 = 0$	$\mathrm{su}(n)$	n-by-n complex matrices A with trace 0 satisfying $A = -A^*$, with Lie bracket the commutator; for $n \geqslant 2$ simple and semisimple	$n^2 - 1$
2. Complex groups[c]					complex
$\mathbb{C}^n$	group operation is addition	Abelian, simply connected, not compact; $\pi_0 = \pi_1 = 0$	$\mathbb{C}^n$	Abelian, thus Lie bracket is zero	n
$\mathbb{C}^\times$	nonzero complex numbers with multiplication	Abelian, not simply connected, not compact; $\pi_0 = 0$, $\pi_1 = \mathbb{Z}$	$\mathbb{C}$	Abelian, thus Lie bracket is zero	1
$\mathrm{GL}(n, \mathbb{C})$	general linear group: invertible n-by-n complex matrices	simply connected, not compact; $\pi_0 = 0$, $\pi_1 = \mathbb{Z}$; for $n = 1$ isomorphic to $\mathbb{C}^\times$	$\mathrm{M}(n, \mathbb{C})$	n-by-n matrices, with Lie bracket the commutator	n^2
$\mathrm{SL}(n, \mathbb{C})$	special linear group: complex matrices with determinant 1	simply connected; for $n \geqslant 2$ not compact; $\pi_0 = \pi_1 = 0$; $\mathrm{SL}(2, \mathbb{C})$ is isomorphic to $\mathrm{Spin}(3, \mathbb{C})$ and $\mathrm{Sp}(2, \mathbb{C})$	$\mathrm{sl}(n, \mathbb{C})$	n-by-n matrices with trace 0, with Lie bracket the commutator; simple, semisimple; $\mathrm{sl}(2, \mathbb{C})$ is isomorphic to $\mathrm{su}(2, \mathbb{C}) \otimes \mathbb{C}$	$n^2 - 1$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Lie group	Description	Properties[a]	Lie algebra	Description of Lie algebra	Dimension
$\mathrm{PSL}(2,\mathbb{C})$	projective special linear group; isomorphic to the Möbius group, to the restricted Lorentz group $\mathrm{SO}^+(3,1,\mathbb{R})$ and to $\mathrm{SO}(3,\mathbb{C})$	not compact; $\pi_0 = 0$, $\pi_1 = \mathbb{Z}_2$	$\mathrm{sl}(2,\mathbb{C})$	2-by-2 matrices with trace 0, with Lie bracket the commutator; $\mathrm{sl}(2,\mathbb{C})$ is isomorphic to $\mathrm{su}(2,\mathbb{C}) \otimes \mathbb{C}$	3
$\mathrm{O}(n,\mathbb{C})$	orthogonal group: complex orthogonal matrices	not connected; for $n \geqslant 2$ not compact; $\pi_0 = \mathbb{Z}_2$, no π_1	$\mathrm{so}(n,\mathbb{C})$	skew-symmetric n-by-n complex matrices, with Lie bracket the commutator	$n(n-1)/2$
$\mathrm{SO}(n,\mathbb{C})$	special orthogonal group: complex orthogonal matrices with determinant 1	for $n \geqslant 2$ not compact; not simply connected; $\pi_0 = 0$, for $n = 2$: $\pi_1 = \mathbb{Z}$, for $n \geq 2$: $\pi_1 = \mathbb{Z}_2$; non-Abelian for $n > 2$, $\mathrm{SO}(2,\mathbb{C})$ is Abelian and isomorphic to $\mathbb{C}^\times$	$\mathrm{so}(n,\mathbb{C})$	skew-symmetric n-by-n complex matrices, with Lie bracket the commutator; for $n = 3$ and $n \geqslant 5$ simple and semisimple	$n(n-1)/2$
$\mathrm{Sp}(2n,\mathbb{C})$	symplectic group: complex symplectic matrices	not compact; $\pi_0 = \pi_1 = 0$	$\mathrm{sp}(2n,\mathbb{C})$	complex matrices that satisfy $JA + A^T J = 0$ where J is the standard skew-symmetric matrix;[b] simple and semi-simple	$n(2n+1)$

a. The *group of components* π_0 of a Lie group is given; the order of π_0 is the number of components of the Lie group. If the group is trivial (0), the Lie group is connected. The *fundamental group* π_1 of a connected Lie group is given. If the group π_1 is trivial (0), the Lie group is simply connected. This table is based on that in the Wikipedia, at en.wikipedia.org/wiki/Table_of_Lie_groups.

b. The standard skew-symmetric matrix J of rank $2n$ is $J_{kl} = \delta_{k,n+l} - \delta_{k+n,l}$.

c. Complex Lie groups and Lie algebras can be viewed as real Lie groups and real Lie algebras of twice the dimension.

MATHEMATICAL CURIOSITIES AND FUN CHALLENGES

Mathematics is a passion in itself.

* *

Mathematics provides many counter-intuitive results. Reading a book on the topic, such as Bernard R. Gelbaum & John M.H. Olmsted, *Theorems and Counter-examples in Mathematics*, Springer, 1993, can help you sharpen your mind.

* *

The distinction between one, two and three dimensions is blurred in mathematics. This is well demonstrated in the text Hans Sagan, *Space Filling Curves*, Springer Verlag, 1994.

* *

Show that two operators A and B obey

$$e^A e^B = \exp(A + B + \frac{1}{2}[A, B] \tag{560}$$
$$+ \frac{1}{12}[[A, B], B] - \frac{1}{12}[[A, B], A] \tag{561}$$
$$- \frac{1}{48}[B, [A, [A, B]]] - \frac{1}{48}[A, [B, [A, B]]] \tag{562}$$
$$+ \dots \tag{563}$$

for most operators A and B. This result is often called the Baker–Campbell–Hausdorff formula or BCH formula.

* *

There are at least seven ways to earn a million dollars with mathematical research. The Clay Mathematics Institute at www.claymath.org offers them for major advances in seven topics:

— proving the Birch and Swinnerton–Dyer conjecture about algebraic equations;
— proving the Poincaré conjecture about topological manifolds;
— solving the Navier–Stokes equations for fluids;
— finding criteria distinguishing P and NP numerical problems;
— proving the Riemann hypothesis stating that the nontrivial zeros of the zeta function lie on a line;
— proving the Hodge conjectures;
— proving the connection between Yang–Mills theories and a mass gap in quantum field theory.

On each of these topics, substantial progress can buy you a house.

* *

Appendix C

UNITS, MEASUREMENTS AND CONSTANTS

Measurements are comparisons with standards. Standards are based on a *unit*. many different systems of units have been used throughout the world. ost standards confer power to the organization in charge of them. Such power can be misused; this is the case today, for example in the computer industry, and was so in the distant past. The solution is the same in both cases: organize an independent and global standard. For units, this happened in the eighteenth century: to avoid misuse by authoritarian institutions, to eliminate problems with differing, changing and irreproducible standards, and – this is not a joke – to simplify tax collection, a group of scientists, politicians and economists agreed on a set of units. It is called the *Système International d'Unités*, abbreviated *SI*, and is defined by an international treaty, the 'Convention du Mètre'. The units are maintained by an international organization, the 'Conférence Générale des Poids et Mesures', and its daughter organizations, the 'Commission Internationale des Poids et Mesures' and the 'Bureau International des Poids et Mesures' (BIPM), which all originated in the times just before the French revolution.

Ref. 782

All SI units are built from seven *base units*, whose official definitions, translated from French into English, are given below, together with the dates of their formulation:

- 'The *second* is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium 133 atom.' (1967)*
- 'The *metre* is the length of the path travelled by light in vacuum during a time interval of 1/299 792 458 of a second.' (1983)
- 'The *kilogram* is the unit of mass; it is equal to the mass of the international prototype of the kilogram.' (1901)*
- 'The *ampere* is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 metre apart in vacuum, would produce between these conductors a force equal to $2 \cdot 10^{-7}$ newton per metre of length.' (1948)
- 'The *kelvin*, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.' (1967)*
- 'The *mole* is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon 12.' (1971)*
- 'The *candela* is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency $540 \cdot 10^{12}$ hertz and has a radiant intensity in that

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

direction of (1/683) watt per steradian.' (1979)*

Note that both time and length units are defined as certain properties of a standard example of motion, namely light. This is an additional example making the point that the observation of motion as the fundamental type of change is a *prerequisite* for the definition and construction of time and space. By the way, the use of light in the definitions had been proposed already in 1827 by Jacques Babinet.*

From these basic units, all other units are defined by multiplication and division. Thus, all SI units have the following properties:

- SI units form a system with *state-of-the-art precision*: all units are defined with a precision that is higher than the precision of commonly used measurements. Moreover, the precision of the definitions is regularly being improved. The present relative uncertainty of the definition of the second is around 10^{-14}, for the metre about 10^{-10}, for the kilogram about 10^{-9}, for the ampere 10^{-7}, for the mole less than 10^{-6}, for the kelvin 10^{-6} and for the candela 10^{-3}.
- SI units form an *absolute* system: all units are defined in such a way that they can be reproduced in every suitably equipped laboratory, independently, and with high precision. This avoids as much as possible any misuse by the standard-setting organization. (The kilogram, still defined with help of an artefact, is the last exception to this requirement; extensive research is under way to eliminate this artefact from the definition – an international race that will take a few more years. There are two approaches: counting particles, or fixing $\hbar$. The former can be achieved in crystals, the latter using any formula where $\hbar$ appears, such as the formula for the de Broglie wavelength or that of the Josephson effect.)
- SI units form a *practical* system: the base units are quantities of everyday magnitude. Frequently used units have standard names and abbreviations. The complete list includes the seven base units, the supplementary units, the derived units and the admitted units.

The *supplementary* SI units are two: the unit for (plane) angle, defined as the ratio of arc length to radius, is the *radian* (rad). For solid angle, defined as the ratio of the subtended area to the square of the radius, the unit is the *steradian* (sr).

The *derived* units with special names, in their official English spelling, i.e., without capital letters and accents, are:

* The respective symbols are s, m, kg, A, K, mol and cd. The international prototype of the kilogram is a platinum–iridium cylinder kept at the BIPM in Sèvres, in France. For more details on the levels of the caesium atom, consult a book on atomic physics. The Celsius scale of temperature θ is defined as: $\theta/°C = T/K - 273.15$; note the small difference with the number appearing in the definition of the kelvin. SI also states: 'When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles.' In the definition of the mole, it is understood that the carbon 12 atoms are unbound, at rest and in their ground state. In the definition of the candela, the frequency of the light corresponds to 555.5 nm, i.e., green colour, around the wavelength to which the eye is most sensitive.

Ref. 783

* Jacques Babinet (1794–1874), French physicist who published important work in optics.

Name	Abbreviation	Name	Abbreviation
hertz	$Hz = 1/s$	newton	$N = kg\,m/s^2$
pascal	$Pa = N/m^2 = kg/m\,s^2$	joule	$J = Nm = kg\,m^2/s^2$
watt	$W = kg\,m^2/s^3$	coulomb	$C = As$
volt	$V = kg\,m^2/As^3$	farad	$F = As/V = A^2s^4/kg\,m^2$
ohm	$\Omega = V/A = kg\,m^2/A^2s^3$	siemens	$S = 1/\Omega$
weber	$Wb = Vs = kg\,m^2/As^2$	tesla	$T = Wb/m^2 = kg/As^2 = kg/Cs$
henry	$H = Vs/A = kg\,m^2/A^2s^2$	degree Celsius	°C (see definition of kelvin)
lumen	$lm = cd\,sr$	lux	$lx = lm/m^2 = cd\,sr/m^2$
becquerel	$Bq = 1/s$	gray	$Gy = J/kg = m^2/s^2$
sievert	$Sv = J/kg = m^2/s^2$	katal	$kat = mol/s$

We note that in all definitions of units, the kilogram only appears to the powers of 1, 0 and -1. The final explanation for this fact appeared only recently. Can you try to formulate the reason?

Challenge 1309 ny

The *admitted* non-SI units are *minute*, *hour*, *day* (for time), *degree* $1° = \pi/180\,rad$, *minute* $1' = \pi/10\,800\,rad$, *second* $1'' = \pi/648\,000\,rad$ (for angles), *litre* and *tonne*. All other units are to be avoided.

All SI units are made more practical by the introduction of standard names and abbreviations for the powers of ten, the so-called *prefixes*:*

Power	Name		Power	Name		Power	Name		Power	Name	
10^1	deca	da	10^{-1}	deci	d	10^{18}	Exa	E	10^{-18}	atto	a
10^2	hecto	h	10^{-2}	centi	c	10^{21}	Zetta	Z	10^{-21}	zepto	z
10^3	kilo	k	10^{-3}	milli	m	10^{24}	Yotta	Y	10^{-24}	yocto	y

as well.

- SI units form a *universal* system: they can be used in trade, in industry, in commerce, at home, in education and in research. They could even be used by extraterrestrial civilizations, if they existed.
- SI units form a *coherent* system: the product or quotient of two SI units is also an SI unit. This means that in principle, the same abbreviation, e.g. 'SI', could be used for every unit.

The SI units are not the only possible set that could fulfil all these requirements, but they are the only existing system that does so.*

Remember that since every measurement is a comparison with a standard, any measurement requires matter to realize the standard (yes, even for the speed standard), and radiation to achieve the comparison. The concept of measurement thus assumes that matter and radiation exist and can be clearly separated from each other.

Page 1490

Planck's natural units

Since the exact form of many equations depends on the system of units used, theoretical physicists often use unit systems optimized for producing simple equations. The chosen units and the values of the constants of nature are related. In microscopic physics, the system of *Planck's natural units* is frequently used. They are defined by setting $c = 1$, $\hbar = 1$, $G = 1$, $k = 1$, $\varepsilon_0 = 1/4\pi$ and $\mu_0 = 4\pi$. Planck units are thus defined from combinations of fundamental constants; those corresponding to the fundamental SI units are given in Table 81.** The table is also useful for converting equations written in natural units back to SI units: just substitute every quantity X by X/X_{Pl}.

Challenge 1311 e

TABLE 81 Planck's (uncorrected) natural units

Name	Definition				Value
Basic units					
the Planck length	l_{Pl}	=	$\sqrt{\hbar G/c^3}$	=	$1.616\,0(12) \cdot 10^{-35}$ m
the Planck time	t_{Pl}	=	$\sqrt{\hbar G/c^5}$	=	$5.390\,6(40) \cdot 10^{-44}$ s
the Planck mass	m_{Pl}	=	$\sqrt{\hbar c/G}$	=	21.767(16) µg
the Planck current	I_{Pl}	=	$\sqrt{4\pi\varepsilon_0 c^6/G}$	=	$3.479\,3(22) \cdot 10^{25}$ A
the Planck temperature	T_{Pl}	=	$\sqrt{\hbar c^5/Gk^2}$	=	$1.417\,1(91) \cdot 10^{32}$ K

* Most non-SI units still in use in the world are of Roman origin. The mile comes from *milia passum*, which used to be one thousand (double) strides of about 1480 mm each; today a nautical mile, once defined as minute of arc on the Earth's surface, is exactly 1852 m). The inch comes from *uncia*/*onzia* (a twelfth – now of a foot). The pound (from *pondere* 'to weigh') is used as a translation of *libra* – balance – which is the origin of its abbreviation lb. Even the habit of counting in dozens instead of tens is Roman in origin. These and all other similarly funny units – like the system in which all units start with 'f', and which uses furlong/fortnight as its unit of velocity – are now officially defined as multiples of SI units.

** The natural units x_{Pl} given here are those commonly used today, i.e., those defined using the constant $\hbar$, and not, as Planck originally did, by using the constant $h = 2\pi\hbar$. The electromagnetic units can also be defined with other factors than $4\pi\varepsilon_0$ in the expressions: for example, using $4\pi\varepsilon_0\alpha$, with the *fine structure constant* α, gives $q_{\mathrm{Pl}} = e$. For the explanation of the numbers between brackets, the standard deviations, see page 920.

the Planck power	P_{Pl}	=	c^5/G	=	$3.6 \cdot 10^{52}$ W
the Planck force	F_{Pl}	=	c^4/G	=	$1.2 \cdot 10^{44}$ N
the Planck pressure	p_{Pl}	=	$c^7/G\hbar$	=	$4.6 \cdot 10^{113}$ Pa
the Planck acceleration	a_{Pl}	=	$\sqrt{c^7/\hbar G}$	=	$5.6 \cdot 10^{51}$ m/s^2
the Planck frequency	f_{Pl}	=	$\sqrt{c^5/\hbar G}$	=	$1.9 \cdot 10^{43}$ Hz
the Planck electric charge	q_{Pl}	=	$\sqrt{4\pi\varepsilon_0 c\hbar}$	=	1.9 aC = 11.7 e
the Planck voltage	U_{Pl}	=	$\sqrt{c^4/4\pi\varepsilon_0 G}$	=	$1.0 \cdot 10^{27}$ V
the Planck resistance	R_{Pl}	=	$1/4\pi\varepsilon_0 c$	=	30.0 Ω
the Planck capacitance	C_{Pl}	=	$4\pi\varepsilon_0\sqrt{\hbar G/c^3}$	=	$1.8 \cdot 10^{-45}$ F
the Planck inductance	L_{Pl}	=	$(1/4\pi\varepsilon_0)\sqrt{\hbar G/c^7}$	=	$1.6 \cdot 10^{-42}$ H
the Planck electric field	E_{Pl}	=	$\sqrt{c^7/4\pi\varepsilon_0\hbar G^2}$	=	$6.5 \cdot 10^{61}$ V/m
the Planck magnetic flux density	B_{Pl}	=	$\sqrt{c^5/4\pi\varepsilon_0\hbar G^2}$	=	$2.2 \cdot 10^{53}$ T

The natural units are important for another reason: whenever a quantity is sloppily called 'infinitely small (or large)', the correct expression is 'as small (or as large) as the corresponding corrected Planck unit'. As explained throughout the text, and especially in the final part, this substitution is possible because almost all Planck units provide, within a correction factor of order 1, the extremal value for the corresponding observable – some an upper and some a lower limit. Unfortunately, these correction factors are not yet widely known. The exact extremal value for each observable in nature is obtained when G is substituted by $4G$, $\hbar$ by $\hbar/2$, k by $k/2$ and $4\pi\varepsilon_0$ by $8\pi\varepsilon_0\alpha$ in all Planck quantities. These extremal values, or *corrected Planck units*, are the *true natural units*. To exceed the extremal values is possible only for some extensive quantities. (Can you find out which ones?)

Page 1466

Challenge 1312 s

OTHER UNIT SYSTEMS

A central aim of research in high-energy physics is the calculation of the strengths of all interactions; therefore it is not practical to set the gravitational constant G to unity, as in the Planck system of units. For this reason, high-energy physicists often only set

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$c = \hbar = k = 1$ and $\mu_0 = 1/\varepsilon_0 = 4\pi$,* leaving only the gravitational constant G in the equations.

In this system, only one fundamental unit exists, but its choice is free. Often a standard length is chosen as the fundamental unit, length being the archetype of a measured quantity. The most important physical observables are then related by

$$\begin{aligned} 1/[l^2] = [E]^2 &= [F] = [B] = [E_{\text{electric}}]\,, \\ 1/[l] = [E] &= [m] = [p] = [a] = [f] = [I] = [U] = [T]\,, \\ 1 &= [v] = [q] = [e] = [R] = [S_{\text{action}}] = [S_{\text{entropy}}] = \hbar = c = k = [\alpha]\,, \\ [l] = 1/[E] &= [t] = [C] = [L] \quad \text{and} \\ [l]^2 = 1/[E]^2 &= [G] = [P] \end{aligned} \tag{564}$$

where we write $[x]$ for the unit of quantity x. Using the same unit for time, capacitance and inductance is not to everybody's taste, however, and therefore electricians do not use this system.**

Often, in order to get an impression of the energies needed to observe an effect under study, a standard energy is chosen as fundamental unit. In particle physics the most common energy unit is the *electronvolt* (eV), defined as the kinetic energy acquired by an electron when accelerated by an electrical potential difference of 1 volt ('protonvolt' would be a better name). Therefore one has $1\,\text{eV} = 1.6 \cdot 10^{-19}\,\text{J}$, or roughly

$$1\,\text{eV} \approx \tfrac{1}{6}\,\text{aJ} \tag{565}$$

which is easily remembered. The simplification $c = \hbar = 1$ yields $G = 6.9 \cdot 10^{-57}\,\text{eV}^{-2}$ and allows one to use the unit eV also for mass, momentum, temperature, frequency, time and length, with the respective correspondences $1\,\text{eV} \equiv 1.8 \cdot 10^{-36}\,\text{kg} \equiv 5.4 \cdot 10^{-28}\,\text{Ns} \equiv 242\,\text{THz} \equiv 11.6\,\text{kK}$ and $1\,\text{eV}^{-1} \equiv 4.1\,\text{fs} \equiv 1.2\,\mu\text{m}$.

Challenge 1314 e

To get some feeling for the unit eV, the following relations are useful. Room temperature, usually taken as 20 °C or 293 K, corresponds to a kinetic energy per particle of 0.025 eV or 4.0 zJ. The highest particle energy measured so far belongs to a cosmic ray with an energy of $3 \cdot 10^{20}$ eV or 48 J. Down here on the Earth, an accelerator able to produce an energy of about 105 GeV or 17 nJ for electrons and antielectrons has been built,

Ref. 787

---

* Other definitions for the proportionality constants in electrodynamics lead to the Gaussian unit system often used in theoretical calculations, the Heaviside–Lorentz unit system, the electrostatic unit system, and the electromagnetic unit system, among others.

Ref. 785

** In the list, l is length, E energy, F force, E_{electric} the electric and B the magnetic field, m mass, p momentum, a acceleration, f frequency, I electric current, U voltage, T temperature, v speed, q charge, R resistance, P power, G the gravitational constant.

The web page www.chemie.fu-berlin.de/chemistry/general/units_en.html provides a tool to convert various units into each other.

Researchers in general relativity often use another system, in which the *Schwarzschild radius* $r_S = 2Gm/c^2$ is used to measure masses, by setting $c = G = 1$. In this case, mass and length have the *same* dimension, and $\hbar$ has the dimension of an area.

Ref. 786

Already in the nineteenth century, George Stoney had proposed to use as length, time and mass units the quantities $l_S = \sqrt{Ge^2/(c^4 4\pi\varepsilon_0)} = 1.4 \cdot 10^{-36}\,\text{m}$, $t_S = \sqrt{Ge^2/(c^6 4\pi\varepsilon_0)} = 4.6 \cdot 10^{-45}\,\text{s}$ and $m_S = \sqrt{e^2/(G4\pi\varepsilon_0)} = 1.9\,\mu\text{g}$. How are these units related to the Planck units?

Challenge 1313 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 82 Some measured visible power (luminous intensity) values

OBSERVATION	LUMINOUS INTENSITY
Candle flame	1 cd
Pocket lamp	2 cd
Parking light of car	10 cd
Full beam of car (with reflector, centre of beam)	60 cd
Cinema lamp	1.5 kcd

Lighthouse	2 Mcd
Largest searchlights	80 Mcd

and one able to produce an energy of 10 TeV or 1.6 μJ for protons will be finished soon. Both are owned by CERN in Geneva and have a circumference of 27 km.

The lowest temperature measured up to now is 280 pK, in a system of rhodium nuclei held inside a special cooling system. The interior of that cryostat may even be the coolest point in the whole universe. The kinetic energy per particle corresponding to that temperature is also the smallest ever measured: it corresponds to 24 feV or 3.8 vJ = $3.8 \cdot 10^{-33}$ J. For isolated particles, the record seems to be for neutrons: kinetic energies as low as 10^{-7} eV have been achieved, corresponding to de Broglie wavelengths of 60 nm.

Ref. 788

CURIOSITIES AND FUN CHALLENGES ABOUT UNITS

Not using SI units can be expensive. In 1999, NASA lost a satellite on Mars because some software programmers had used imperial units instead of SI units in part of the code. As a result, the Mars Climate Orbiter crashed into the planet, instead of orbiting it; the loss was around 100 million euro.*

* *

A *gray* is the amount of radioactivity that deposits 1 J on 1 kg of matter. A *sievert* is the unit of radioactivity adjusted to humans by weighting each type of human tissue with a factor representing the impact of radiation deposition on it. Four to five sievert are a lethal dose to humans. In comparison, the natural radioactivity present inside human bodies leads to a dose of 0.2 mSv per year. An average X-ray image implies an irradiation of 1 mSv; a CAT scan 8 mSv.

Ref. 789

* *

Are you confused by the candela? The definition simply says that 683 cd = 683 lm/sr corresponds to 1 W/sr. The candela is thus a unit for light power per (solid) angle, or *luminous intensity*, except that it is corrected for the eye's sensitivity: the candela measures only *visible* power per angle.

* This story revived an old (and false) urban legend that states that only three countries in the world do not use SI units: Liberia, the USA and Myanmar.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 83 Some measured illuminance values

OBSERVATION	ILLUMINANCE
Faint star	0.1 nlx
Sirius	10 µlx
phot (old illuminance unit)	10 µlx
Jupiter	20 µlx
Full moon	0.01 to 0.24 lx
Street at night, low traffic, poor lighting	0.1 to 3 lx
Street at night, high traffic	10 to 30 lx
For reading	50 to 100 lx
Cinema screen	100 lx
Workplace	0.2 to 5 klx
Cloudy day	1 klx
Sunny day	120 klx
Film in cinema projector	5 Mlx
Painful to the eye	100 Mlx

Similarly, 683 lm = 683 cd sr corresponds to 1 W. So both the lumen and the watt measure power, or energy flux, but the lumen measures only the *visible* part of the power or energy flux. This difference is expressed by inserting 'radiant' or 'luminous': thus, the Watt measures *radiant* flux, whereas the lumen measures *luminous* flux.

The factor 683 is historical. An ordinary candle emits a luminous intensity of about a candela. Therefore, at night, a candle can be seen up to a distance of 10 or 20 kilometres. A 100 W incandescent light bulb produces 1700 lm, and the brightest light emitting diodes about 5 lm. Cinema projectors produce around 2 Mlm, and the brightest flashes, like lightning, 100 Mlm.

Challenge 1315 e

The *irradiance* of sunlight is about 1300 W/m^2 on a sunny day; on the other hand, the *illuminance* is only 120 klm/m^2 = 120 klux or 170 W/m^2. (A cloud-covered summer day or a clear winter day produces about 10 klux. Illuminance is essentially what we call 'brightness' in everyday life.) These numbers show that most of the energy from the Sun that reaches the Earth is outside the visible spectrum.

On a glacier, near the sea shore, on the top of a mountain, or in particular weather condition the brightness can reach 150 klux. The brightest lamps, those used during surgical operations, produce 120 klux. Humans need about 30 lux for comfortable reading. Museums are often kept dark because water-based paintings are degraded by light above 100 lux, and oil paintings by light above 200 lux. The full moon produces 0.1 lux, and the sky on a dark moonless night about 1 mlux. The eyes lose their ability to distinguish colours somewhere between 0.1 lux and 0.01 lux; the eye stops to work below 1 nlux. Technical devices to produce images in the dark, such as night goggles, start to work at 1 µlux. By the way, the human body itself *shines* with about 1 plux, a value too small to be detected with the eye, but easily measured with specialized apparatus. The origin of this emission is still a topic of research.

Ref. 790

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

The highest achieved light intensities are in excess of $10^{18}\,W/m^2$, more than 15 orders of magnitude higher than the intensity of sunlight. They are produced by tight focusing of pulsed lasers. The electric field in such light pulses is of the same order as the field inside
Ref. 791 atoms; such a beam therefore ionizes all matter it encounters.

* *

The *luminous density* is a quantity often used by light technicians. Its unit is $1\,cd/m^2$, unofficially called 1 Nit and abbreviated 1 nt. Eyes see purely with rods from $0.1\,\mu cd/m^2$ to $1\,mcd/m^2$; they see purely with cones above $5\,cd/m^2$; they see best between 100 and $50\,000\,cd/m^2$; and they get completely overloaded above $10\,Mcd/m^2$: a total range of 15 orders of magnitude.

* *

The Planck length is roughly the de Broglie wavelength $\lambda_B = h/mv$ of a man walking
Ref. 792 comfortably ($m = 80\,kg$, $v = 0.5\,m/s$); this motion is therefore aptly called the 'Planck stroll.'

* *

The Planck mass is equal to the mass of about 10^{19} protons. This is roughly the mass of a human embryo at about ten days of age.

* *

The second does not correspond to 1/86 400th of the day any more, though it did in the year 1900; the Earth now takes about 86 400.002 s for a rotation, so that the *International Earth Rotation Service* must regularly introduce a leap second to ensure that the Sun is at the highest point in the sky at 12 o'clock sharp.* The time so defined is called *Universal Time Coordinate*. The speed of rotation of the Earth also changes irregularly from day to day due to the weather; the average rotation speed even changes from winter to summer because of the changes in the polar ice caps; and in addition that average decreases over time, because of the friction produced by the tides. The rate of insertion of leap seconds is therefore higher than once every 500 days, and not constant in time.

* *

The most precisely measured quantities in nature are the frequencies of certain millisecond pulsars,** the frequency of certain narrow atomic transitions, and the Rydberg constant of *atomic* hydrogen, which can all be measured as precisely as the second is defined. The caesium transition that defines the second has a finite linewidth that limits the achievable precision: the limit is about 14 digits.

* *

The most precise clock ever built, using microwaves, had a stability of 10^{-16} during a

* Their website at hpiers.obspm.fr gives more information on the details of these insertions, as does maia.usno.navy.mil, one of the few useful military websites. See also www.bipm.fr, the site of the BIPM.

** An overview of this fascinating work is given by J. H. TAYLOR, Pulsar timing and relativistic gravity, *Philosophical Transactions of the Royal Society, London A* **341**, pp. 117–134, 1992.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 793 Ref. 794 running time of 500 s. For longer time periods, the record in 1997 was about 10^{-15}; but values around 10^{-17} seem within technological reach. The precision of clocks is limited for short measuring times by noise, and for long measuring times by drifts, i.e., by systematic effects. The region of highest stability depends on the clock type; it usually lies between 1 ms for optical clocks and 5000 s for masers. Pulsars are the only type of clock for which this region is not known yet; it certainly lies at more than 20 years, the time elapsed at the time of writing since their discovery.

* *

Ref. 795 The shortest times measured are the lifetimes of certain 'elementary' particles. In particular, the lifetime of certain D mesons have been measured at less than 10^{-23} s. Such times are measured using a bubble chamber, where the track is photographed. Can you estimate how long the track is? (This is a trick question – if your length cannot be observed with an optical microscope, you have made a mistake in your calculation.) Challenge 1316 s

* *

The longest times encountered in nature are the lifetimes of certain radioisotopes, over 10^{15} years, and the lower limit of certain proton decays, over 10^{32} years. These times are thus much larger than the age of the universe, estimated to be fourteen thousand million years. Ref. 796

* *

The least precisely measured of the fundamental constants of physics are the gravitational constant G and the strong coupling constant α_s. Even less precisely known are the age of the universe and its density (see Table 86). Page 923

* *

The precision of mass measurements of solids is limited by such simple effects as the adsorption of water. Can you estimate the mass of a monolayer of water – a layer with thickness of one molecule – on a metal weight of 1 kg? Challenge 1317 s

* *

Variations of quantities are often much easier to measure than their values. For example, in gravitational wave detectors, the sensitivity achieved in 1992 was $\Delta l/l = 3 \cdot 10^{-19}$ for lengths of the order of 1 m. In other words, for a block of about a cubic metre of metal it is possible to measure length changes about 3000 times smaller than a proton radius. These set-ups are now being superseded by ring interferometers. Ring interferometers measuring frequency differences of 10^{-21} have already been built; and they are still being improved. Ref. 797 Ref. 798

* *

The Swedish astronomer Anders Celsius (1701–1744) originally set the freezing point of water at 100 degrees and the boiling point at 0 degrees. Later the scale was reversed. However, this is not the whole story. With the official definition of the kelvin and the degree Celsius, at the standard pressure of 1013.25 Pa, water boils at 99.974 °C. Can you explain why it is not 100 °C any more? Ref. 799 Challenge 1318 s

* *

In the previous millennium, thermal energy used to be measured using the unit *calorie*, written as cal. 1 cal is the energy needed to heat 1 g of water by 1 K. To confuse matters, 1 kcal was often written 1 Cal. (One also spoke of a large and a small calorie.) The value of 1 kcal is 4.1868 kJ.

* *

SI units are adapted to humans: the values of heartbeat, human size, human weight, human temperature and human substance are no more than a couple of orders of magnitude near the unit value. SI units thus (roughly) confirm what Protagoras said 25 centuries ago: 'Man is the measure of all things.'

* *

Some units systems are particularly badly adapted to humans. The most infamous is shoe size S. It is a pure number calculated as

$$\begin{aligned} S_{\text{France}} &= 1.5\,\text{cm}^{-1}(l + 1 \pm 1\,\text{cm}) \\ S_{\text{central Europe}} &= 1.5748\,\text{cm}^{-1}(l + 1 \pm 1\,\text{cm}) \\ S_{\text{Anglosaxon men}} &= 1.181\,\text{cm}^{-1}(l + 1 \pm 1\,\text{cm}) - 22 \end{aligned} \tag{566}$$

where l is the length of a foot and the correction length depends on the manufacturing company. In addition, the Anglosaxon formula is not valid for women and children, where the first factor depends, for marketing reasons, both on manufacturer and size itself. The ISO standard requires, unsurprisingly, to use foot length in millimetres.

* *

The table of SI prefixes covers 72 orders of magnitude. How many additional prefixes will be needed? Even an extended list will include only a small part of the infinite range of possibilities. Will the Conférence Générale des Poids et Mesures have to go on forever, defining an infinite number of SI prefixes? Why?

Challenge 1319 s

* *

The French philosopher Voltaire, after meeting Newton, publicized the now famous story that the connection between the fall of objects and the motion of the Moon was discovered by Newton when he saw an apple falling from a tree. More than a century later, just before the French Revolution, a committee of scientists decided to take as the unit of force precisely the force exerted by gravity on a *standard apple*, and to name it after the English scientist. After extensive study, it was found that the mass of the standard apple was 101.9716 g; its weight was called 1 newton. Since then, visitors to the museum in Sèvres near Paris have been able to admire the standard metre, the standard kilogram and the standard apple.*

* To be clear, this is a joke; no standard apple exists. It is *not* a joke however, that owners of several apple trees in Britain and in the US claim descent, by rerooting, from the original tree under which Newton had his insight. DNA tests have even been performed to decide if all these derive from the same tree. The result was, unsurprisingly, that the tree at MIT, in contrast to the British ones, is a fake.

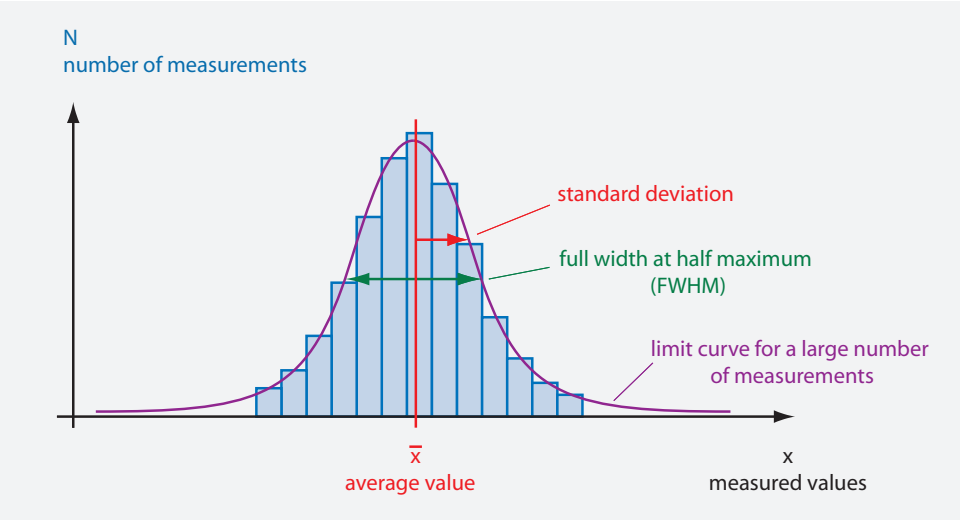

FIGURE 419 A precision experiment and its measurement distribution

Precision and accuracy of measurements

As explained on page 315, *precision* means how well a result is reproduced when the measurement is repeated; *accuracy* is the degree to which a measurement corresponds to the actual value. Lack of precision is due to accidental or *random errors*; they are best measured by the *standard deviation*, usually abbreviated σ; it is defined through

$$\sigma^2 = \frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2 \,, \tag{567}$$

where $\bar{x}$ is the average of the measurements x_i. (Can you imagine why $n-1$ is used in the formula instead of n?) Challenge 1320 s

For most experiments, the distribution of measurement values tends towards a normal distribution, also called *Gaussian distribution*, whenever the number of measurements is increased. The distribution, shown in Figure 419, is described by the expression

$$N(x) \approx \mathrm{e}^{-\frac{(x-\bar{x})^2}{2\sigma^2}} \,. \tag{568}$$

The square σ^2 of the standard deviation is also called the *variance*. For a Gaussian distribution of measurement values, 2.35σ is the full width at half maximum. Challenge 1321 e

Lack of accuracy is due to *systematic errors*; usually these can only be estimated. This estimate is often added to the random errors to produce a *total* experimental error, sometimes also called *total uncertainty*. Ref. 801

The following tables give the values of the most important physical constants and particle properties in SI units and in a few other common units, as published in the standard references. The values are the world averages of the best measurements made up to the Ref. 802

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

present. As usual, experimental errors, including both random and estimated systematic errors, are expressed by giving the standard deviation in the last digits; e.g. 0.31(6) means – roughly speaking – 0.31 ± 0.06. In fact, behind each of the numbers in the following tables there is a long story which is worth telling, but for which there is not enough room here.*

What are the limits to accuracy and precision? There is no way, even in principle, to measure a length x to a *precision* higher than about 61 digits, because $\Delta x/x > l_{\mathrm{Pl}}/d_{\mathrm{horizon}} = 10^{-61}$. (Is this valid also for force or for volume?) In the third final of our text, studies of clocks and metre bars strengthen this theoretical limit.

Challenge 1322 ny
Page 1428

But it is not difficult to deduce more stringent practical limits. No imaginable machine can measure quantities with a higher precision than measuring the diameter of the Earth within the smallest length ever measured, about 10^{-19} m; that is about 26 digits of precision. Using a more realistic limit of a 1000 m sized machine implies a limit of 22 digits. If, as predicted above, time measurements really achieve 17 digits of precision, then they are nearing the practical limit, because apart from size, there is an additional practical restriction: cost. Indeed, an additional digit in measurement precision often means an additional digit in equipment cost.

Basic physical constants

In principle, all quantitative properties of matter can be calculated with quantum theory. For example, colour, density and elastic properties can be predicted using the values of the following constants using the equations of the standard model of high-energy physics.

Ref. 802
Page 1290

TABLE 84 Basic physical constants

Quantity	Symbol	Value in SI units	Uncert.[a]
number of space-time dimensions		3 + 1	0 [b]
vacuum speed of light[c]	c	299 792 458 m/s	0
vacuum permeability[c]	μ_0	$4\pi \cdot 10^{-7}$ H/m	0
		= 1.256 637 061 435 ... μH/m	0
vacuum permittivity[c]	$\varepsilon_0 = 1/\mu_0 c^2$	8.854 187 817 620 ... pF/m	0
original Planck constant	h	$6.626\,068\,76(52) \cdot 10^{-34}$ Js	$7.8 \cdot 10^{-8}$
reduced Planck constant	$\hbar$	$1.054\,571\,596(82) \cdot 10^{-34}$ Js	$7.8 \cdot 10^{-8}$
positron charge	e	0.160 217 646 2(63) aC	$3.9 \cdot 10^{-8}$
Boltzmann constant	k	$1.380\,650\,3(24) \cdot 10^{-23}$ J/K	$1.7 \cdot 10^{-6}$

gravitational coupling constant	$\kappa = 8\pi G/c^4$	$2.076(3) \cdot 10^{-43}$ s^2/kg m	$1.5 \cdot 10^{-3}$
fine structure constant,[d]	$\alpha = \frac{e^2}{4\pi\varepsilon_0\hbar c}$	1/137.035 999 76(50)	$3.7 \cdot 10^{-9}$
e.m. coupling constant	$= g_{\mathrm{em}}(m_e^2 c^2)$	= 0.007 297 352 533(27)	$3.7 \cdot 10^{-9}$

* Some of the stories can be found in the text by N. W. Wise, *The Values of Precision*, Princeton University Press, 1994. The field of high-precision measurements, from which the results on these pages stem, is a world on its own. A beautiful introduction to it is J. D. Fairbanks, B. S. Deaver, C. W. Everitt & P. F. Michaelson, eds., *Near Zero: Frontiers of Physics*, Freeman, 1988.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

QUANTITY	SYMBOL	VALUE IN SI UNITS	UNCERT.[a]
Fermi coupling constant,[d]	$G_F/(\hbar c)^3$	$1.166\,39(1)\cdot 10^{-5}\,\mathrm{GeV}^{-2}$	$8.6\cdot 10^{-6}$
weak coupling constant	$\alpha_w(M_Z) = g_w^2/4\pi$	1/30.1(3)	$1\cdot 10^{-2}$
weak mixing angle	$\sin^2\theta_W(\overline{MS})$	0.231 24(24)	$1.0\cdot 10^{-3}$
weak mixing angle	$\sin^2\theta_W$ (on shell) $= 1-(m_W/m_Z)^2$	0.2224(19)	$8.7\cdot 10^{-3}$
strong coupling constant[d]	$\alpha_s(M_Z) = g_s^2/4\pi$	0.118(3)	$25\cdot 10^{-3}$

a. Uncertainty: standard deviation of measurement errors.
b. Only down to 10^{-19} m and up to 10^{26} m.
c. Defining constant.
d. All coupling constants depend on the 4-momentum transfer, as explained in the section on renormalization. *Fine structure constant* is the traditional name for the electromagnetic coupling constant g_{em} in the case of a 4-momentum transfer of $Q^2 = m_e^2c^2$, which is the smallest one possible. At higher momentum transfers it has larger values, e.g. $g_{em}(Q^2 = M_W^2c^2) \approx 1/128$. The strong coupling constant has higher values at lower momentum transfers; e.g., $\alpha_s(34\,\mathrm{GeV}) = 0.14(2)$.

Page 1194

Why do all these constants have the values they have? The answer is different in each case. For any constant having a dimension, such as the quantum of action $\hbar$, the numerical value has only historical meaning. It is $1.054\cdot 10^{-34}$ Js because of the SI definition of the joule and the second. The question why the value of a dimensional constant is not larger or smaller always requires one to understand the origin of some dimensionless number giving the ratio between the constant and the corresponding natural unit. Understanding the sizes of atoms, people, trees and stars, the duration of molecular and atomic processes, or the mass of nuclei and mountains, implies understanding the ratios between these values and the corresponding natural units. The key to understanding nature is thus the understanding of all ratios, and thus of all dimensionless constants. The story of the most important ratios is told in the concluding part of the adventure.

The basic constants yield the following useful high-precision observations.

TABLE 85 Derived physical constants

QUANTITY	SYMBOL	VALUE IN SI UNITS	UNCERT.
Vacuum wave resistance	$Z_0 = \sqrt{\mu_0/\varepsilon_0}$	376.730 313 461 77... Ω	0

a. The shape of the Earth is described most precisely with the World Geodetic System. The last edition dates from 1984. For an extensive presentation of its background and its details, see the www.wgs84.com website. The International Geodesic Union refined the data in 2000. The radii and the flattening given here are those for the 'mean tide system'. They differ from those of the 'zero tide system' and other systems by about 0.7 m. The details constitute a science in itself.

b. Measured centre to centre. To find the precise position of the Moon at a given date, see the www.fourmilab.ch/earthview/moon_ap_per.html page. For the planets, see the page www.fourmilab.ch/solar/solar.html and the other pages on the same site.

c. Angles are defined as follows: 1 degree = $1^\circ = \pi/180$ rad, 1 (first) minute = $1' = 1^\circ/60$, 1 second (minute) = $1'' = 1'/60$. The ancient units 'third minute' and 'fourth minute', each 1/60th of the preceding, are not in use any more. ('Minute' originally means 'very small', as it still does in modern English.)

If the number π is *normal*, i.e., if all digits and digit combinations in its decimal expansion appear with the same limiting frequency, then every text ever written or yet to be written, as well as every word ever spoken or yet to be spoken, can be found coded in its sequence. The property of normality has not yet been proven, although it is suspected to hold. Does this mean that all wisdom is encoded in the simple circle? No. The property is nothing special: it also applies to the number 0.12345678910111213141516171819202 1... and many others. Can you specify a few examples?

Challenge 1325 s

By the way, in the graph of the exponential function e^x, the point $(0,1)$ is the only point with two rational coordinates. If you imagine painting in blue all points on the plane with two rational coordinates, the plane would look quite bluish. Nevertheless, the graph goes through only one of these points and manages to avoid all the others.

Appendix D

SOURCES OF INFORMATION ON MOTION

> No place affords a more striking conviction of the vanity of human hopes than a public library.
>
> Samuel Johnson

> In a consumer society there are inevitably two kinds of slaves: the prisoners of addiction and the prisoners of envy.
>
> Ivan Illich*

In the text, outstanding books introducing neighbouring domains are presented in footnotes. The bibliographies at the end of each part collect general material in order to satisfy further curiosity about what is encountered in this mountain ascent. All citations can also be found by looking up the author's name in the index. To find additional information, either libraries or the internet can help.

In a library, review articles of recent research appear in journals such as *Reviews of Modern Physics*, *Reports on Progress in Physics*, *Contemporary Physics* and *Advances in Physics*. Good pedagogical introductions are found in the *American Journal of Physics*, the *European Journal of Physics* and *Physik in unserer Zeit*. Another useful resource is *Living Reviews in Relativity*, found at www.livingreviews.org.

Overviews on research trends occasionally appear in magazines such as *Physics World*, *Physics Today*, *Europhysics Journal*, *Physik Journal* and *Nederlands tijdschrift voor natuurkunde*. For coverage of all the sciences together, the best sources are the magazines *Nature*, *New Scientist*, *Naturwissenschaften*, *La Recherche* and the cheap but excellent *Science News*.

Research papers appear mainly in *Physics Letters B*, *Nuclear Physics B*, *Physical Review D*, *Physical Review Letters*, *Classical and Quantum Gravity*, *General Relativity and Gravitation*, *International Journal of Modern Physics* and *Modern Physics Letters*. The newest results and speculative ideas are found in conference proceedings, such as the *Nuclear Physics B Supplements*. Research articles also appear in *Fortschritte der Physik*, *Zeitschrift für Physik C*, *La Rivista del Nuovo Cimento*, *Europhysics Letters*, *Communications in Mathematical Physics*, *Journal of Mathematical Physics*, *Foundations of Physics*, *International Journal of Theoretical Physics* and *Journal of Physics G*. There is also the purely electronic *New Journal of Physics*, which can be found at the www.njp.org website.

Papers on the description of motion without time and space which appear *after* this text is published can be found via the *Scientific Citation Index*. It is published in printed

* Ivan Illich (b. 1926 Vienna, d. 2002 Bremen), Austrian theologian and social and political thinker.

To receive preprints by email, send an email to an address of the form gr-qc@arxiv.org (or the corresponding abbreviation in place of 'gr-qc'), with a subject line consisting simply of the word 'help', without the quotes.

form and as compact disc, and allows, one to search for all publications which cite a given paper. Then, using the bimonthly *Physics Abstracts*, which also exists in both paper and electronic form, you can look up the abstract of the paper and check whether it is of interest.

But by far the simplest and most efficient way to keep in touch with ongoing research on motion is to use the *internet*, the international computer network. To anybody with a personal computer connected to a telephone, most theoretical physics papers are available free of charge, as *preprints*, i.e., before official publication and checking by referees, at the arxiv.org website. Details are given in Table 88. A service for finding subsequent preprints that cite a given one is also available.

In the last decade of the twentieth century, the internet expanded into a combination of library, media store, discussion platform, order desk, brochure collection and time waster. Today, commerce, advertising and – unfortunately – crime of all kind are also an integral part of the web. With a personal computer, a modem and free browser software, one can look for information in millions of pages of documents. The various parts of the documents are located in various computers around the world, but the user does not need to be aware of this.*

* Several decades ago, the provocative book by Ivan Illich, *Deschooling Society*, Harper & Row, 1971,

Physics	

listed four basic ingredients for any educational system:

1. access to *resources* for learning, e.g. books, equipment, games, etc. at an affordable price, for everybody, at any time in their life;

2. for all who want to learn, access to *peers* in the same learning situation, for discussion, comparison, cooperation and competition;

3. access to *elders*, e.g. teachers, for their care and criticism towards those who are learning;

4. exchanges between students and *performers* in the field of interest, so that the latter can be models for the former. For example, there should be the possibility to listen to professional musicians and reading the works of specialist writers. This also gives performers the possibility to share, advertise and use their skills.

Illich develops the idea that if such a system were informal – he then calls it a 'learning web' or 'opportunity web' – it would be superior to formal, state-financed institutions, such as conventional schools, for the development of mature human beings. These ideas are deepened in his following works, *Deschooling Our Lives*, Penguin, 1976, and *Tools for Conviviality*, Penguin, 1973.

Today, any networked computer offers one or more of the following: *email* (electronic mail), FTP (file transfer to and from another computer), access to *Usenet* (the discussion groups on specific topics, such as particle physics), and the powerful *world-wide web*. (Roughly speaking, each of those includes the ones before.) In a rather unexpected way, all these facilities of the internet have transformed it into the backbone of the 'opportunity web' discussed by Illich. However, as in any school, it strongly depends on the user's discipline whether the internet actually does provide a learning web.

* It is also possible to use both the internet and to download files through FTP with the help of email only. But the tools change too often to give a stable guide here. Ask your friend.

Do you want to study physics without actually going to university? Nowadays it is possible to do so via email and internet, in German, at the University of Kaiserslautern.* In the near future, a nationwide project in Britain should allow the same for English-speaking students. As an introduction, use the latest update of this physics text!

> Das Internet ist die offenste Form der geschlossenen Anstalt.**

589 An electrodynamics text completely written with (mathematical) forms is Kurt Meetz & Walter L. Engl, Elektromagnetische Felder – mathematische und physikalische Grundlagen, Springer, 1980. Cited on page 714.

590 J. Travis, Twirl those organs into place – getting to the heart of how a heart knows left from right, *Science News* **156**, 21 August, 1999. A good book on asymmetries in nature is H. Brunner, *Rechts oder links*, Wiley–Vch, 1999. Cited on page 717.

591 See for example the discussion by M. C. Corballis & I. L. Beale, On telling left from right, *Scientific American* **224**, pp. 96–104, March 1971. Cited on page 718.

592 Wolfgang Rindler, *Essential Relativity – Special, General, and Cosmological*, revised 2nd edition, Springer Verlag, 1977, page 247. There is also the beautiful paper by M. Le Bellac & J.-M. Lévy-Leblond, Galilean electrodynamics, *Nuovo Cimento B* **14**, p. 217, 1973, that explains the possibilities but also the problems appearing when trying to define the theory non-relativistically. Cited on page 719.

593 L.-C. Tu, J. Luo & G. T. Gilles, The mass of the photon, *Reports on Progress of Physics* **68**, pp. 77–130, 2005. Cited on pages 719 and 720.

594 The system for typing by thought alone is described in many papers, such as B. Blankertz, F. Losch, M. Krauledat, G. Dornhege, G. Curio &

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

K.-R. Müller, The Berlin Brain-Computer Interface: accurate performance from first session in BCI-naïve subjects, *IEEE Transactions on biomedial engineering* **55**, pp. 2452–2462, 2008. See the website www.bbci.de for more information. Cited on page 721.

595 For a captivating account on the history of the ideas on light, see David Park, *The Fire Within the Eye: a Historical Essay on the Nature and Meaning of Light*, Princeton University Press, 1997. For an example of the complex history of optics, see the famous text by Alhazen or Ibn al-Haytham, *Book of Optics* 1021. However, no Arabic website allows to read the text, and the Arabic Wikipedia articles on the topic are much shorter than the French or English ones. Indeed, like most ancient Middle-East thinkers, Alhazen is better known in Europe than in his home region. A Latin translation of the Book of Optics can be read at the imgbase-scd-ulp.u-strasbg.fr/displayimage.php?album=44&pos=0 website of the Université de Strasbourg. Cited on page 723.

596 See the text by Raymond L. Lee & Alistair B. Fraser, *The Rainbow Bridge: Rainbows in Art, Myth, and Science*, Pennsylvania State University Press, 2000. A chapter can be found at the www.nadn.navy.mil/Oceanography/RainbowBridge/Chapter_8.html website. Cited on page 726.

597 The beautiful slit experiment was published by E. A. Montie, E. C. Cosman, 't Hooft, van der Mark & C. W. J. Beenakker, Observation of the optical analogue of quantized conductance of a point contact, *Nature* **350**, pp. 594–595, 18 April 1991, and in the longer version E. A. Montie, E. C. Cosman, 't Hooft, van der Mark & C. W. J. Beenakker, Observation of the optical analogue of the quantised conductance of a point contact, *Physica B* **175**, pp. 149–152, 1991. The result was also publicized in numerous other scientific magazines. Cited on pages 727 and 1370.

598 A recent measurement of the frequency of light is presented in Th. Udem, A. Huber, B. Gross, J. Reichert, M. Prevedelli, M. Weitz & T. W. Hausch, Phase-coherent measurement of the hydrogen 1S–2S transition frequency with an optical frequency interval divider chain, *Physical Review Letters* **79**, pp. 2646–2649, 6 October 1997. Another is C. Schwob, L. Jozefowski, de Beauvoir, L. Hilico, F. Nez, L. Julien, F. Biraben, O. Acef & A. Clairon, Optical frequency measurement of the 2S-12D transitions in hydrogen and deuterium: Rydberg constant and Lamb shift determinations, *Physical Review Letters* **82**, pp. 4960–4963, 21 June 1999. Cited on page 728.

599 The discoverors of two such methods were awarded the 2005 Nobel Prize for physics. Cited on page 728.

600 The best introduction to mirages are the web pages by Andrew Young at mintaka.sdsu.edu/GF/mintaka/mirintro.html. He explains the many types that exist: inferior mirages, superior mirages, mock mirages, Wegener-type mirages, etc., and also gives many references, clearly showing which ones give correct and which one give incorrect explanations. There is no modern review article on the topic yet. For a curious aspect, see G. Horváth, J. Gál & R. Wehner, Why are water-seeking insects not attracted by mirages? The polarization pattern of mirages, *Naturwissenschaften* **83**, pp. 300–303, 1997. Cited on page 730.

601 W. K. Haidinger, Über das direkte Erkennen des polarisierten Lichts, *Poggendorf's Annalen* **63**, pp. 29–39, 1844, W. K. Haidinger, Beobachtung des Lichtpolarisationsbüschels in geradlinig polarisiertem Lichte, *Poggendorf's Annalen* **68**, pp. 73–87, 1846, W. K. Haidinger, Dauer des Eindrucks der Polarisationsbüschel auf der Netzhaut, *Poggendorf's Annalen* **93**, pp. 318–320, 1854. Cited on page 730.

602 See the chapter on polarization brushes in Marcel G. J. Minnaert, *Light and Colour in the Outdoors*, Springer, 1993, or the original book series, Marcel G. J. Minnaert, *De natuurkunde van 't vrije veld*, Thieme & Cie, 1937. For more details, see G. P. Mission,

621 The resulting colouring of the Sun's rim is shown clearly on Andrew Young's web page mintaka.sdsu.edu/GF/explain/simulations/std/rims.html. His website mintaka.sdsu.edu/GF offers the best explanation of the green flash, including the various types that exist (explained at mintaka.sdsu.edu/GF/papers/Zenit/glance.html), how to observe it, and the numerous physical effects involved. Detailed simulations and extensive material is available. See also his paper A. T. Young, Sunset science – III. Visual adaptation and green flashes,*Journal of the Optical Society of America A* **17**, pp. 2129–2139, 2000. Cited on page 750.

622 There are also other ways to see the green ray, for longer times, namely when a mirage appears at sunset. An explanation with colour photograph is contained in M. Vollmer, Gespiegelt in besonderen Düften ...– Oasen, Seeungeheuer und weitere Spielereien der Fata Morgana, *Physikalische Blätter* **54**, pp. 903–909, 1998. Cited on page 750.

623 See the wonderful website by Les Cowley on atmospheric optics, www.atoptics.co.uk. Or the book David K. Lynch & William Livingston,*Color and Light in Nature*, second edition, Cambridge University Press, 2001. They updated and expanded the fascination for colours in nature, such as, for example, the halos around the Moon and the Sun, or the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

colour of shadows,, that was started by the beautiful and classic book by Marcel Minnaert mentioned on page 89. Cited on page 750.

624 This famous discovery is by Brent Berlin & Paul Kay, *Basic Color Terms: Their Universality and Evolution*, University of California Press, 1969. Their ongoing *world colour survey* is eagerly awaited. Of course there are also ongoing studies to find possible exceptions; the basic structure is solid, as shown in the conference proceedings C. L. Hardin & Luisa Maffi, *Colour Categories in Thought and Language*, Cambridge University Press, 1997. Cited on page 751.

625 For a thorough discussion of the various velocities connected to wave trains, see the classic text by Louis Brillouin, *Wave Propagation and Group Velocity*, Academic Press, New York, 1960. It expands in detail the theme discussed by Arnold Sommerfeld, Über die Fortpflanzung des Lichtes in dispergierenden Medien, *Annalen der Physik,* 4th series, **44**, pp. 177–202, 1914. See also Arnold Sommerfeld, *Optik*, Dietrichssche Verlagsbuchandlung, Wiesbaden 1950, section 22. An English translation Arnold Sommerfeld, *Lectures on Theoretical Physics: Optics*, 1954, is also available. Cited on pages 753 and 754.

626 Changing the group velocity in fibres is now even possible on demand, as shown by M. González-Herráez, K.-Y. Song & L. Thévenaz, Optically controlled slow and fast light in optical fibers using stimulated Brillouin scattering, *Applied Physics Letters* **87**, p. 081113, 2005. They demonstrate group velocities from $0.24c$ to plus infinity and beyond, to negative values. Cited on page 754.

Another experiment was carried out by S. Chu & S. Wong, Linear pulse propagation in an absorbing medium, *Physical Review Letters* **48**, pp. 738–741, 1982. See also S. Chu & D. Styer, Answer to question #52. Group velocity and energy propagation, *American Journal of Physics* **66**, pp. 659–661, 1998. Another example was described in 1993 by the group of Raymond Chiao for the case of certain nonlinear materials in R. Chiao, P. G. Kwait & A. M. Steinberg, Faster than light?, *Scientific American* **269**, p. 52, August 1993, and R. Y. Chiao, A. E. Kozhekin & G. Kurizki, Tachyonlike excitations in inverted two-level media, *Physical Review Letters* **77**, pp. 1254–1257, 1996. On still another experimental set-up using anomalous dispersion in caesium gas, see L. J. Wang, A. Kuzmich & A. Dogarin, Gain-assisted superluminal light propagation, *Nature* **406**, pp. 277–279, 20 July 2000.

627 Y. P. Terletskii, *Paradoxes in the Theory of Relativity*, Plenum Press, 1968. Cited on page 754.

628 See the excellent explanation by Kirk T. McDonald, Negative group velocity, *American Journal of Physics* **69**, pp. 607–614, 2001. Cited on page 754.

629 The prediction of negative refraction is due to V. G. Veselago, The electrodynamics of substances with simultaneously negative values of ε and μ, *Soviet Physics Uspekhi* **10**, p. 509, 1968. (The original paper in Russian is from 1967.) The explanation with different refraction directions was published by P. M. Valanju, R. M. Walser & A. P. Valanju, Wave refraction in negative-index media: always positive and very inhomogeneous, *Physical Review Letters* **88**, p. 187401, 8 May 2002. Also Fermat's principle is corrected, as explained in V. G. Veselago, About the wording of Fermat's principle for light propagation in media with negative refraction index, arxiv.org/abs/cond-mat/0203451. Cited on page 755.

630 The first example of material system with a negative refraction index were presented by David Smith and his team. R. A. Schelby, D. R. Smith & S. Schultz, Experimental verification of a negative index of refraction, *Science* **292**, p. 77-79, 2001. More recent examples are A. A. Houck, J. B. Brock & I. L. Chuang, Experimental observations

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of a left-handed material that obeys Snell's law, *Physical Review Letters* **90**, p. 137401, 2003, C. G. Parazzoli, R. B. Greegor, K. Li, B. E. C. Koltenbah & M. Tanielian, Experimental verification and simulation of negative index of refraction using Snell's law, *Physical Review Letters* **90**, p. 107401, 2003. S. Foteinopoulou, E. N. Economou & C. M. Soukoulis, Refraction in media with a negative refractive index, *Physical Review Letters* **90**, p. 107402, 2003. Cited on page 755.

Cited on page 756.

635 G. Nimtz, A. Enders & H. Spieker, *Journal de Physique I (Paris)* **4**, p. 565, 1994. Unfortunately, Nimtz himself seems to believe that he transported energy or signals faster than light; he is aided by the often badly prepared critics of his quite sophisticated experiments. See A. Enders & G. Nimtz, *Physikalische Blätter* **49**, p. 1119, Dezember 1993, and the weak replies in *Physikalische Blätter* **50**, p. 313, April 1994. See also A. M. Steinberg, *Journal de Physique I (Paris)* **4**, p. 1813, 1994, A. M. Steinberg, P. G. Kwiat & R. Y. Chiao, *Physical Review Letters* **71**, pp. 708–711, 1993, and A. Ranfagni, P. Fabeni, G. P. Pazzi & D. Mugnai, *Physical Review E* **48**, p. 1453, 1993. Cited on page 757.

636 A summary of all evidence about the motion of the aether is given by R. S. Shankland, S. W. McCuskey, F. C. Leone & G. Kuerti, New analysis of the interferometer observations of Dayton C. Miller, *Review of Modern Physics* **27**, pp. 167–178, 1955. An older text is H. Witte, *Annalen der Physik* **26**, p. 235, 1908. Cited on page 758.

637 The history of the concept of vacuum can be found in the book by E. Grant, *Much Ado About Nothing*, Cambridge University Press, 1981, and in the extensive reference text by Edmund T. Whittaker, *A History of the Theories of Aether and Electricity*, Volume 1: *The Classical Theories*, Volume 2: *The Modern Theories*, Tomash Publishers, American Institute of Physics 1951, 1987. Cited on page 758.

The various *aether models* – gears, tubes, vortices – proposed in the nineteenth century were dropped for various reasons. Since many models used to explain electric and magnetic fields as motion of some entities, it was concluded that the speed of light would depend on electric or magnetic fields. One type of field was usually described by linear motion of the entities, the other by rotatory or twisting motion; both assignments are possible. As a consequence, aether must be a somewhat strange fluid that flows perfectly, but that resists rotation of volume elements, as McCullogh deduced in 1839. However, experiments show

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

that the speed of light in vacuum does not depend on electromagnetic field intensity. Vortices were dropped because real world vortices were found out to be unstable. All models received their final blow when they failed to meet the requirements of special relativity.

638 This happened to Giovanni Bellini (*c.* 1430–1516) the great Venetian Renaissance painter, who even put this experience into writing, thus producing one of the greatest 'gaffes' ever. If you take a photograph of the effect with a remotely controlled camera, you can prove that your camera is holy as well. Cited on page 760.

675 W. T. Scott, Who was Earnshaw?, *American Journal of Physics* **27**, pp. 418–419, 1959. Cited on page 783.

676 The trick is to show that $\operatorname{div} \boldsymbol{E} = 0$, $\operatorname{curl} \boldsymbol{E} = 0$, thus $E\nabla^2 E = 0$ and, from this, $\nabla^2 E^2 \geqslant 0$; there are thus no local electric field maxima in the absence of free charges. The same proof works for the magnetic field. However, bodies with dielectric constants *lower* than their environment *can* be levitated in static electric fields. An example is gas bubbles in liquids, as shown by T. B. Jones & G. W. Bliss, Bubble dielectrophoresis, *Journal of Applied Physics* **48**, pp. 1412–1417, 1977. Cited on page 783.

677 See A. K. Geim, M. D. Simon, M. I. Boamfa & L. O. Heflinger, Magnet levitation at your fingertips, *Nature* **400**, pp. 323–324, 1999. Cited on page 784.

Ertmer, *Europhysics Letters* **34**, p. 651, 1996, D. Haubrich, H. Schadwinkel, F. Strauch, B. Ueberholz, R. Wynands & D. Meschede, *Europhysics Letters* **34**, p. 663, 1996. Cited on page 785.

680 See for example Mark Buchanan, And God said...let there be levitating strawberries, flying frogs and humans that hover over Seattle, *New Scientist* pp. 42–43, 26 July 1997, or C. Wu, Floating frogs, *Science News* **152**, pp. 632–363, 6 December 1997, and C. Wu, Molecular magnetism takes off, *Physics World* April 1997, page 28. The experiments by Andre Geim, Jan Kees Maan, Humberto Carmona and Peter Main were made public by P. Rodgers, *Physics World* **10**, p. 28, 1997. Some of the results can be found in M. V. Berry & A. K. Geim, Of flying frogs and levitrons, *European Journal of Physics* **18**, pp. 307–313, 1997. See also their www-hfml.sci.kun.nl/hfml/levitate.html website. Cited on page 785.

681 The well-known toy allows levitation without the use of any energy source and is called the 'Levitron'. It was *not* invented by Bill Hones of Fascination Toys & Gifts in Seattle, as the www.levitron.com website explains. The toy is discussed by Ron Edge, Levitation using only permanent magnets, *Physics Teacher* **33**, p. 252, April 1995. It is also discussed in M. V. Berry, The Levitron^{TM}: an adiabatic trap for spins, *Proceedings of the Royal Society A* **452**, pp. 1207–1220, 1996, (of Berry's phase fame) as well as by M. D. Simon, L. O. Heflinger & S. L. Ridgeway, Spin stabilized magnetic levitation, *American Journal of Physics* **65**, pp. 286–92, 1997, and by T. B. Jones, M. Washizu & R. Gans, Simple theory for the Levitron, *Journal of Applied Physics* **82**, pp. 883–889, 1997. Cited on page 786.

682 The drill trick and the building of a Levitron are described in the beautiful lecture script by Josef Zweck, *Physik im Alltag*, Skript zur Vorlesung im WS 1999/2000 der Universität Regensburg. Cited on page 786.

683 The prediction about quantized levitation is by Stephen B. Haley, Length quantization in levitation of magnetic microparticles by a mesoscopic superconducting ring, *Physical Review Letters* **74**, pp. 3261–3264, 1995. The topic is discussed in more detail in Stephen B. Haley, Magnetic levitation, suspension, and superconductivity: macroscopic and mesoscopic, *Physical Review B* **53**, p. 3506, 1996, reversed in order with Stephen B. Haley, Quantized levitation of superconducting multiple-ring systems, *Physical Review B* **53**, p. 3497, 1996, as well as Stephen B. Haley, Quantized levitation by multiply-connected superconductors, LT-21 Proceedings, in *Czechoslovak Journal of Physics* **46**, p. 2331, 1996. In 1998, there was not yet an experimental confirmation (Stephen Haley, private communication). Cited on page 786.

684 Detailed descriptions of many of these effects can be found in the excellent overview edited by Manfred von Ardenne, Gerhard Musiol & Siegfried Reball, *Effekte der Physik und ihre Anwendungen*, Harri Deutsch, 2004. Cited on page 786.

700 See for example the beautiful textbook by Stephen C. Stearns & Rolf F. Hoekstra, *Evolution: An Introduction*, Oxford University Press, 2000. For fascinating story of evolution for non-specialists, see Richard Fortey, *Life – An Unauthorized Biography*, Harper Collins, 1997, or also Menno Schilthuizen, *Frogs, Flies & Dandelions – the Making of Species*, Oxford University Press/ 2001. See also Stephen J. Gould, *The Panda's thumb*, W.W. Norton & Co., 1980, one of the several interesting and informative books on evolutionary biology by the best writer in the field. An informative overview over the results of evolution, with the many-branched family tree that it produced, is given on the phylogeny.arizona.edu/tree website. About the results of evolution for human beings, see the informative text by K. Kusch & S. Kusch, *Der Mensch in Zahlen*, Spektrum Akademischer Verlag, 2nd edn., 2000. The epochal work by Charles Darwin, *On the Origin of Species*, can be found on the web, e.g. on the entisoft.earthlink.net/origspec.htm and on the www.darwin-online.org.uk websites. Cited on page 805.

701 A simple description is Malcolm Ross Macdonald, *The Origin of Johnny*, Jonathan Cape, 1976. See also Bas Haring, *Kaas en de evolutietheorie*, Houtekiet, 2001. Cited on page 805.

702 Richard Bandler, *Using Your Brain for a Change*, Real People Press, p. 18, 1985. Cited on page 805.

703 There is disagreement among experts about the precise timing of this experience. Some say that only birth itself is that moment. However, there are several standard methods to recall memories of early life, even of the time before birth; one is described and used by J. K. Stettbacher, *Making Sense of Suffering*, Penguin, New York, 1991, translated from the German original. Even more impressive examples are given by N. J. Mayer, *Der Kainkomplex – neue Wege der systemischen Familientherapie*, Integral Verlag, 1998. Cited on page 805.

704 Sanjida O'Connell, *Mindreading – How We Learn to Love and Lie*, Arrow, 1998. This interesting book describes the importance of lying in the development of a human being, and explains the troubles those people have who cannot read other minds and thus cannot lie, such as autistics. Cited on pages 807 and 840.

705 The approach to describe observations as related parts is called structuralism; the starting point for this movement was de Saussure's *Cours de linguistique générale* (see the footnote on page 817). A number of thinkers have tried to use the same approach in philosophy, mythology and literature theory, though with little success. An overview of the (modest) success of structuralism in linguistics and its failure in other fields is given by L. Jackson, *The Poverty of Structuralism: Literature and Structuralist Theory*, Longman, 1991. The author argues that when one reduces systems to interactions, one neglects the specific content and properties of the elements of the system, and this approach prevents a full understanding of the system under discussion. Cited on page 807.

706 For a view of the mental abilities different from that of Piaget (described on page 807), a presently much discussed author is the Soviet experimental psychologist Lev Vigotsky, whose path-breaking ideas and complicated life are described, e.g., in Lev Vigotsky, *Mind in Society*, Harvard University Press, 1978, or in René van der Veer & Jaan Valsiner, *Understanding Vigotsky: a Quest for Synthesis*, Blackwell Publishers, 1994. More extensive material can be found in the extensive work by René van der Veer & Jaan Valsinger, *The Vigotsky Reader*, Blackwell, 1994. Cited on page 807.

707 A somewhat unconventional source for more details is the beautiful text by Bruno Bettelheim, The Uses of Enchantment: the Meaning and Importance of Fairy Tales, Knopf, 1976. Cited on page 808.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

708 A simple introduction is MANFRED SPITZER, *Lernen – Gehirnforschung und Schule des Lebens*, Elsevier, 2007. Cited on page 808.

709 Quoted in V. HARLEN, R. RAPPMANN & P. SCHATA, *Soziale Plastik – Materialien zu Joseph Beuys*, Achberger Verlag, 1984, p. 61. Cited on page 808.

710 The problems appearing when one loses the ability to classify or to memorise are told in the beautiful book by the neurologist OLIVER SACKS, *The Man Who Mistook His Wife for a Hat*, Picador, 1985, which collects many case studies he encountered in his work. More astonishing cases are collected in his equally impressive text *An Anthropologist on Mars*, Picador, 1995.

See also the beautiful text DONALD D. HOFFMAN, *Visual Intelligence – How We Create What We See*, W.W. Norton & Co., 1998, and the ari.ss.uci.edu/cogsci/personnel/hoffman.html website associated to it. Cited on pages 808 and 811.

711 For a passionate introduction to the connections between language and the brain from a Chomskian perspective, see the bestselling book by STEVEN PINKER, *The Language Instinct – How the Mind Creates Language*, Harper Perennial, 1994. The green idea sentence is discussed in a chapter of the book. Cited on pages 808, 845, and 862.

712 An introduction to neurology is JOSEPH LEDOUX, *Synaptic Self: How Our Brains Become Who We Are*, Viking Press, 2002. Cited on page 808.

713 An overview of the status of the research into the origin of bipedalism is given by B. WOOD, Four legs good, two legs better, *Nature* **363**, pp. 587–588, 17 June 1983. Cited on page 808.

714 A good introduction into the study of classifiers is JAMES A. ANDERSON, *An Introduction to Neural Networks*, MIT Press, 1995. An introduction to computer science is given in GLENN BROOKSHEAR, *Computer Science, An Overview*, 6th edition, Addison Wesley, 2000, or in RICK DECKER & STUART HIRSHFIELD, *The Analytical Engine: An Introduction to Computer Science Using the Internet*, Brooks/Cole Publishers, 1998. Cited on page 808.

715 More about the connection between entropy and computers can be found in the classic paper by R. LANDAUER, Irreversibility and heat generation in the computing process, *IBM Journal of Research and Development* **5**, pp. 183–191, 1961, and in C. H. BENNETT & R. LANDAUER, The fundamental physical limits of computation, *Scientific American* **253**, pp. 48–56, 1985. Cited on page 813.

716 W. H. ZUREK, Thermodynamic cost of computation, algorithmic complexity and the information metric, *Nature* **341**, pp. 119–124, 14 August 1989. Cited on page 813.

717 L. SZILARD, Über die Entropieverminderung in einem thermodynamischen System bei Eingriffen intelligenter Wesen, *Zeitschrift für Physik* **53**, p. 840, 1929. This classic paper can also be found in English translation in the collected works by Leo Szilard. Cited on page 813.

718 J.J. Hopfield/ *Nature* **376**, pp. 33–36, 1995. This paper by one of the fathers of the field presents one possibility by which the *timing* of nerve signals, instead of the usually assumed firing frequency, could also carry information. Cited on page 813.

719 The details of the properties of the firing patterns of neurons are nicely described in the article by M. MAHOWALD & R. DOUGLAS, A silicon neuron, *Nature* **354**, pp. 515–518, 19/26 December 1991, in which they show how to simulate a neuron's electrical behaviour using a silicon circuit. Cited on page 813.

720 A. MECHELLI, J. T. CRINION, U. NOPPENEY, J. O'DOBERTY, J. ASHBURNER, R. S. FRACKOWIAK & C. J. PRICE, Neurolinguistics: structural plasticity in the bilingual brain, *Nature* **431**, p. 757, 2004. Cited on page 814.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

721 The discussion whether the brain is or is not superior to a computer is nicely summarised by G. Vollmer, Algorithmen, Gehirne, Computer – Was sie können und was sie nicht können, Teil I und Teil II, *Naturwissenschaften* **78**, p. 481, 1991, and **78**, pp. 533–542, 1991. Cited on page 815.

722 However, the language with the largest available dictionary is Dutch, with the 40 volumes of the Wordenboek der Nederlandsche Taal, which appeared between 1864 and 1998. It has almost 400 000 entries. Cited on page 818.

723 The list and the remark on discovery on concepts is due to a personal communication from Anna Wierzbicka. A longer list is published in her book *Semantics, Primes and Universals*, Oxford University Press, 1996. Cited on pages 819 and 838.

724 W. S. Hatcher, *Foundations of Mathematics*, W.B. Saunders Co., Philadelphia, 1968. There is also the article by P. J. Cohen & R. Hersch, Non-Cantorian set theory, *Scientific American* **217**, pp. 104–116, 1967. Cohen was the mathematician who in 1963 proved that the negation of the continuum hypothesis could be added to the axioms of set theory and still produce a consistent theory; he calls such sets *non-Cantorian*. Cited on page 824.

725 See the beautiful article by I. Stewart, Fair shares for all, *New Scientist*, pp. 42–46, 17 June 1995. Cited on page 824.

726 The proof of the independence of the continuum hypothesis came in two parts. First, Kurt Gödel proved in 1940 that an axiom can be consistently added to ZFC set theory so that the continuum hypothesis is correct. Then, in 1963, Paul Cohen proved that an axiom can be consistently added to ZFC set theory so that the continuum hypothesis is false. Cited on page 826.

727 Rudy Rucker, *Infinity and the Mind – the Science and Philosophy of the Infinite*, Bantam, Toronto, 1983. Cited on page 826.

728 This general division of mathematics is nicely explained in the text by Pierre Basieux, *Die Architektur der Mathematik – Denken in Strukturen*, Rororo, 2000. Cited on page 827.

729 The issue is treated in Thomas Aquinas, *Summa Theologica*, in question 52 of the first part. The complete text, several thousand pages, can be found on the www.newadvent.org website. We come back to it in the part on quantum theory, in the section on the Pauli exclusion principle. It seems that the whole question goes back to Peter (the) Lombard, *Liber Sententiarum c.* 1150. Cited on page 828.

799 Following a private communication by Richard Rusby, this is the value of 1997, whereas it was estimated as 99.975 °C in 1989, as reported by Gareth Jones & Richard Rusby, Official: water boils at 99.975 °C, *Physics World* **2**, pp. 23–24, September 1989, and R. L. Rusby, Ironing out the standard scale, *Nature* **338**, p. 1169, March 1989. For more details on temperature measurements, see page 349. Cited on page 918.

800 J. Short, Newton's apples fall from grace, *New Scientist*, **2098**, p. 5, 6 September 1997. More details can be found in R. G. Keesing, The history of Newton's apple tree, *Contemporary Physics* **39**, pp. 377–391, 1998. Cited on page 919.

801 The various concepts are even the topic of a separate international standard, ISO 5725, with the title *Accuracy and precision of measurement methods and results*. A good introduction is John R. Taylor, *An Introduction to Error Analysis: the Study of Uncertainties in Physical Measurements*, 2nd edition, University Science Books, Sausalito, 1997. Cited on page 920.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

802 P. J. Mohr & B. N. Taylor, CODATA recommended values of the fundamental physical constants: 1998, *Reviews of Modern Physics* **59**, p. 351, 2000. This is the set of constants resulting from an international adjustment and recommended for international use by the Committee on Data for Science and Technology (CODATA), a body in the International Council of Scientific Unions, which brings together the International Union of Pure and Applied Physics (IUPAP), the International Union of Pure and Applied Chemistry (IUPAC) and other organizations. The website of IUPAC is www.iupac.org. Cited on pages 920 and 921.

803 The details are given in the well-known astronomical reference, Kenneth Seidelmann, *Explanatory Supplement to the Astronomical Almanac*, 1992. Cited on page 924.

804 For information about the number π, as well as about other constants, the website oldweb.cecm.sfu.ca/pi/pi.html provides lots of data and references. It also has a link to the overview at mathworld.wolfram.com/Pi.html and to many other sites on the topic. Simple formulae for π are

$$\pi + 3 = \sum_{n=1}^{\infty} \frac{n\, 2^n}{\binom{2n}{n}} \tag{570}$$

or the beautiful formula discovered in 1996 by Bailey, Borwein and Plouffe

$$\pi = \sum_{n=0}^{\infty} \frac{1}{16^n} \left(\frac{4}{8n+1} - \frac{2}{8n+4} - \frac{1}{8n+5} - \frac{1}{8n+6} \right) . \tag{571}$$

The site also explains the newly discovered methods for calculating specific binary digits of π without having to calculate all the preceding ones. By the way, the number of (consecutive) digits known in 1999 was over 1.2 million million, as told in *Science News* **162**, p. 255, 14 December 2002. They pass all tests of randomness, as the mathworld.wolfram.com/PiDigits.html website explains. However, this property, called *normality*, has never been proven; it is the biggest open question about π. It is possible that the theory of chaotic dynamics will lead to a solution of this puzzle in the coming years.

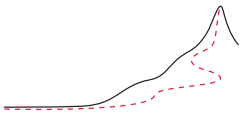
Another method to calculate π and other constants was discovered and published by D. V. Chudnovsky & G. V. Chudnovsky, The computation of classical constants, *Proceedings of the National Academy of Sciences (USA)* **86**, pp. 8178–8182, 1989. The Chudnowsky brothers have built a supercomputer in Gregory's apartment for about 70 000 euros, and for many years held the record for calculating the largest number of digits of π. They have battled for decades with Kanada Yasumasa, who held the record in 2000, calculated on an industrial supercomputer. New formulae to calculate π are still occasionally discovered.

For the calculation of Euler's constant γ see also D. W. DeTemple, A quicker convergence to Euler's constant, *The Mathematical Intelligencer*, pp. 468–470, May 1993.

Challenge 1328 r
Challenge 1329 s

Note that little is known about the basic properties of some numbers; for example, it is still not known whether $\pi + e$ is a rational number or not! (It is believed that it is not.) Do you want to become a mathematician? Cited on page 926.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



CHALLENGE HINTS AND SOLUTIONS

Challenge 996, page 674: The liquid drops have to detach from the flow exactly inside the metal counter-electrodes. There is always a tiny charge somewhere on the metal structures (due to cosmic rays, rubbing, previous charging, etc.). In Figure 420, this initial charge is the positive charge drawn on the lower left and upper right metal structure. When the water droplets form, they get a charge that is opposite to that of the metal surrounding the region where they form. The negative droplets fall into the other metal structure. Through the negative charge accumulating there, the positive charge in the first structure increases. When the charge on the metal structure increases, the charge separation in the droplets is more efficient. In other words, water droplet formation inside the metal structures *amplifies* any initial charge. After a while, the charge value and the associated voltage are so high that it leads to a loud bang (if everything is dry, including the air.) Then the process starts again. In fact, a vaguely similar charge separation mechanism leads to cloud charging and to lightning. If you want to build a Kelvin generator at home, have a look at the de.wikipedia.org/wiki/Kelvin-Generator web page, or search for other internet site on the topic.

To avoid the sparks in the fuel tanks of its cars, Opel simply earthed the metal tube at the tank inlet; they had forgotten to ensure electric contact between the tube and the rest of the car.

The explosion of fuel can also occur if you pour fuel into your car from a metal container. Several times, fuel thieves were 'punished' by an explosion triggered by static electricity when they tried to pour stolen fuel into their own car.

On every airport you can see how the problem is avoided: before even attaching the fuel tube to an aeroplane, the worker attaches a conducting cable to connect the truck (or the tank) to the aeroplane.

Challenge 997, page 674: We look at the two spark through a rapidly rotating mirror. In this way, small timing differences lead to position differences of the two sparks. In the 19th century, the speed values measured in this way varied between 6000 km/s and way over 100 000 km/s, because the speed depends on the effective capacitance and inductivity of wire and set-up. Only if these effects can be neglected is the measured speed the same as that of light in vacuum, namely around 300 000 km/s. In modern cables, the speed is often around a third of this value.

Page 682

Challenge 998, page 674: A lot of noise appeared while the metal pendulum banged wildly between the two fixed bells.

Challenge 999, page 677: No.

Challenge 1001, page 678: The field at a distance of 1 m from an electron is 1.4 nV/m.

Challenge 1002, page 678: A simple geometrical effect: anything flowing out homogeneously from a sphere diminishes with the square of the distance.

Challenge 1003, page 679: One has $F = \alpha\hbar c N_A^2/4R^2 = 3 \cdot 10^{12}$ N, an enormous force, corresponding to the weight of 300 million tons. It shows the enormous forces that keep matter together. Obviously, there is no way to keep 1 g of positive charge together, as the repulsive forces among the charges would be even larger.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

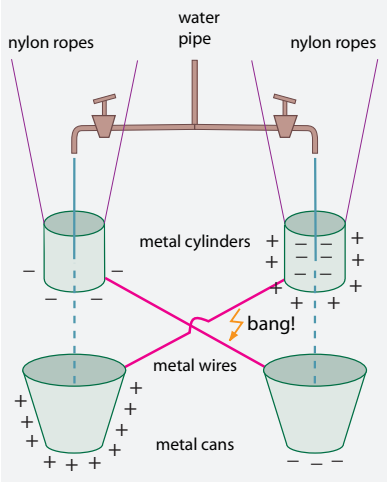


FIGURE 420 The key process in the Kelvin generator: charge separation during droplet formation

Challenge 1004, page 680: To show the full equivalence of Coulomb's and Gauss's 'laws', first show that it holds for a single point charge. Then expand the result for more than one point charge. That gives Gauss's 'law' in integral form, as given just before this challenge.

To deduce the integral form of Gauss's 'law' for a single point charge, one has to integrate over the closed surface. The essential point here is to note that the integration can be carried out for an inverse square dependence only. This dependence allows to transform the scalar product between the local field and the area element into a normal product between the charge and the solid angle Ω:

$$\boldsymbol{E}\,\mathrm{d}\boldsymbol{A} = \frac{q\mathrm{d}A\cos\theta}{4\pi\varepsilon_0 r^2} = \frac{q\mathrm{d}\Omega}{4\pi\varepsilon_0}\,. \tag{572}$$

In case that the surface is closed the integration is then straightforward.

To deduce the differential form of (the static) Gauss's 'law', namely

$$\nabla\boldsymbol{E} = \frac{\rho}{\varepsilon_0}\,, \tag{573}$$

make use of the definition of the charge density ρ and of the purely mathematical relation

$$\int_{\mathrm{closedsurface}} \boldsymbol{E}\,\mathrm{d}\boldsymbol{A} = \int_{\mathrm{enclosedvolume}} \nabla\boldsymbol{E}\,\mathrm{d}V\,, \tag{574}$$

This mathematical relation, valid for any vector field $\boldsymbol{E}$, is called *Gauss's theorem*. It simply states that the flux is the volume integral of the divergence.

To deduce the full form of Gauss's law, including the time-derivative of the magnetic field, include relativistic effects by changing viewpoint to a moving observer.

Challenge 1006, page 680: No; batteries only separate charges and pump them around.

Challenge 1007, page 680: Uncharged bodies can attract each other if they are made of charged constituents neutralizing each other, and if the charges are constrained in their mobility. The charge fluctuations then lead to attraction. Most molecules interact among each other in this way; such forces are also at the basis of surface tension in liquids and thus of droplet formation.

Challenge 1009, page 682: The ratio q/m of electrons and that of the free charges inside metals is not exactly the same.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1011, page 683: Find out a way to test the issue, perform the experiment, and publish it!

Challenge 1012, page 684: If you can, publish the result. Researchers have tried to put people on the ocean during clouded days, have tried experiments in dark rooms, but nothing has been found so far. The experiences of people in magnetic resonance imaging equipment is inconclusive so far.

Challenge 1014, page 689: No.

Challenge 1016, page 690: The correct version of Ampère's 'law' is

$$\nabla \times \boldsymbol{B} - \frac{1}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{j} \tag{575}$$

whereas the expression mentioned in the text misses the term $\frac{\partial \boldsymbol{E}}{\partial t}$.

For another way to state the difference, see Richard P. Feynman, Robert B. Leighton & Matthew Sands, *The Feynman Lectures on Physics*, volume II, Addison Wesley, p. 21-1, 1977.

Challenge 1017, page 691: Only boosts with relativistic speeds mix magnetic and electric fields to an appreciable amount.

Challenge 1019, page 691: The dual field $*\boldsymbol{F}$ is defined on page 707.

Challenge 1021, page 692: Scalar products of four vectors are always, by construction, Lorentz invariant quantities.

Challenge 1024, page 693: Almost all neutral particles are made of charged ones. So the argument holds for them as well. There is only one exception: neutrinos. For them, the argument is not valid.

Challenge 1025, page 693: The signal speed in metals is higher than the electron speed, namely around the speed of light. This speed determines the magnetic field strength.

Page 773

Challenge 1026, page 695: The illumination of the sun changes the ionization in the upper atmosphere and provokes convection in the ionosphere. The tides move the ions in the ocean and in the atmosphere. These currents lead to magnetic fields which can be seen in sensitive compass needles.

Page 699

Challenge 1027, page 695: If you find such an effect and are able to demonstrate it, publish it in a didactic journal.

Challenge 1028, page 695: Usually, the cables of high voltage lines are too warm to be comfortable.

Challenge 1029, page 695: Blond children tend to have the thinnest hair, thus giving the greatest effect. Dry weather is needed to avoid that the moisture in the air discharges the head thus preventing the hair to raise at all.

Challenge 1030, page 695: Move them to form a T shape.

Challenge 1032, page 696: For three and more switches, on uses inverters; an inverter is a switch with two inputs and two outputs which in one position, connects first and second input to first and second output respectively, and in the other position connects the first input to the second output and vice versa. (There are other possibilities, though; wires can be saved using electromagnetic relay switches.)

Challenge 1034, page 697: It is possible; however, the systems so far are not small and are dangerous for human health. The idea to collect solar power in deep space and then beam it to the Earth as microwaves has often been aired. Finances and dangers have blocked it so far.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1036, page 697: Glue two mirrors together at a right angle. Or watch yourself on TV using a video camera.

Challenge 1037, page 698: This is again an example of combined triboluminescence and triboelectricity. See also the websites scienceworld.wolfram.com/physics/Triboluminescence.html and www.geocities.com/RainForest/9911/tribo.htm.

Challenge 1039, page 699: Pepper is lighter than salt, and thus reacts to the spoon before the salt does.

Challenge 1040, page 700: For a wavelength of 546.1 nm (standard green), that is a bit over 18 wavelengths.

Challenge 1041, page 700: The angular size of the Sun is too large; diffraction plays no role here.

Challenge 1042, page 700: Just use a high speed camera.

Challenge 1043, page 700: The current flows perpendicularly to the magnetic field and is thus deflected. It pulls the whole magnet with it.

Challenge 1044, page 701: Light makes seven turns of the Earth in one second.

Challenge 1045, page 701: At 10 pc=32.6 al, the Sun would have apparent magnitude 4.7. At 20 pc=65.2 al, it would appear 4 times fainter, thus about 1.5 magnitudes more, therefore with an apparent visual magnitude of about 6.2. This is near the limit magnitude of the eye. The actual limiting magnitude of the eye is neither constant nor universal, so the distance of 50 light years is not a sharo limit. The limiting magnitude, – like the night vision, or *scotopic sensitvity* – depends on the partial pressure of oxygen in the atmosphere the observer is breathing, on the clarity of the air, on the zenith distance, and, above all, on the degree of dark adaptation. An eye exposed to the full brightness of the night sky in a very dark location far from light pollution is still not completely dark-adapted. You can easily see 7th-magnitude stars by blocking off most of the sky and just looking at a little patch of it. Some observers, under ideal conditions, have reliably reported seeing stars near 8th magnitude.

Challenge 1047, page 702: The most simple equivalent to a coil is a rotating mass being put into rotation by the flowing water. A transformer would then be made of two such masses connected through their axis.

Challenge 1050, page 702: The charged layer has the effect that almost only ions of one charge pass the channels. As a result, charges are separated on the two sides of the liquid, and a current is generated.

Challenge 1053, page 703: Leakage currents change the picture. The long term voltage ratio is given by the leakage resistance ratio $V_1/V_2 = R_1/R_2$, as can be easily verified in experiments.

Challenge 1061, page 709: Some momentum is carried away by the electromagnetic field.

Challenge 1062, page 710: Field lines and equipotential surfaces are always orthogonal to each other. Thus a field line cannot cross an equipotential surface twice.

Challenge 1073, page 716: The argument is the same as for the increase in entropy: reverse processes are possible, but the probability is so low that they do not appear in practice. The extremely low probability is due to the fluctuations induced by the environment.

Challenge 1074, page 717: Just draw a current through a coil with its magnetic field, then draw the mirror image of the current and redraw the magnetic field.

Challenge 1075, page 717: Other asymmetries in nature include the helicity of the DNA molecules making up the chromosomes and many other molecules in living systems, the right hand preference of most humans, the asymmetry of fish species which usually stay flat on the bottom of the seas.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1076, page 718: This is not possible at all using gravitational or electromagnetic systems or effects. The only way is to use the weak nuclear interaction, as shown in the chapter on the nucleus.

Page 1275

Challenge 1077, page 718: The Lagrangian does not change if one of the three coordinates is changed by its negative value.

Challenge 1078, page 718: The image flips up: a 90 degree rotation turns the image by 180 degrees.

Challenge 1079, page 718: Imagine E and B as the unite vectors of two axes in complex space. Then any rotation of these axes is also a generalized duality symmetry.

Challenge 1080, page 719: The fine structure constant is changed to its inverse value. Thus 1/137.036 becomes 137.036. This implies that the particle and the vacuum concept change completely. It is possible, nowadays, to make sense of this so-called *strong-coupling* situation; that is the reason for the general interest of theoreticians into dualities.

Challenge 1081, page 721: The angular momentum was put into the system when it was formed. If we bring a point charge from infinity along a straight line to its final position close to a magnetic dipole, the magnetic force acting on the charge is not directed along the line of motion. It therefore creates a non-vanishing torque about the origin. See J. M. Aguirregabiria & A. Hernandez, The Feynman paradox revisited, *European Journal of Physics* 2, pp. 168–170, 1981.

Challenge 1082, page 722: Show that even though the radial magnetic field of a spherical wave is vanishing by definition, Maxwell's equations would require it to be different from zero. Since electromagnetic waves are transversal, it is also sufficient to show that it is impossible to comb a hairy sphere without having a (double) vortex or two simple vortices. Despite these statements, quantum theory changes the picture somewhat: the emission probability of a photon from an excited atom in a degenerate state is spherically symmetric exactly.

Challenge 1086, page 722: The emitted radiation is strongly suppressed because the size of the dipole (the plug) is much smaller than the wavelength of the field.

Challenge 1088, page 726: In every case of interference, the energy is redistributed into other directions. This is the general rule; sometimes it is quite tricky to discover this other direction.

Challenge 1089, page 726: The author regularly sees about 7 lines; assuming that the distance is around 20 μm, this makes about 3 μm per line. The wavelength must be smaller than this value and the frequency thus larger than 100 THz. The actual values for various colours are given in the table of the electromagnetic spectrum.

Challenge 1091, page 727: He noted that when a prism produces a rainbow, a thermometer placed in the region after the colour red shows a temperature rise.

Challenge 1092, page 729: Birefringence appears when the refraction is polarization dependent. Only two linear independent polarizations are possible, thus there is no trirefringence in nature. This holds true also for crystals which have three different indices of refraction in three directions!

Challenge 1093, page 730: Light reflected form a water surface is partly polarized. Mirages are not.

Challenge 1097, page 735: Figure 421 shows the transverse field E_t drawn in red. We assume that the charge moves at a small initial velocity v_0 and decelerates to zero velocity during a time t_0. After a time T has elapsed, the radiation pulse has travelled a distance $R = cT$, where $T \ll t_0$. The figure shows that the transverse field E_t is related to the radial field E_r by

$$\frac{E_t}{E_r} = \frac{v_0 T \sin\theta}{c t_0} = \frac{aR \sin\theta}{c^2} \,. \tag{576}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

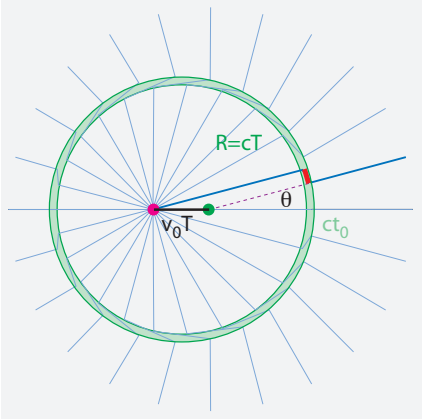

FIGURE 421 Calculating the transverse field of an accelerated charge

Inserting Coulomb's expression for the radial field one gets

$$E_t = \frac{1}{4\pi\varepsilon_0 c^2}\frac{a\sin\theta}{R} \,. \tag{577}$$

The magnitude of the transversal field depends on the angle θ; this is clearly visible in Figure 363 on page 736.

Challenge 1098, page 737: Such an observer would experience a wavy but static field, which cannot exist, as the equations for the electromagnetic field show.

Challenge 1099, page 737: You would never die. Could you reach the end of the universe?

Challenge 1100, page 738: Syrup shows an even more beautiful effect in the following setting. Take a long transparent tube closed at one end and fill it with syrup. Shine a red helium–neon laser into the tube from the bottom. Then introduce a linear polarizer into the beam: the light seen in the tube will form a spiral. By rotating the polarizer you can make the spiral advance or retract. This effect, called the *optical activity* of sugar, is due to the ability of sugar to rotate light polarization and to a special property of plants: they make only one of the two mirror forms of sugar.

Challenge 1101, page 739: The thin lens formula is

$$\frac{1}{d_o} + \frac{1}{d_i} = \frac{1}{f} \,. \tag{578}$$

It is valid for diverging and converging lenses, as long as their own thickness is negligible. The strength of a lens can thus be measured with the quantity $1/f$. The unit $1\,\mathrm{m}^{-1}$ is called a *diopter*; it is used especially for reading glasses. Converging lenses have positive, diverging lenses negative values.

However, the thin lens formula is only an approximation, and is never used in lens design. It is a relic of old textbooks. Modern lens designers always use Gaussian optic for calculations. (See, for example, Francis A. Jenkins & Harvey E. White, *Fundamentals of Optics*, McGraw-Hill, 1957.)

Challenge 1103, page 740: A light microscope is basically made of two converging lenses. One lens – or lens system – produces an enlarged real image and the second one produces an enlarged virtual image of the previous real image. Figure 422 also shows that microscopes always turn images upside down. Due to the wavelength of light, light microscopes have a maximum resolution

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

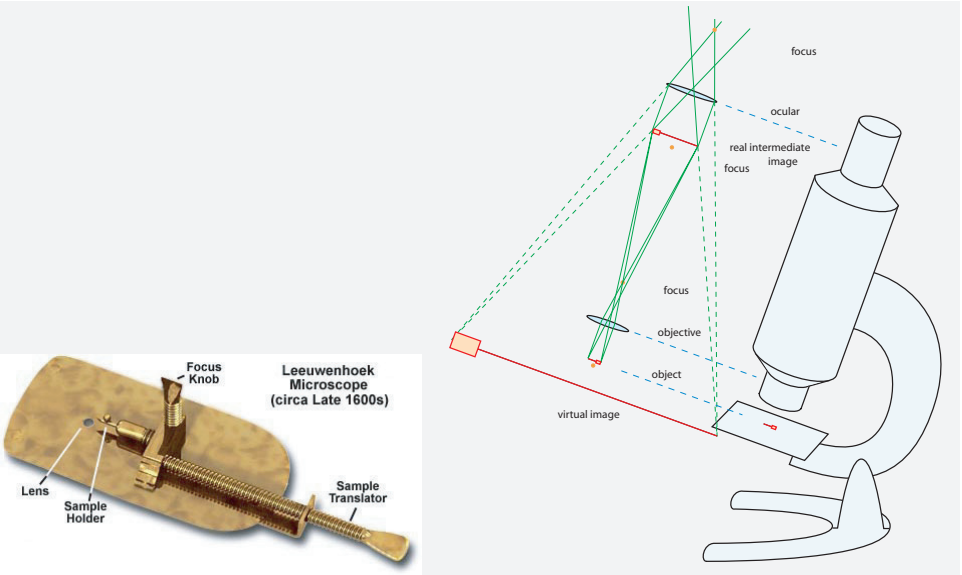

FIGURE 422 One lens made the first microscope (length *c.* 8 cm, to be held close to the eye) but two converging lenses make a modern microscope

of about 1 µm. Note that the magnification of microscopes is unlimited; what is limited is their resolution. This is exactly the same behaviour shown by digital images. The *resolution* is simply the size of the smallest possible pixel that makes sense.

Challenge 1105, page 741: The dispersion at the lens leads to different apparent image positions, as shown in Figure 423. For more details on the dispersion in the human eye and the ways of using it to create three-dimensional effects, see the article by C. Ucke & R. Wolf, Durch Farbe in die dritte Dimension, *Physik in unserer Zeit* **30**, pp. 50–53, 1999.

Challenge 1106, page 741: The 1 mm beam would return 1000 times as wide as the 1 m beam. A perfect 1 m-wide beam of green light would be 209 m wide on the Moon; can you deduce this result from the (important) formula that involves distance, wavelength, initial diameter and final diameter? Try to guess this beautiful formula first, and then deduce it. In reality, the values are a few times larger than the theoretical minimum thus calculated. See the www.csr.utexas.edu/mlrs and ilrs.gsfc.nasa.gov websites.

Challenge 1107, page 741: It is often said that evolution tuned the number of cones in the eye to the maximum resolution with open pupil; the experts on the subject however maintain that there are somewhat larger numbers of cones.

Challenge 1108, page 741: The answer should lie between one or two dozen kilometres, assuming ideal atmospheric circumstances.

Challenge 1113, page 745: A surface of 1 m^2 perpendicular to the light receives about 1 kW of radiation. It generates the same pressure as the weight of about 0.3 mg of matter. That generates 3 µPa for black surfaces, and the double for mirrors.

Challenge 1115, page 746: The shine side gets twice the momentum transfer as the black side, and thus should be pushed backwards.

Challenge 1118, page 747: A polarizer can do this.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

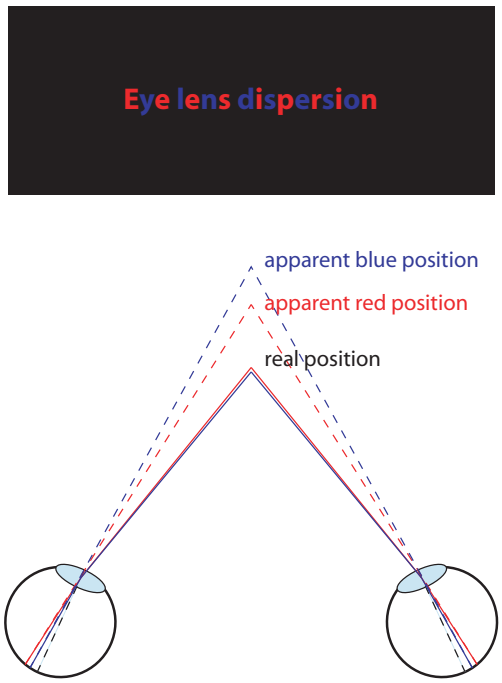

FIGURE 423 The relation between the colour effect and the lens dispersion

Challenge 1121, page 748: The interference patterns change when colours are changed. Rainbows also appear because different colours are due to different frequencies.

Challenge 1123, page 748: The full rainbow is round like a circle. You can produce one with a garden hose, if you keep the hose in your hand while you stand on a chair, with your back to the evening Sun. (Well, one small part is missing; can you imagine which part?) The circle is due to the spherical shape of droplets. If the droplets were of different shape, *and* if they were all aligned, the rainbow would have a different shape than a simple circle.

Challenge 1128, page 753: Film a distant supernova explosion and check whether it happens at the same time for each colour separately.

Challenge 1130, page 754: The first part of the forerunner is a feature with the shortest possible effective wavelength; thus it is given by taking the limit for infinite frequency.

Challenge 1131, page 755: The light is pulsed; thus it is the energy velocity.

Challenge 1132, page 755: Inside matter, the energy is transferred to atoms, then back to light, then to the next atoms, etc. That takes time and slows down the propagation.

Challenge 1134, page 758: This is true even in general relativity, when the bending of the vacuum is studied.

Challenge 1135, page 758: Almost no light passes; the intensity of the little light that is transmitted depends exponentially on the ratio between wavelength and hole diameter. One also says that after the hole there is an evanescent wave.

Challenge 1138, page 760: Not really; a Cat's-eye uses two reflections at the sides of a cube. A living cat's eye has a large number of reflections. The end effect is the same though: light returns back to the direction it came from.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1139, page 760: There is a blind spot in the eye; that is a region in which images are not perceived. The brain than assumes that the image at that place is the same than at its borders. If a spot falls exactly inside it, it disappears.

Challenge 1141, page 763: The eye and brain surely do not switch the up and the down direction at a certain age. Besides, where does the idea come from that babys see upside-down?

Challenge 1142, page 764: The eye and vision system subtract patterns that are constant in time.

Challenge 1144, page 765: In fact, there is no way that a hologram of a person can walk around and frighten a real person. A hologram is always transparent; one can always see the background through the hologram. A hologram thus always gives an impression similar to what moving pictures usually show as ghosts.

Challenge 1145, page 768: The average temperature of the Earth is thus 287 K. The energy from the Sun is proportional to the fourth power of the temperature. The energy is spread (roughly) over half the Earth's surface. The same energy, at the Sun's surface, comes from a much smaller surface, given by the same angle as the Earth subtends there. We thus have $E \sim 2\pi R_{\text{Earth}}^2 T_{\text{Earth}}^4 = T_{\text{Sun}}^4 R_{\text{Earth}}^2 \alpha^2$, where α is half the angle subtended by the Sun. As a result, the temperature of the Sun is estimated to be $T_{\text{Sun}} = (T_{\text{Earth}}^4/\alpha^2)^{0.25} = 4\,\text{kK}$.

Challenge 1149, page 769: Because the maximum of a spectrum in wavelengths and in frequencies is not the same, thus does *not* and cannot follow $c = f\lambda$.

Challenge 1152, page 769: At high temperature, all bodies approach black bodies. The colour is more important than other colour effects. The oven and the objects have the same temperature. Thus they cannot be distinguished from each other. To do so nevertheless, illuminate the scene with powerful light and then take a picture with small sensitivity. Thus one always needs bright light to take pictures of what happens inside fires.

Challenge 1153, page 770: The green surface seen at a low high angle is larger than when seen vertically, where the soil is also seen; the soil is covered by the green grass in low angle observation.

Challenge 1154, page 771: It is indeed true. Modern telescopes have a large surface collecting light (up to 50 m^2) and have extremely sensitive detectors. The number of photons emitted by a match lit on the moon into the direction of a large telescope (how many?) is sufficient to trigger the detector.

Challenge 1155, page 771: Of course not, as the group velocity is not limited by special relativity. The energy velocity is limited, but is not changed in this experiments.

Challenge 1157, page 771: The Prussian explorer Alexander von Humboldt extensively checked this myth in the nineteenth century. He visited many mine pits and asked countless mine workers in Mexico, Peru and Siberia about their experiences. He also asked numerous chimney-sweeps. Neither him nor anybody else had ever seen the stars during the day.

Challenge 1158, page 773: See challenge 638.

Challenge 1159, page 774: The electrons move slowly, but the speed of electrical signals is not given by the electron speed, but by the time at which the electrons move. Imagine long queue of cars (representing electrons) waiting in front of a red traffic light. All drivers look at the light. As soon as it turns green, everybody starts driving. Even though the driving speed might be only 10 m/s, the speed of traffic flow onset was that of light. It is this latter speed which is the speed of electrical signals.

Water pipes tell the same story. A long hose provides water almost in the same instant as the tap is opened, even if the water takes a long time to arrive from the tap to the end of the hose. The speed with which the water reacts is gives by the speed for pressure waves in water. Also for

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

water hoses the signal speed, roughly given by the sound speed in water, is much higher than the speed of the water flow.

Challenge 1160, page 774: One can measure current fluctuations, or measure smallest charges, showing that they are always multiples of the same unit. The latter method was used by Millikan.

Challenge 1163, page 775: Earth's potential would be $U = -q/(4\pi\varepsilon_o R) = 60\,\mathrm{MV}$, where the number of electrons in water must be taken into account.

Challenge 1164, page 775: There is always a measurement error when measuring field values, even when measuring a 'vanishing' electromagnetic field.

Challenge 1165, page 777: The human body is slightly conducting and changes the shape of the field and thus effectively short circuits it. Usually, the field cannot be used to generate energy, as the currents involved are much too small. (Lightning bolts are a different story, of course. They are due – very indirectly – to the field of the Earth, but they are too irregular to be used consistently. Franklin's lightning rod is such an example.)

Challenge 1166, page 777: The field at the surface of a sphere of radius r is given by $E = Q/4\pi\varepsilon_0 r^2$. Inserting $E = 200\,\mathrm{V/m}$, one gets $Q = 0.9\,\mathrm{MC}$.

Challenge 1167, page 780: If you find a method that is different from the known estimates, publish it.

Challenge 1169, page 782: This should be possible in the near future; but both the experiment, which will probably measure brain magnetic field details, and the precise check of its seriousness will not be simple.

Challenge 1175, page 786: All the illusions of the flying act look as if the magician is hanging on lines, as observed by many, including the author. (Photographic flashes are forbidden, a shimmery background is set up to render the observation of the lines difficult, no ring is ever actually pulled over the magician, the aquarium in which he floats is kept open to let the fishing lines pass through, always the same partner is 'randomly' chosen from the public, etc.) Information from eyewitnesses who have actually seen the fishing lines used by David Copperfield explains the reasons for these set-ups. The usenet news group alt.magic.secrets, in particular Tilman Hausherr, was central in clearing up this issue in all its details, including the name of the company that made the suspension mechanism.

Challenge 1177, page 786: Any new one is worth a publication.

Challenge 1178, page 790: Sound energy is also possible, as is mechanical work.

Challenge 1179, page 792: Space-time deformation is not related to electricity; at least at everyday energies. Near Planck energies, this might be different, but nothing has been predicted yet.

Challenge 1181, page 793: Ideal absorption is blackness (though it can be redness or whiteness at higher temperatures).

Challenge 1182, page 793: Indeed, the Sun emits about $4 \cdot 10^{26}\,\mathrm{W}$ from its mass of $2 \cdot 10^{30}\,\mathrm{kg}$, about $0.2\,\mathrm{mW/kg}$. The adult human body (at rest) emits about 100 W (you can check this in bed at night), thus about $1.2\,\mathrm{W/kg}$. This is about 6000 times more than the Sun.

Challenge 1183, page 793: The charges in a metal rearrange in a way that the field inside remains vanishing. This makes cars and aeroplanes safe against lightning. Of course, if the outside field varies so quickly that the rearrangement cannot follow, fields *can* enter the Faraday cage. (By the way, also fields with long wavelengths penetrate metals; remote controls regularly use frequencies of 25 kHz to achieve this.) However, one should wait a bit before stepping out of a car after lightning has hit, as the car is on rubber wheels with low conduction; waiting gives the charge time to flow into the ground.

For gravity and solid cages, mass rearrangement is not possible, so that there is no gravity shield.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

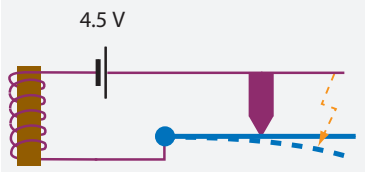

FIGURE 424 How to get electrical shocks from a 4.5 V battery

Challenge 1187, page 795: This is a touchy topic. It is not clear whether 50 Hz fields are dangerous to humans. There is a high probability that they are not; but the issue is not settled.

Challenge 1188, page 795: The number of photons times the quantum of action $\hbar$.

Challenge 1190, page 796: The charging stops because a negatively charged satellite repels electrons and thus stops any electron collecting mechanism. Electrons are captured more frequently than ions because it is easier for them than for ions to have an inelastic collision with the satellite, due to their larger speed at a given temperature.

Challenge 1191, page 796: Any loss mechanism will explain the loss of energy, such as electrical resistance or electromagnetic radiation. After a fraction of a second, the energy will be lost. This little problem is often discussed on the internet.

Challenge 1193, page 796: Use the wire as shown in Figure 424. *If* the oscillation is properly tuned in frequency, and *if* the contact detaches properly at the tip, and *if* you touch the two contacts with a strong grip, you will get a stronger shock than you can stand.

Challenge 1197, page 806: The issue is: is the 'universe' a concept? More about this issue in the final part of the text.

Challenge 1199, page 810: When thinking, physical energy, momentum and angular momentum are conserved, and thermodynamic entropy is not destroyed. Any experiment showing anything different would point to unknown processes. However, there is no evidence for such processes.

Challenge 1200, page 811: The best method cannot be much shorter than what is needed to describe 1 in 6000 million, or 33 bits. The Dutch and UK post code systems (including the letters NL or UK) are not far from this value and thus can claim to be very efficient.

Challenge 1201, page 811: For complex systems, when the unknowns are numerous, the advance is thus simply given by the increase in answers. For the universe as a whole, the number of open issues is quite low, as shown on page 1340; here there has not been much advance in the last years. But the advance is clearly measurable in this case as well.

Challenge 1202, page 811: Is it possible to use the term 'complete' when describing nature?

Challenge 1205, page 812: There are many baths in series: thermal baths in each light-sensitive cell of the eyes, thermal baths inside the nerves towards the brain and thermal baths inside brain cells.

Challenge 1207, page 813: Yes.

Challenge 1210, page 820: Physicists claim that the properties of objects, of space-time and of interactions form the smallest list possible. However, this list is longer than the one found by linguists! The reason is that physicists have found primitives that do not appear in everyday life. In a sense, the aim of physicists is limited by list of unexplained questions of nature, given on page 1340.

Challenge 1211, page 821: Neither has a defined content, clearly stated limits or a domain of application.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1212, page 821: Impossible! That would not be a concept, as it has no content. The solution to the issue must be and will be different.

Challenge 1213, page 823: To neither. This paradox shows that such a 'set of all sets' does not exist.

Challenge 1214, page 824: The most famous is the class of all sets that do not contain themselves. This is not a set, but a class.

Challenge 1215, page 824: Dividing cakes is difficult. A simple method that solves many – but not all – problems among N persons P1...PN is the following:

— P1 cuts the cake into N pieces.
— P2 to PN choose a piece.
— P1 keeps the last part.
— P2...PN assemble their parts back into one.
— Then P2...PN repeat the algorithm for one person less.

The problem is much more complex if the reassembly is not allowed. A *just* method (in finite many steps) for 3 people, using nine steps, was published in 1944 by Steinhaus, and a *fully satisfactory* method in the 1960s by John Conway. A fully satisfactory method for four persons was found only in 1995; it has 20 steps.

Challenge 1216, page 824: $(x, y) := \{x, \{x, y\}\}$.

Challenge 1217, page 825: Hint: show that any countable list of reals misses at least one number. This was proven for the first time by Cantor. His way was to write the list in decimal expansion and then find a number that is surely not in the list. Second hint: his world-famous trick is called the diagonal argument.

Challenge 1218, page 826: Hint: all reals are limits of series of rationals.

Challenge 1220, page 827: Yes, but only provided division by zero is not allowed, and numbers are restricted to the rationals and reals.

Challenge 1221, page 827: There are infinitely many of them. But the smallest is already quite large: 10169491525423728813559322033898305084745762711864406779 66. If the number six is changed in the puzzle, one gets that the smallest solution for 1 is 1, for 4 is 102564, for 5 is 142857, for 8 is 1012658227848, for 2 is 105263157894736842, for 7 is 1014492753623188405797, for 3 is 1034482758620689655172413793, and for 9 is 1011235955056179775280898876404494382022471 9. The smallest solution for 6 is the largest of this list.

Challenge 1222, page 828: $0 := \varnothing$, $1 := \{\varnothing\}$, $2 := \{\{\varnothing\}\}$ etc.

Challenge 1223, page 831: Subtraction is easy. Addition is not commutative only for cases when infinite numbers are involved: $\omega + 2 \neq 2 + \omega$.

Challenge 1224, page 831: Examples are $1 - \varepsilon$ or $1 - 4\varepsilon^2 - 3\varepsilon^3$.

Challenge 1225, page 832: The answer is 57; the cited reference gives the details.

Challenge 1226, page 834: $2^{2^{22}}$ and $4^{4^{4^4}}$.

Challenge 1228, page 834: The child is minus 0.75 years old, or minus 9 months old; the father is thus very near the mother.

Challenge 1229, page 834: This is not an easy question. The first nontrivial numbers are 7, 23, 47, 59, 167 and 179. See ROBERT MATTHEWS, Maximally periodic reciprocals, *Bulletin of the Institute of Mathematics and its Applications* **28**, pp. 147–148, 1992. Matthews shows that a number n for which $1/n$ generates the maximum of $n - 1$ decimal digits in the decimal expansion is a special sort of prime number that can be deduced from the so-called *Sophie Germain primes S*;

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

one must have $n = 2S + 1$, where both S and $2S + 1$ must be prime and where S mod 20 must be 3, 9, or 11.

Thus the first numbers n are 7, 23, 47, 59, 167 and 179, corresponding to values for S of 3, 11, 23, 29, 83 and 89. In 1992, the largest known S that meets the criteria was

$$S = (39051 \cdot 2^{6002}) - 1 \,, \tag{579}$$

a 1812-digit long Sophie Germain prime number that is 3 mod 20. It was discovered by Wilfred Keller. This Sophie Germain prime leads to a prime n with a decimal expansion that is around 10^{1812} digits long before it starts repeating itself. Read your favourite book on number theory to find out more. Interestingly, the solution to this challenge is also connected to that of challenge 1221. Can you find out more?

Challenge 1230, page 834: Klein did not belong to either group. As a result, some of his nastier students concluded that he was not a mathematician at all.

Challenge 1231, page 834: A barber cannot belong to either group; the definition of the barber is thus contradictory and has to be rejected.

Challenge 1232, page 834: See the members.shaw.ca/hdhcubes/cube_basics.htm web page for more information on magic cubes.

Challenge 1233, page 835: Such an expression is derived with the intermediate result $(1-2^2)^{-1}$. The handling of divergent series seems absurd, but mathematicians know how to give the expression a defined content. (See GODFREY H. HARDY, *Divergent Series*, Oxford University Press, 1949.) Physicists often use similar expressions without thinking about them, in quantum field theory.

Challenge 1234, page 845: 'All Cretans lie' is *false*, since the opposite, namely 'some Cretans say the truth' is true in the case given. The trap is that the opposite of the original sentence is usually, but *falsely*, assumed to be 'all Cretans say the truth'.

Challenge 1235, page 845: The statement cannot be false, due to the first half and the 'or' construction. Since it is true, the second half must be true and you are an angel.

Challenge 1241, page 846: This can be debated; in any case it is definitely known that both statements are lies, as shown on page 1173.

Challenge 1244, page 847: There is no way to settle this.

Challenge 1247, page 847: The light bulb story seems to be correct. The bulb is very weak, so that the wire is not evaporating.

Challenge 1248, page 847: The origin might be the number of people present in the last supper in the New Testament; or the forgotten 13th sign of the Zodiac. There is no truth in this superstition. In fact, every superstition is a lie. However, beware of people who are jealous of those who do not care about superstitions, and who get violent as a reaction.

Challenge 1249, page 847: Without exception so far, all those who pretend to have been stigmatized have wounds in the *palms* of their hands. However, in crucifixion, the nails are driven through the *wrist*, because nails driven through the palms cannot carry the weight of a human body: the palms would tear open.

Challenge 1250, page 848: The term 'multiverse' is both a belief and a lie.

Challenge 1252, page 848: In which frame of reference? How? Beware of anybody making that statement: he is a crook.

Challenge 1256, page 853: Only induction allows to make use of similarities and thus to define concepts.

Challenge 1257, page 855: This depends on the definition (of the concept) of deity used.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 1440

Challenge 1258, page 856: Yes, as we shall find out.

Challenge 1259, page 856: Yes, as observation implies interaction.

Challenge 1260, page 856: Lack of internal contradictions means that a concept is valid as a thinking tool; as we use our thoughts to describe nature, mathematical existence is a specialized version of physical existence, as thinking is itself a natural process. Indeed, mathematical concepts are also useful for the description of the working of computers and the like.

Another way to make the point is to stress that all mathematical concepts are built from sets and relations, or some suitable generalizations of them. These basic building blocks are taken from our physical environment. Sometimes the idea is expressed differently; many mathematicians have acknowledged that certain mathematical concepts, such as natural numbers, are taken directly from experience.

Challenge 1261, page 857: Examples are Achilles, Odysseus, Mickey Mouse, the gods of polytheism and spirits.

Challenge 1263, page 858: Torricelli made vacuum in a U-shaped glass tube, using mercury, the same liquid metal used in thermometers. Can you imagine how? A more difficult question: where did he get mercury from?

Challenge 1264, page 859: Stating that something is infinite can be allowed, if the statement is falsifiable. An example is the statement 'There are infinitely many mosquitoes.'

Other statements are not falsifiable, such as 'The universe continue without limit behind the horizon.' Such a statement is a belief, not a fact.

Challenge 1265, page 861: They are not sets either and thus not collections of points.

Challenge 1266, page 862: There is still no possibility to interact with all matter and energy, as this includes oneself.

Challenge 1267, page 867: No. There is only a generalization encompassing the two.

Challenge 1268, page 868: An explanation of the universe is not possible, as the term explanation require the possibility to talk about systems outside the one under consideration. The universe is not part of a larger set.

Challenge 1269, page 868: Both can in fact be seen as two sides of the same argument: there is no other choice;there is only one possibility. The rest of nature shows that it has to be that way, as everything depends on everything.

Challenge 1272, page 878: $|z|^2$ is the *determinant* of the matrix $z = \begin{pmatrix} a & b \\ -b & a \end{pmatrix}$.

Challenge 1276, page 878: Use Cantor's diagonal argument, as in challenge 1217.

Challenge 1281, page 881: Any rotation by an angle 2π is described by -1. Only a rotation by 4π is described by $+1$; quaternions indeed describe spinors.

Challenge 1283, page 883: Just check the result component by component. See also the mentioned reference.

Challenge 1285, page 885: For a Gaussian integer $n + im$ to be prime, the integer $n^2 + m^2$ must be prime, and in addition, a condition on n mod 3 must be satisfied; which one and why?

Challenge 1289, page 887: The metric is regular, positive definite and obeys the triangle inequality.

Challenge 1293, page 889: The solution is the set of all two by two matrices, as each two by two matrix specifies a linear transformation, if one defines a transformed point as the product of the point and this matrix. (Only multiplication with a fixed matrix can give a linear transformation.) Can you recognize from a matrix whether it is a rotation, a reflection, a dilation, a shear, or a stretch along two axes? What are the remaining possibilities?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1296, page 890: The (simplest) product of two functions is taken by point-by-point multiplication.

Challenge 1297, page 890: The norm $\|f\|$ of a real function f is defined as the supremum of its absolute value:

$$\|f\| = \sup_{x \in \mathrm{R}} |f(x)| \,. \tag{580}$$

In simple terms: the maximum value taken by the absolute of the function is its norm. It is also called 'sup'-norm. Since it contains a supremum, this norm is only defined on the subspace of *bounded* continuous functions on a space X, or, if X is compact, on the space of all continuous functions (because a continuous function on a compact space must be bounded).

Challenge 1301, page 895: Take out your head, then pull one side of your pullover over the corresponding arm, continue pulling it over the over arm; then pull the other side, under the first, to the other arm as well. Put your head back in. Your pullover (or your trousers) will be inside out.

Challenge 1302, page 895: Both can be untied.

Challenge 1306, page 899: The transformation from one manifold to another with different topology can be done with a tiny change, at a so-called *singular point*. Since nature shows a minimum action, such a tiny change cannot be avoided.

Challenge 1307, page 901: The product $M^\dagger M$ is Hermitean, and has positive eigenvalues. Thus H is uniquely defined and Hermitean. U is unitary because $U^\dagger U$ is the unit matrix.

Challenge 1312, page 913: Planck limits can be exceeded for extensive observables for which many particle systems can exceed single particle limits, such as mass, momentum, energy or electrical resistance.

Challenge 1316, page 918: Do not forget the relativistic time dilation.

Challenge 1317, page 918: About 10 μg.

Challenge 1318, page 918: Since the temperature of the triple point of water is fixed, the temperature of the boiling point is fixed as well. Historically, the value of the triple point has not been well chosen.

Challenge 1319, page 919: Probably the quantity with the biggest variation is mass, where a prefix for $1\,\mathrm{eV/c^2}$ would be useful, as would be one for the total mass in the universe, which is about 10^{90} times larger.

Challenge 1320, page 920: The formula with $n - 1$ is a better fit. Why?

Challenge 1323, page 923: No, only properties of parts of the universe. The universe itself has no properties, as shown on page 1444.

Challenge 1324, page 924: The slowdown goes *quadratically* with time, because every new slowdown adds to the old one!

Challenge 1325, page 926: The double of that number, the number made of the sequence of all even numbers, etc.

Challenge 1328, page 954: This could be solved with a trick similar to those used in the irrationality of each of the two terms of the sum, but nobody has found one.

Challenge 1329, page 954: There are still many discoveries to be made in modern mathematics, especially in topology, number theory and algebraic geometry. Mathematics has a good future.

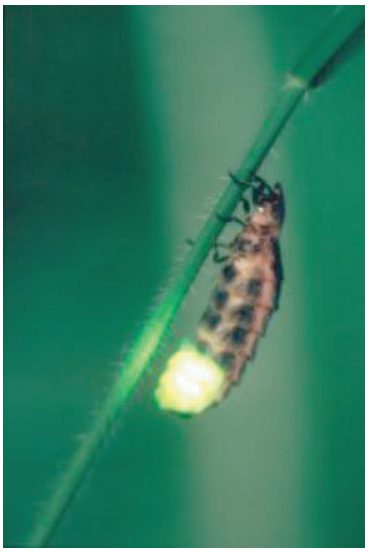
Fourth Part



Quantum Theory:

The Smallest Change

In our quest to understand how things move,
we discover that there is a minimal change in nature,
implying that motion is fuzzy,
that matter is not permanent,
that boxes are never tight,
that matter is composed of elementary units,
and that light and interactions are streams of particles.
The minimal change explains why antimatter exists,
why particles are unlike gloves,
why copying machines do not exist,
and that probabilities are reasonable.

Contents

976 33 Minimum action – quantum theory for poets

The effects of the quantum of action on rest 979 • The consequences of the quantum of action for objects 979 • Why 'quantum'? 981 • The effect of the quantum of action on motion 983 • Quantum limits and surprises 985 • Transformation, growth and Democritus 986 • Randomness 989 • Waves 990 • Quantum flows 990 • Quantum information 991 • Curiosities and fun challenges about the quantum of action 992

994 34 Light – the strange consequences of the quantum of action

What is the faintest lamp? 994 • What is light? – Again 999 • The size of photons 1000 • Are photons countable? – Squeezed light 1000 • The positions of photons 1003 • Are photons necessary? 1004 • How can a wave be made up of particles? 1006 • Can light move faster than light? – Virtual photons 1012 • Indeterminacy of electric fields 1013 • Curiosities and fun challenges about photons 1013

1016 35 Motion of matter – beyond classical physics

Wine glasses and pencils – no rest 1016 • Cool gas 1017 • No infinite precision 1017 • Flows and the quantization of matter 1017 • Knocking tables and quantized conductivity 1018 • Quantized liquid flow 1019 • Matter quantons and their motion – matter waves 1019 • Mass and acceleration of quantons 1021 • Velocities of quantons 1022 • Why are atoms not flat? Why do shapes exist? 1022 • Rotation of quantons – the lack of north poles 1023 • Silver, Stern and Gerlach – polarization of quantons 1025 • The quantum description of physical systems 1027 • The quantum description of motion 1028 • The state evolution – dispersion of quantons 1030 • Tunnelling and limits on memory – damping of quantons 1032 • Phase and the Aharonov–Bohm effect 1034 • The motion of quantons with spin 1035 • Relativistic wave equations 1036 • Virtual particles 1037 • Compositeness 1037 • Curiosities and fun challenges about quantum matter 1039

1041 36 Colours and other interactions between light and matter

What are stars made of? 1041 • What determines the colours of atoms? 1042 • Relativistic hydrogen 1046 • Relativistic wave equations – again 1047 • Antimatter 1049 • Curiosities and fun challenges about colour 1050 • The strength of electromagnetism 1050

1052 37 Permutation of particles – are particles like gloves?

Why does indistinguishability appear in nature? 1054 • Can particles be counted? 1055 • What is permutation symmetry? 1055 • Indistinguishability and symmetry 1056 • The behaviour of photons 1057 • Bunching and antibunching 1058 • The energy dependence of permutation symmetry 1058 • Indistinguishability in quantum field theory 1059 • How accurately is permutation symmetry verified? 1060 • Copies, clones and gloves 1061

1063 38 Rotations and statistics – visualizing spin

The belt trick 1066 • Angels, Pauli's exclusion principle and the hardness of matter 1068 • Spin, statistics and composition 1069 • Is spin a rotation about an axis? 1070 • Why is fencing with laser beams impossible? 1071 • Rotation requires antiparticles 1071 • A summary on spin and indistinguishability 1072 • Limits and open questions of quantum statistics 1073

1074 39 Superpositions and probabilities – quantum theory without ideology

1074 **Why are people either dead or alive?**
Summary on decoherence, life and death 1080

1081 **What is a system? What is an object?**
Is quantum theory non-local? – A bit about the Einstein-Podolsky-Rosen paradox 1082 • Curiosities and fun challenges about superpositions 1084

1086 **What is all the fuss about measurements in quantum theory?**
Hidden variables 1091 • Summary on probabilities and determinism 1093 • What is the difference between space and time? 1095 • Are we good observers? 1096 • What connects information theory, cryptology and quantum theory? 1096 • Is the universe a computer? 1097 • Does the universe have a wave function? And initial conditions? 1097

1099 Bibliography

Chapter 33

MINIMUM ACTION – QUANTUM THEORY FOR POETS

> Natura [in operationibus suis] non facit saltus.*
> 15th century

Climbing Motion Mountain up to this point, we completed three legs. We came across Galileo's mechanics (the description of motion for kids), then continued with Einstein's relativity (the description of motion for science-fiction enthusiasts), and finally explored Maxwell's electrodynamics (the description of motion for business people). These three classical descriptions of motion are impressive, beautiful and useful. However, they have a small problem: they are wrong. The reason is simple: none of them describes *life*.

Whenever we observe a flower, such as the one of Figure 425, we enjoy its bright colours, its wild smell, its soft and delicate shape or the fine details of its symmetry. None of the three classical descriptions of nature can explain any of these properties; neither do they explain the impression that the flower makes on our senses. Classical physics can describe certain aspects of the impression, but it cannot explain their origins. For such an explanation, we need *quantum theory*. In fact, we will discover that in life, *every type of pleasure* is an example of quantum motion.** Take any example of a pleasant situation: for example, a beautiful evening sky, a waterfall, a caress, or a happy child. Classical physics is not able to explain it: the colours, shapes and sizes involved remain mysterious.

Challenge 1330 s

In the early days of physics, this limitation was not seen as a shortcoming, because neither senses nor material properties were thought to be related to motion – and pleasure was not considered a serious subject of investigation for a respectable researcher. However, we have since learned that our senses of touch, smell and sight are primarily *detectors of motion*. Without motion, there would be no senses. Furthermore, all detectors are made of matter. During the exploration on electromagnetism we began to understand that all properties of matter are due to motions of charged constituents. Density, stiffness, colour, and all other material properties result from the electromagnetic behaviour of the Lego bricks of matter: namely, the molecules, the atoms and the electrons. Thus, the properties of matter are also consequences of motion. Moreover, we saw that these tiny constituents are *not* correctly described by classical electrodynamics. We even found that light itself behaves unclassically. Therefore the inability of classical physics to describe matter and the senses is indeed due to its intrinsic limitations.

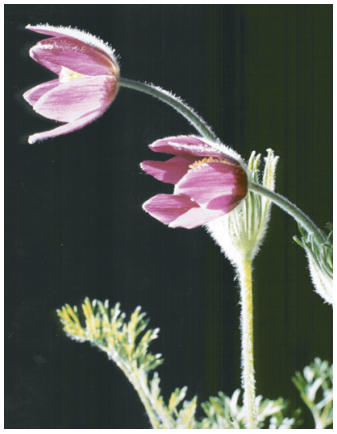

FIGURE 425 An example of a quantum machine (© Ata Masafumi)

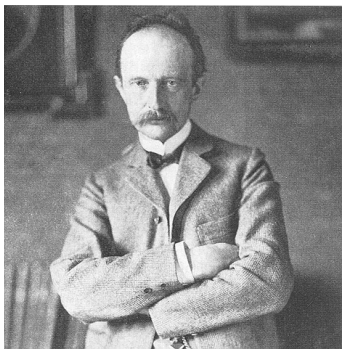

FIGURE 426 Max Planck (1858–1947)

In fact, every failure of classical physics can be traced back to a single, fundamental discovery made in 1899 by Max Planck:* Ref. 806

▷ *In nature, actions smaller than* $\hbar/2 = 0.53 \cdot 10^{-34}$ Js *are not observed.*

All attempts to observe actions smaller than this fail.** In other words, in nature – as in a good film – there is always some action. The existence of a minimal action – the so-called *quantum principle* – is in complete contrast with classical physics. (Why?) However, it has Challenge 1331 s

* For more about Max Planck and his accomplishments, see the footnote on page 768.

** In fact, the quantum principle cited here is a slight simplification: the constant originally introduced by Planck was the (unreduced) $h = 2\pi\hbar$. The factors 2π and $1/2$ leading to the final quantum principle were found somewhat later, by other researchers.

This somewhat unconventional, but didactically useful, approach to quantum theory is due to Niels Bohr. Nowadays, it is hardly ever encountered in the literature; this may be the first time in many decades that it has been used in a teaching text. Ref. 807

Niels Bohr (b. 1885 Copenhagen, d. 1962 Copenhagen) made Copenhagen University into one of the centres of development of quantum theory, overshadowing Göttingen. He developed the description of the atom in terms of quantum theory, for which he received the 1922 Nobel Prize in Physics. He had to flee Denmark in 1943 after the German invasion, because of his Jewish background, but returned there after the war.

TABLE 90 How to convince yourself and others that there is a minimum action, or minimum change $\hbar$ in nature

Issue	Method
Local change or action values $< \hbar$ are not observed	check all observations
Change values $< \hbar$ are non-local	check all observations
Local change or action values $< \hbar$ cannot be produced	check all attempts
Local change or action values $< \hbar$ cannot be imagined	solve all paradoxes
A smallest local change or action value $\hbar$ is consistent	1 – show that all consequences, however weird, are confirmed by observation
	2 – deduce quantum theory from it and check it

passed an enormous number of experimental tests, many of which we will encounter in this part of our mountain ascent. Planck discovered the principle when studying the properties of incandescent light, i.e., light emanating from hot bodies. But the quantum principle also applies to motion of matter, and even, as we will see later, to motion of space-time. Incidentally, the factor 1/2 results from historical accidents in the definition of the constant $\hbar$ (which is pronounced 'aitch-bar'). Despite this missing factor, $\hbar$ is called the *quantum of action*, or alternatively *Planck's (reduced) constant*.

Page 768

The quantum principle states that no experiment can measure an action smaller than $\hbar/2$. For a long time, Einstein tried to devise experiments to overcome this limit. But he failed in all his attempts: nature does not allow it, as Bohr showed again and again.

In physics – as in the theatre – action is a measure of the *change* occurring in a system. Therefore, a minimum action implies that *there is a minimum change in nature*. Thus the quantum of action would perhaps be better named the *quantum of change*. If we compare two observations, there will always be change between them. (What is called 'change' in everyday life is often called 'change of state' by physicists; the meaning is the same.)

Can a minimum change exist in nature? Table 90 shows that we need to explore three

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

points to accept the idea. We need to show that no higher speed is *observed* in nature, that no higher speed *can* ever be observed, and show that *all* consequences of invariance, however weird they may be, apply to nature. In fact, this is all of quantum theory. Therefore, these checks are all we do in the remaining of this part of our adventure. But before we explore some of the experiments that confirm the existence of a smallest change, we present some of its more surprising consequences.

The effects of the quantum of action on rest

Since action is a measure of change, a minimum observable action means that two successive observations of the same system always differ by at least $\hbar/2$. In every system, there is always *something* happening. As a consequence, in nature *there is no rest*. Everything moves, all the time, at least a little bit. *Natura facit saltus.** True, these jumps are tiny, as $\hbar/2$ is so small. But for example, the quantum of action implies that in a mountain – an archetypal 'system at rest' – all the atoms and electrons are continually buzzing around. Rest can be observed only macroscopically, and only as a long-time or many-particle average.

Page 976

Since there is a minimum action for all observers, and since there is no rest, in nature *there is no perfectly straight or perfectly uniform motion*. Forget all you have learnt so far. Inertial motion is an approximation! An object can move in straight, uniform motion only approximately, and only when observed over long distances or long times. We will see later that the more massive the object is, the better the approximation is. (Can you confirm this?) So *macroscopic* observers can still talk about space-time symmetries; and *special* relativity can thus be reconciled with quantum theory.

Challenge 1332 s

Also free fall, or motion along a geodesic, exists only as a long-time average. So *general* relativity, which is based on the existence of freely-falling observers, cannot be correct when actions of the order of $\hbar$ are involved. Indeed, the reconciliation of the quantum principle with general relativity – and thus with curved space – is a big challenge. (The solution is simple only for weak, everyday fields.) The issues involved are so mind-shattering that they form a separate, final, part of this mountain ascent. We thus explore situations without gravity first.

The consequences of the quantum of action for objects

Have you ever wondered why leaves are green? You probably know that they are green because they absorb blue (short-wavelength) and red (long-wavelength) light, while allowing green (medium-wavelength) light to be reflected. How can a system filter out the small and the large, and let the middle pass through? To do so, leaves must somehow *measure* the frequency. But we have seen that classical physics does not allow measurement of time (or length) intervals, as any measurement requires a measurement unit, and classical physics does not allow such units to be defined. On the other hand, it takes only a few lines to confirm that with the help of the quantum of action $\hbar$ (and the Boltzmann constant k, which Planck's discovered at the same time), fundamental units for *all* measurable quantities can be defined, including time and therefore frequency. (Can you find a combination of c, G and $\hbar$ that gives a time? It will only take a few minutes.) When

Page 317

Challenge 1333 s

* 'Nature makes jumps.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 428 An artist's impression of a water molecule

Planck had found all such combinations, he was as happy as a child; he knew straight away that he had made a fundamental discovery, even though (in 1899) quantum theory did not yet exist. He even told his seven-year-old son Erwin about it, while walking with him through the woods around Berlin. Planck explained to his son that he had made a discovery as important as universal gravity. Indeed, Planck knew that he had found the key to understanding many of the effects that were then unexplained. In particular, without the quantum of action, colours could not exist: every colour is a quantum effect.*

Planck also realized that the quantum of action allows us to understand the *size* of all things. (Can you find the combination of c, G and $\hbar$ that yields a length?) With the quantum of action, it was finally possible to determine the maximum size of mountains, of trees and of humans. Planck knew that the quantum of action confirmed what Galileo had already deduced long before him: that sizes are due to fundamental, minimal scales in nature.

Challenge 1335 e

Page 254

The size of objects is related to the size of atoms. In turn, the size of atoms is a direct consequence of the quantum of action. Can you derive an approximation for the size of atoms, knowing that it is given by the motion of electrons of mass m_e and charge e, constrained by the quantum of action? This connection, a simple formula, was discovered in 1910 by Arthur Erich Haas, 15 years before quantum theory was formulated. At the time, he was widely ridiculed. Nowadays, the formula is found in all textbooks.**

Challenge 1336 s

In determining the size of atoms, the quantum of action has another important consequence: Gulliver's travels are impossible. There are no tiny people and no giant ones. Classically, nothing speaks against the idea; but the quantum of action prevents it. Can you supply the detailed argument?

Challenge 1337 s

But if rest does not exist, how can *shapes* exist? Any shape of everyday life, including that of a flower, is the result of body parts remaining *at rest* with respect to each other. Now, all shapes result from interactions between the constituents of matter, as shown most clearly in the shapes of molecules. But how can a molecule, such as the water molecule H_2O, shown in Figure 428, have a shape? In fact, a molecule does not have

* In fact, it is also possible to define all measurement units in terms of c, G and e, the electron charge. Why is this not satisfactory?

Challenge 1334 s

** Before the discovery of $\hbar$, the only simple length scale for the electron was the combination $e^2/(4\pi\varepsilon_0 m_e c^2) \approx 3\,\mathrm{fm}$; this is ten thousand times smaller than an atom.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 429 Max Born (1882–1970)

a *fixed* shape, but its shape fluctuates, as would be expected from the quantum of action. Despite the fluctuations, every molecule does have an *average* shape, because different angles and distances correspond to different energies. Again, these average length and angle values only exist because the quantum of action yields fundamental length scales in nature. Without the quantum of action, there would be *no* shapes in nature.

The *mass* of an object is also a consequence of the quantum of action, as we will see later on. Since all material properties – such as density, colour, stiffness or polarizability – are defined as combinations of length, time and mass units, we find that all material properties arise from the quantum of action.

In short, the quantum of action determines the size, shape, colour, mass, and all other properties of objects, from stones to whipped cream. Measurements are only possible at all because of the existence of the quantum of action.

Why 'quantum'?

Quantum effects surround us on all sides. However, since the minimum action is so small, its effects on *motion* appear mostly, but not exclusively, in *microscopic* systems. The study of such systems was called *quantum mechanics* by Max Born, one of the major contributors to the field.* Later, the term *quantum theory* became more popular.

Quantum theory arises from the existence of *minimum* measurable values in nature, precisely as Galileo had speculated in the seventeenth century. As discussed in detail earlier on, it was Galileo's insistence on these *piccolissimi quanti* that got him into trouble. We will soon discover that the idea of a smallest change is necessary for a precise and

Page 252

* Max Born (b. 1882 Breslau, d. 1970 Göttingen) first studied mathematics, then turned to physics. A professor at Göttingen University, he made the city one of the world centres of physics. He developed quantum mechanics with his assistants Werner Heisenberg and Pascual Jordan, and then applied it to scattering, solid-state physics, optics and liquids. He was the first to understood that the state function describes a probability amplitude. He and Wolf together wrote what is still the main textbook on optics.

Ref. 809

Born attracted to Göttingen the most brilliant talents of the time, receiving as visitors Hund, Pauli, Nordheim, Oppenheimer, Goeppert-Mayer, Condon, Pauling, Fock, Frenkel, Tamm, Dirac, Mott, Klein, Heitler, London, von Neumann, Teller, Wigner, and dozens of others. Being Jewish, Born lost his job in 1933; he emigrated, and became professor in Edinburgh, where he stayed for 20 years. Physics at Göttingen never recovered from this loss. For his elucidation of the meaning of the wave function he received the 1954 Nobel Prize in Physics.

FIGURE 430 Werner Heisenberg (1901–1976)

accurate description of nature. Born adopted Galileo's term for the new branch of physics. The English language adopted the Latin singular 'quantum' instead of the Italian plural 'quanti'.

Note that the term 'quantum' does *not* imply that all measurement values are *multiples* of a smallest one: this is so only in a few rare cases.

Quantum theory is the description of microscopic motion. But when is quantum theory necessary? Table 91 shows that all processes on atomic and molecular scales, including biological and chemical processes, involve actions with values that are near the quantum of action. So do processes of light emission and absorption. These phenomena can *only* be described with quantum theory.

Table 91 also shows that the term 'microscopic' has a different meaning for a physicist and for a biologist. For a biologist, a system is microscopic if it requires a microscope for its observation. For a physicist, a system is microscopic if its characteristic action is of the order of the quantum of action. In other words, for a physicist a system is microscopic if it is *not* visible in a (light) microscope. To increase the confusion, some quantum physicists nowadays call their own class of microscopic systems 'mesoscopic', while others call their systems 'nanoscopic'. Both terms were introduced only to attract attention and funding: they are useless.

The effect of the quantum of action on motion

There is another way to characterize the difference between a microscopic, or quantum, system and a macroscopic, or classical, one. A minimum action implies that the difference between the action values S of two successive observations of the same system, a time Δt apart, is limited. One has

$$S(t+\Delta t) - S(t) = (E+\Delta E)(t+\Delta t) - Et = E\Delta t + t\Delta E + \Delta E\Delta t \geqslant \frac{\hbar}{2} \,. \qquad (581)$$

Now the values of the energy E and time t – but not of ΔE or Δt – can be set to zero if we choose a suitable observer. Thus, the existence of a quantum of action implies that in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

any system the evolution is constrained by

$$\Delta E \Delta t \geqslant \frac{\hbar}{2} \,, \tag{582}$$

where E is the energy of the system and t is its age, so that ΔE is the change of energy and Δt is the time between two successive observations.

Challenge 1339 e By a similar reasoning , we find that for any system the position and momentum are constrained by

$$\Delta x \Delta p \geqslant \frac{\hbar}{2} \,, \tag{583}$$

where Δx is the indeterminacy in position and Δp is the indeterminacy in momentum. These two famous relations were called *indeterminacy relations* by their discoverer, Werner Heisenberg.* In English they are often called 'uncertainty relations'; however, this term is incorrect: the quantities are not uncertain, but *undetermined*. Because of the quantum of action, system observables have *no* definite value. There is no way to ascribe a precise value to momentum, position, or any other observable of a quantum system.

Any system whose indeterminacy is of the order of $\hbar$ is a quantum system; if the indeterminacy product is much larger, the system is classical, and classical physics is sufficient for its description. So even though classical physics assumes that there are *no* measurement indeterminacies in nature, a system is classical only if its indeterminacies are *large* compared to the minimum possible ones. Therefore quantum theory is necessary whenever one tries to measure some quantity as precisely as possible. In fact, every measurement is itself a quantum process.

The indeterminacy relations again show that *motion cannot be observed to infinite precision*. In other words, the microscopic world is *fuzzy*. This fact has many important consequences and many strange ones. For example, if motion cannot be observed with infinite precision, the very concept of motion needs to be handled with great care, as it cannot be applied in certain situations. In a sense, the rest of our quest is just an exploration of the implications of this result.

In fact, as long as space-time is *flat*, it turns out that we *can* retain the concept of motion to describe observations, provided we remain aware of the limitations implied

* It is often said that the indeterminacy relation for energy and time has a different weight from that for momentum and position. This is a wrong idea, propagated by the older generation of physicists, which has survived through many textbooks for over 70 years. Just forget it. It is essential to remember that all four quantities appearing in the inequalities describe the *internal* properties of the system. In particular, t is a time variable deduced from changes observed *inside* the system, and not the time coordinate measured by an outside clock; similarly, the position x is not the external space coordinate, but the position characterizing the system.

Ref. 810 Werner Heisenberg (1901–1976) was an important German theoretical physicist and an excellent table-tennis and tennis player. In 1925, as a young man, he developed, with some help from Max Born and Pascual Jordan, the first version of quantum theory; from it he deduced the indeterminacy relations. For these achievements he received the Nobel Prize for physics in 1932. He also worked on nuclear physics and on turbulence. During the Second World War, he worked on the German nuclear-fission programme. After the war, he published several successful books on philosophical questions in physics, and tried unsuccessfully – with some half-hearted help from Wolfgang Pauli – to find a unified description of nature based on quantum theory, the 'world formula'.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

by the quantum principle.

Quantum limits and surprises

The quantum of action implies the existence of short-time deviations from energy, momentum and angular-momentum conservation in microscopic systems. In the first part of our mountain ascent, we realized that any type of non-conservation implies the existence of *surprises* in nature. Well, here are some of them.

Page 186

Since precisely uniform motion does not exist, a system moving in one dimension only – such as the hand of a clock – always has the possibility of moving a bit in the opposite direction, thus leading to incorrect readings. Indeed, quantum theory predicts that clocks have essential limitations, and that perfect clocks do not exist. It is also impossible to avoid that an object makes small displacement sideways. In fact, quantum theory implies that, strictly speaking, neither uniform nor one-dimensional motion exists.

Quantum limitations apply also to metre rules. It is impossible to ensure that the rule is completely at rest with respect to the object being measured. Thus the quantum of action implies, on one hand, that measurements are possible, and on the other, that their accuracy is limited.

It also follows from the quantum of action that any inertial or freely-falling observer must be *large*, as only large systems approximate inertial motion. *An observer cannot be microscopic.* If humans were not macroscopic, they could neither observe nor study motion.

Because of the finite accuracy with which microscopic motion can be observed, faster-than-light motion is possible in the microscopic domain. Quantum theory thus predicts *tachyons*, at least over short time intervals. For the same reason, *motion backwards in time* is possible over microscopic times and distances. In short, a quantum of action implies the existence of microscopic time travel. Of course, this remains impossible in the macroscopic domain, such as everyday life.

But there is more: the quantum of action implies that *there is no permanence in nature*. Imagine a moving car suddenly disappearing for good. In such a situation, neither momentum nor energy would be conserved. The action change for such a disappearance is large compared to $\hbar$, so that its observation would contradict even classical physics – as you may wish to check. However, the quantum of action allows a *microscopic* particle, such as an electron, to disappear for a *short* time, provided it reappears afterwards.

Challenge 1340 s

The quantum of action also implies that *the vacuum is not empty*. If one looks at empty space twice, the two observations being separated by a tiny time interval, some energy will be observed the second time. If the time interval is short enough, then because of the quantum of action, matter particles will be observed. Indeed, particles can appear anywhere from nowhere, and disappear just afterwards: the action limit requires it. In summary, nature exhibits short-term appearance and disappearance of matter. In other words, the classical idea of an *empty* vacuum is correct only when the vacuum is observed over a *long* time.

The quantum of action implies that compass needles cannot work. If we look twice in quick succession at a compass needle, or even at a house, we usually observe that it stays oriented in the same direction. But since physical action has the same dimensions as angular momentum, a minimum value for action implies a minimum value for angular

Challenge 1341 e

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 431 Hills are never high enough

momentum. Even a macroscopic object has a minimum value for its rotation. In other words, quantum theory predicts that *everything rotates*. Something can be non-rotating only approximately, when observations are separated by long time intervals.

For microscopic systems, the limits on rotation have different effects. If the rotation angle can be observed – as for molecules – the system behaves like macroscopic object: its position and orientation are fuzzy. But for a system whose rotation angle cannot be observed, the quantum of action limits the angular momentum to multiples of $\hbar/2$. As a result, all microscopic bound systems – such as molecules, atoms, or nuclei – contain rotational motion and rotating components.

Transformation, growth and Democritus

Page 28

At the beginning of our adventure, we mentioned that the Greeks distinguished three types of changes: transport, growth, and transformation. We also mentioned that Democritus had deduced that all these types of changes – including life and death – were in fact the same, and due to the motion of atoms. The quantum of action makes exactly this point.

First of all, a minimum action implies that cages in zoos are dangerous and banks are not safe. A cage is a feature that it needs a lot of energy to overcome. Mathematically, the wall of a cage is an energy hill, like the one shown in Figure 431. Imagine that a particle with momentum p approaches one side of the hill, which is assumed to have width Δx.

In everyday life – and thus in classical physics – the particle will never be observed on the other side of the hill if its kinetic energy $p^2/2m$ is *less* than the height E of the hill. But imagine that the missing momentum to overcome the hill, $\Delta p = \sqrt{2mE} - p$, satisfies $\Delta x \Delta p \leqslant \hbar/2$. The particle will have the possibility to overcome the hill, despite its insufficient energy. The quantum of action thus implies that a hill of width

$$\Delta x \leqslant \frac{\hbar/2}{\sqrt{2mE} - p} \tag{584}$$

is *not* an obstacle to a particle of mass m. But this is not all. Since the value of the particle momentum p is itself uncertain, a particle can overcome the hill even if the hill is *wider* than the value (584) – although the broader it is, the lower the probability will be. So any particle can overcome *any* obstacle. This is called the *tunnelling effect*, for obvious reasons.

In short, the minimum-action principle implies that there are no tight boxes in nature. Thanks to the tunnelling effect, *matter is not impenetrable*, in contrast to everyday, classi-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

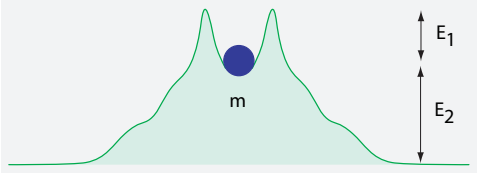

FIGURE 432 Leaving enclosures

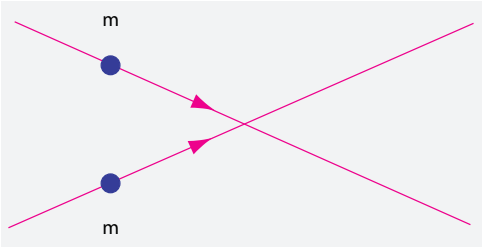

FIGURE 433 Identical objects with crossing paths

cal observation. Can you explain why lion cages work *despite* the quantum of action? Challenge 1342 s

By the way, the quantum of action also implies that a particle with a kinetic energy greater than the energy height of a hill can be reflected by the hill. Classically, this is impossible. Can you explain it? Challenge 1343 ny

The minimum-action principle also implies that bookshelves are dangerous. Shelves are obstacles to motion. A book on a shelf is in the same situation as the mass in Figure 432: the mass is surrounded by energy hills hindering its escape to the outer, lower-energy world. But thanks to the tunnelling effect, escape is always possible. The same picture applies to a branch of a tree, a nail in a wall, or anything attached to anything else. Things can never be permanently fixed together. In particular, we will discover that every example of light emission – even radioactivity – results from this effect. The quantum of action thus implies that *decay is part of nature*. Note that decay often appears in everyday life, under a different name: *breaking*. In fact, all breakages require the quantum of action for their description. Obviously, the cause of breaking is often classical, but the *mechanism* of breaking is always quantum. Only objects that obey quantum theory can break. In short, there are no stable excited systems in nature. For the same reason, by the way, no memory can be perfect. (Can you confirm this?) Ref. 811 Challenge 1344 ny

Taking a more general view, *ageing* and *death* also result from the quantum of action. Death, like ageing, is a composition of breaking processes. Breaking is a form of decay, and is due to tunnelling. Death is thus a quantum process. Classically, death does not exist. Might this be the reason why so many people believe in immortality or eternal youth? Challenge 1345 s

We will also discover that the quantum of action is the reason for the importance of the action observable in classical physics. In fact, the existence of a *minimal* action is the reason for the *least*-action principle of classical physics.

A minimum action also implies that matter cannot be continuous, but must be composed of smallest entities. Indeed, any flow of a truly continuous material would contradict the quantum principle. Can you give the precise argument? Of course, at this point Challenge 1346 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

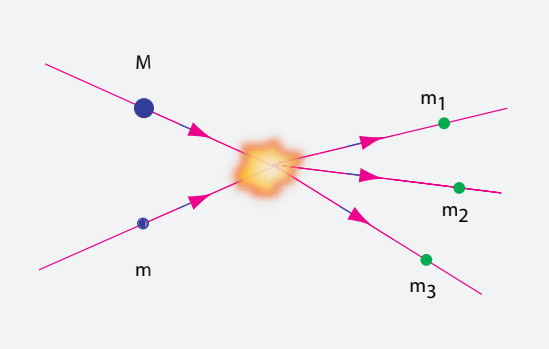

FIGURE 434 Transformation through reaction

in our adventure, the non-continuity of matter is no longer a surprise. But the quantum of action implies that even *radiation* cannot be continuous. As Albert Einstein was the first to state clearly, light is made of quantum particles.

More generally, the quantum of action implies that in nature *all flows and all waves are made of microscopic particles*. The term 'microscopic' (or 'quantum') is essential, as such particles do *not* behave like little stones. We have already encountered several differences, and we will encounter others shortly. For these reasons, there should be a special name for microscopic particles; but so far all proposals, of which *quanton* is the most popular, have failed to catch on.

The quantum of action has several strange consequences for microscopic particles. Take two such particles with the same mass and composition. Imagine that their paths cross, and that at the crossing they approach each other very closely, as shown in Figure 433. A minimum action implies that in such a situation, if the distance becomes small enough, the two particles can switch roles, without anybody being able to avoid, or notice, it. Thus, in a volume of gas it is *impossible* – thanks to the quantum of action – to follow particles moving around and to say which particle is which. Can you confirm this deduction, and specify the conditions, using the indeterminacy relations? In summary, in nature *it is impossible to distinguish between identical particles*. Can you guess what happens in the case of light?

Challenge 1347 s

Challenge 1348 s

But matter deserves still more attention. Imagine again two particles – even two different ones – approaching each other very closely, as shown in Figure 434. We know that if the approach distance gets small, things get fuzzy. Now, the minimum-action principle makes it possible for something to happen in that small domain as long as resulting outgoing products have the same total linear momentum, angular momentum and energy as the incoming ones. Indeed, ruling out such processes would imply that arbitrarily small actions could be observed, thus eliminating nature's fuzziness, as you may wish to check for yourself. In short, *a minimum action allows transformation of matter*. One also says that the quantum of action allows particle *reactions*. In fact, we will discover that *all* kinds of reactions in nature, including breathing, digestion, and all other chemical and nuclear reactions, are due just to the existence of the quantum of action.

Challenge 1349 e

One type of process that is especially dear to us is growth. The quantum of action implies that all growth happens in small steps. Indeed, all growth processes in nature are

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 435 A famous quantum effect: how do train windows manage to show two superimposed images?

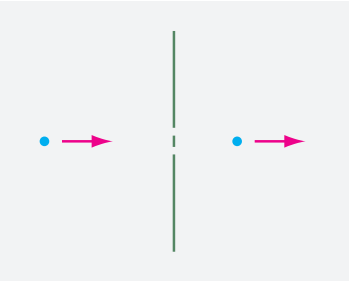

FIGURE 436 A particle and a screen with two nearby slits

quantum processes.

So Democritus was both right and wrong. He was right in deducing fundamental constituents for matter and radiation. He was right in unifying all change in nature – from transport to transformation and growth – as motion of particles. But he was wrong in assuming that the small particles behave like stones.

Randomness

The quantum of action has other interesting consequences. Because of the indeterminacy relations, it is impossible to obtain definite values for both the momentum and the position of a particle. Obviously, this is also impossible for the individual components of an experimental set-up or an observer. Therefore, initial conditions – both for a system and for an experimental set-up – cannot be exactly duplicated. A minimum action thus implies that whenever an experiment on a microscopic system is performed twice, the outcomes will be different. They could only be the same if both the system and the observer were in exactly the same configuration each time. This turns out to be impossible, because of the second principle of thermodynamics and also because of the quantum principle. Therefore, *microscopic systems behave randomly*. Obviously, there will be some *average* outcome; nevertheless, microscopic observations are probabilistic. Albert Einstein found this conclusion of quantum theory the most difficult to swallow. The quantum of action implies that the behaviour of quantum systems is strikingly different from that of classical systems. But the conclusion is unavoidable: nature behaves randomly.

Every *window* proves that nature behaves randomly. Everybody knows that one can use a train window either to look at the *outside* landscape or, by concentrating on the reflected image, to observe some interesting person *inside* the carriage. In other words, glass reflects some of the light particles and lets some others pass through. More precisely, glass reflects a random selection of light particles; yet the average proportion is constant. Partial reflection is thus similar to the tunnelling effect. Indeed, the partial reflection of photons in glass is a result of the quantum of action. Again, the situation can be *described* by classical physics, but the precise amount of reflection cannot be *explained* without quantum theory. Without the quantum of action, train journeys would be much more

boring.

Waves

The quantum of action implies an important result about the *paths* of particles. If a particle travels from one point to another, there is no way to say which path it has taken in between. Indeed, in order to distinguish between two possible, but slightly different, paths, actions smaller than $\hbar/2$ would have to be measured. In particular, if a particle is sent through a screen with two sufficiently close slits, it is impossible to say which slit the particle passed through. This impossibility is fundamental. Matter is predicted to exhibit interference.

We already know phenomena of motion for which it is not possible to say with precision which path is taken when two slits are crossed: *waves* behave in this way. All waves
Page 238 are subject to the indeterminacy relations

$$\Delta\omega\Delta t \geqslant \frac{1}{2} \quad \text{and} \quad \Delta k\Delta x \geqslant \frac{1}{2} \,. \tag{585}$$

We saw above that quantum systems are subject to

$$\Delta E\Delta t \geqslant \frac{\hbar}{2} \quad \text{and} \quad \Delta p\Delta x \geqslant \frac{\hbar}{2} \,. \tag{586}$$

We are thus led to ascribe a frequency and a wavelength to a quantum system:

$$E = \hbar\omega \quad \text{and} \quad p = \hbar k = \hbar\frac{2\pi}{\lambda} \,. \tag{587}$$

The energy–frequency relation was deduced by Albert Einstein in 1905; it is found to be valid in particular for all examples of light emission and light absorption. In 1923 and 1924, Louis de Broglie* predicted that the relation should hold also for all quantum *matter*
Page 1019 particles. The experimental confirmation came a few years later. (This is thus another example of a discovery that was made about 20 years too late.) In short, the quantum of action implies that matter particles behave like waves.

Quantum flows

The quantum of action, the smallest change, implies that flows cannot be arbitrary weak.
Page 276 This applies to *all* flows: in particular, it applies to rivers, solid matter flows, gas flows, light beams, energy flows, entropy flows, momentum flows, angular momentum flows,

* Louis de Broglie (b. 1892 Dieppe, d. 1987 Paris), French physicist and professor at the Sorbonne. The energy–frequency relation for light had earned Albert Einstein his Nobel Prize already in 1921. De Broglie expanded it to predict the wave nature of the electron (and of all other quantum matter particles): this was the essence of his doctoral thesis. The prediction was confirmed experimentally a few years later, in 1927. For the prediction of the wave nature of matter, de Broglie received the Nobel Prize for physics in 1929. Being an aristocrat, he did no more research after that. For example, it was Schrödinger who then wrote down the wave equation, even though de Broglie could equally have done so.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

probability flows, signals of all kind, electrical charge flows, colour charge flows and weak charge flows.

Water flows in rivers, like any other matter flow, cannot be arbitrary small: the quantum of action implies that there is a smallest matter flow in nature. Depending on the situation, the smallest matter flow is a molecule, an atom or a smaller particle. Indeed, the quantum of action is also at the origin of the observation of a smallest charge in electric current. Since all matter can flow, the quantum of action implies that *all matter has particle aspects*.

In the same way, the quantum of action, the smallest change, implies that light cannot be arbitrarily faint. There is a smallest illumination in nature; it is called a *photon* or a *light quantum*. Now, light is a wave, and the argument can be made for any other wave as well. In short, the quantum of action thus implies that *all waves have particle aspects*. This has been proved for light waves, water waves, X rays, sound waves, plasma waves, fluid whirls and any other wave type that has ever been observed. (Gravitational waves have not yet been observed; it is expected that their particle-like aspects, the *gravitons*, exist also in this case.)

In summary, the quantum of action states: *if it moves, it is made of quantum particles, or quantons*. Later on we will explore and specify the exact differences between a quantum particle and a particle in everyday life.

Quantum information

In computer science, the smallest unit of change is called a 'bit'. The existence of a smallest change in nature implies that computer (or information) science can be used to describe nature, and in particular quantum theory. However, it can describe only the 'software' side. The 'hardware' side of nature is also required. The hardware of nature enters the description whenever the actual value $\hbar$ of the quantum of action must be introduced.

As we explore the similarities and differences between nature and information science, we will discover that the quantum of action implies that macroscopic physical systems cannot be copied – or 'cloned', as quantum theorists like to say. Nature does not allow copies of macroscopic objects. In other words, perfect copying machines do not exist. The quantum of action makes it impossible to gather and use all information in a way that allows production of a perfect copy. As a consequence, we will deduce that the precise order in which measurements are performed in an experiment matters. When the order of measurements can be reversed without affecting the net result, physicists speak of 'commutation'. The quantum of action implies that physical observables do not commute.

We will also find that the quantum of action implies that systems are not always independent, but can be 'entangled'. This term, introduced by Erwin Schrödinger, describes one of the most absurd consequences of quantum theory. Entanglement makes everything in nature connected to everything else. Entanglement produces effects that seem (but are not) faster than light. Entanglement produces a (fake) form of non-locality. Entanglement also implies that trustworthy communication cannot exist.

Page 1081

Ref. 812

Don't all these deductions look wrong, or at least crazy? In fact, if you or your lawyer made any of these statements in court, maybe even under oath, you would probably end up in prison! However, all the above statements are correct: they are all confirmed by experiment. And there are many more surprises to come. You may have noticed that, in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the preceding examples, we have made no explicit reference to electricity, to the nuclear interactions, or to gravity. In these domains the surprises are even more astonishing. Observation of antimatter, electric current without resistance, the motion inside muscles, vacuum energy, nuclear reactions in stars, and maybe soon the boiling of empty space, will fascinate you as much as they have fascinated, and still fascinate, thousands of researchers.

In particular, the consequences of the quantum of action for the early universe are mind-boggling. Just try to explore for yourself its consequences for the big bang. Together, all these topics will lead us a long way towards the top of Motion Mountain. They are so strange, so incredible, and so numerous, that quantum physics can rightly be called the description of motion for *crazy* scientists. In a sense, this generalizes our previous definition of quantum physics as the description of motion related to pleasure.

Challenge 1350 d

It is sometimes said that 'nobody understands quantum theory'. This is wrong. In fact, it is worse than wrong: it is disinformation. Dictatorships use disinformation to prevent people from making up their own mind and from enjoying life. But the consequences of the quantum of action can be understood and enjoyed by everybody. In order to do so, our first task on our way towards the top of Motion Mountain will be the study of our classical standard of motion: the motion of light.

> Nie und nirgends hat es Materie ohne
> Bewegung gegeben, oder kann es sie geben.
> Friedrich Engels, *Anti-Dühring*.*

Curiosities and fun challenges about the quantum of action

Even if we accept that no experiment performed so far contradicts the minimum action, we still have to check that the minimum action does not contradict reason. In particular, the minimum action must also be consistent with all *imagined* experiments. This is not self-evident.

* *

Angular momentum has the same dimensions as action. A smallest action implies that there is a smallest angular momentum in nature. How can this be, given that some particles have spin zero, i.e., have no angular momentum?

Challenge 1351 s

* *

Could we have started the whole discussion of quantum theory by stating that there is a minimum angular momentum instead of a minimum action?

Challenge 1352 s

* *

Niels Bohr, besides propagating the idea of a minimum action, was also an enthusiast of the complementarity principle. This is the idea that certain pairs of observables of a system – such as position and momentum – have linked *precision*: if one of the pair is known to high precision, the other is necessarily known with low precision. Can you deduce this principle from the minimum action?

Challenge 1353 s

Ref. 813 * 'Never and nowhere has matter existed, nor can it exist, without motion.' Friedrich Engels (1820–1895) was one of the theoreticians of Marxism, often also called Communism.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

When electromagnetic fields come into play, the value of the action (usually) depends on the choice of the vector potential, and thus on the choice of gauge. We saw in the section on electrodynamics that a suitable choice of gauge can change the value of the action by adding or subtracting any desired amount. Nevertheless, there is a smallest action in nature. This is possible, because in quantum theory, physical gauge changes cannot add or subtract any amount, but only multiples of *twice* the minimum value. Thus they do not allow us to go below the minimum action.

* *

Challenge 1354 s Adult plants stop growing in the dark. Without light, the reactions necessary for growth cease. Can you show that this is a quantum effect, not explainable by classical physics?

* *

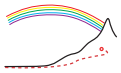
Challenge 1355 s Most quantum processes in everyday life are electromagnetic. Can you show that the quantum of action must also hold for nuclear processes?

* *

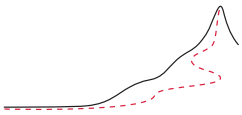
Challenge 1356 s Is the quantum of action independent of the observer, even near the speed of light? This question was the reason why Planck contacted the young Einstein, inviting him to Berlin, thus introducing him to the international physics community.

* *

Challenge 1357 ny The quantum of action implies that *Tom Thumb* cannot exist, that fractals cannot exist in nature, and that '*Moore's law*' of semiconductor electronics, which states that the number of transistors on a chip doubles every two years, cannot be correct. Why not?



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 34

LIGHT – THE STRANGE CONSEQUENCES OF THE QUANTUM OF ACTION

> Alle Wesen leben vom Lichte,
> jedes glückliche Geschöpfe.
> Friedrich Schiller, *Wilhelm Tell*.*

What is the faintest lamp?

If all the colours of materials are quantum effects, as just argued, it becomes especially interesting to study the properties of light itself. If in nature there is a minimum change, then there should also be a minimum illumination. This was already predicted in ancient Greece, for example by Epicurus (341–271 BCE). He stated that light is a stream of little particles, so that the smallest possible illumination would be that of a single light particle.

Ref. 814

Ref. 815

In the 1930s, Brumberg and Vavilov found a beautiful way to check this prediction using the naked eye, despite our inability to consciously detect single photons. In fact, the experiment is so simple that it could have been performed at least a century earlier; but nobody had had a sufficiently daring imagination to try it. The two researchers constructed a small shutter that could be opened for time intervals of 0.1 s. From the other side, in a completely dark room, they illuminated the opening with extremely weak green light: about 200 aW at 505 nm. At that intensity, whenever the shutter opens, on average about 50 photons can pass. This is just the sensitivity threshold of the eye. To perform the experiment, they repeatedly looked into the open shutter. The result was simple but surprising. Sometimes they observed light, and sometimes they did not. Whether they did or did not was completely random. Brumberg and Vavilov gave the simple explanation that at low lamp powers, because of fluctuations, the number of photons is above the eye threshold half the time, and below it the other half. The fluctuations are random, and so the detection is as well. This would *not* happen if light were a continuous stream: in that case, the eye would detect light at every opening of the shutter. (At higher light intensities, the percentage of non-observations quickly decreases, in accordance with the explanation given.) Nobody knows how the theory of light would have developed if this simple experiment had been performed 100 years earlier.

The experiment can become clearer if we use certain devices to help us. A simple way is to start with a screen behind a prism illuminated with white light. The light is split into colours. As the screen is placed further and further away, the illumination intensity cannot become arbitrarily small, as that would contradict the quantum of action. To check

* 'From light all beings live.' Friedrich Schiller (b. 1759 Marbach, d. 1805 Weimar), German poet, playwright and historian.

Figure to be included

FIGURE 437 How to experience single photon effects (see text)

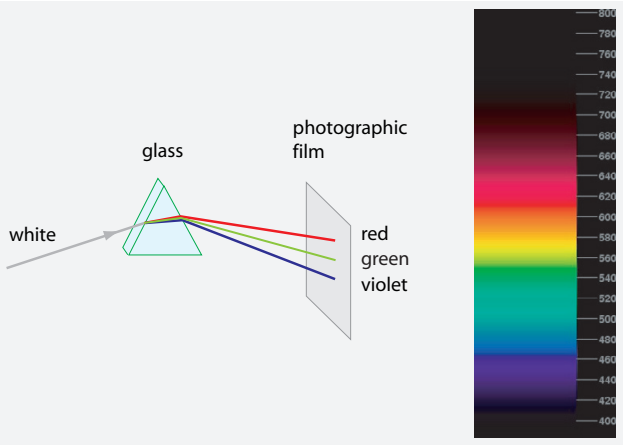

FIGURE 438 How does a white-light spectrum appear at extremely long screen distances? (The short-screen-distance spectrum shown, © Andrew Young, is optimized for CRT display, not for colour printing, as explained on mintaka.sdsu.edu/GF/explain/optics/rendering.html.)

this prediction, we only need some black-and-white photographic film. Film is blackened by daylight of any colour; it becomes dark grey at medium intensities and light grey at lower intensities. Looking at an extremely light grey film under the microscope, we discover that, even under uniform illumination, the grey shade is actually composed of black spots, arranged more or less densely. Nowadays, this can also be performed with photomultipliers. Photomultipliers can also detect single photons. As shown in Figure 439, low-intensity light does *not* produce a homogeneous colour: on the contrary, low-intensity produces a random pattern of equal spots.

This is a general observation: whenever sensitive light detectors are constructed with the aim of 'seeing' as accurately as possible (and thus in environments as dark as possible), one finds that light manifests as a stream of *light quanta*. Nowadays they are usually called *photons*, a term that appeared in 1926. Light of low or high intensity corresponds simply to a stream with a small or large number of photons.

A particularly interesting example of a low-intensity source of light is a single atom. Atoms are tiny spheres. When they radiate light or X-rays, the radiation should be emitted as spherical waves. But in all experiments, it is found that each atom emits only a 'blob' of light. The light emitted by an atom is *never* found to form a spherical wave, as

Figure to be included

FIGURE 440 An atom radiating one photon triggers only one detector and recoils in only one direction

one might expect from everyday physics. Whenever a radiating atom is surrounded by many detectors, only a *single* detector is triggered.

All experiments in dim light show that the continuum description of light is incorrect. All these experiments prove directly that light is a stream of particles, as Epicurus had proposed in ancient Greece. More precise measurements confirm the role of the quantum of action: every photon leads to the *same* amount of change. Photons of the same frequency blackens a film or trigger a scintillation screen in the same way. The amount of change induced by a single photon is the *minimal* amount of change that light can produce.

If there were no minimum action, light could be packaged into arbitrarily small amounts. In other words, the classical description of light by a *continuous* vector potential $A(t, x)$, or electromagnetic field $F(t, x)$, whose evolution is described by a principle of least action, is *wrong*. Continuous functions do not describe the observed particle effects. A modified description is required. The modification has to be significant only at

Page 714

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

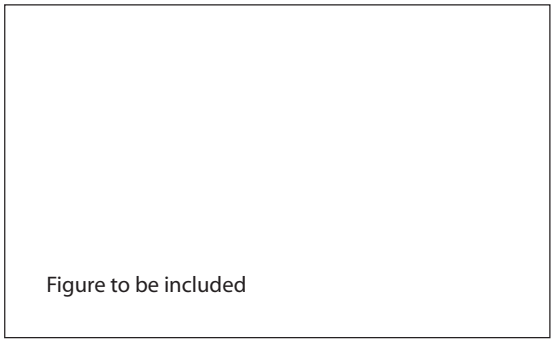

FIGURE 441 Detectors that allow photon counting

low light intensities, since at high intensities the classical Lagrangian accurately describes all experimental observations.*

At which intensities does light cease to behave as a continuous wave? Human eyesight does not allow us to consciously distinguish single photons, although experiments show
Ref. 816 that the hardware of the eye is in principle able to do so. The faintest stars that can be seen at night produce a light intensity of about $0.6\,\mathrm{nW/m^2}$. Since the pupil of the eye is small, and we are not able to see individual photons, photons must have energies smaller than 100 aJ. Brumberg and Vavilov's experiment yields an upper limit of around 20 aJ.

An exact value for the quantum of action found in light must be deduced from laboratory experiment. Today, recording and counting individual photons is a standard procedure. Photon counters are part of many spectroscopy set-ups, such as those used to measure tiny concentrations of materials. For example, they are used to detect drugs in human hair.

In general, all experiments show that a beam of light of frequency f or angular frequency ω, which determines its colour, is accurately described as a stream of photons, each with the same energy E, given by

$$E = \hbar\, 2\pi f = \hbar\,\omega\ . \tag{588}$$

This relation shows that for light, the smallest measurable action is given by the quantum of action $\hbar$. This is *twice* the smallest action observable in nature; the reasons for and implications of the factor 2 will unfold during the rest of our walk. In summary, *colour* is a property of photons. A coloured light beam is a hailstorm of corresponding photons.

The value of *Planck's constant* can be determined from measurements of black bodies
Page 768 or other light sources. The result,

$$\hbar = 1.1 \cdot 10^{-34}\,\mathrm{Js}\ , \tag{589}$$

is so small that we can understand why photons go unnoticed by humans. For example,
Challenge 1358 e a green photon with a wavelength of 555 nm has an energy of 0.37 aJ. Indeed, in normal

* The transition from the classical case to the quantum case used to be called *quantization*. This concept, and the ideas behind it, are only of historical interest today.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

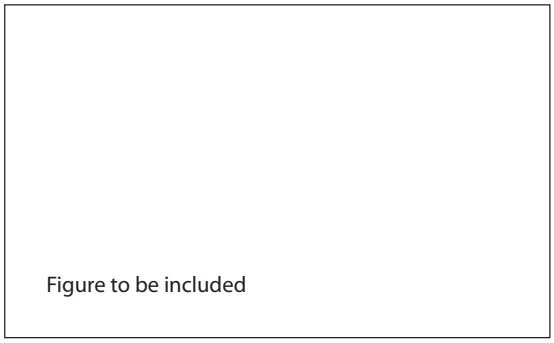

FIGURE 442 Compton's experiment: photons have momentum

light conditions the photons are so numerous that the continuum approximation for the electromagnetic field is highly accurate. In the dark, the insensitivity of the signal processing of the human eye – in particular the slowness of the light receptors – makes photon counting impossible. However, the eye is not far from the maximum possible sensitivity. From the numbers given above about dim stars, we can estimate that humans are able to see *consciously*, under ideal conditions, flashes of about half a dozen photons.

Ref. 816

Challenge 1359 ny

Let us explore the remaining properties of photons. First, photons have no measurable (rest) mass or electric charge. Can you confirm this? In fact, experiments can only give an upper limit for both quantities. The present experimental upper limit for the (rest) mass of a photon is 10^{-52} kg, and for the charge is $5 \cdot 10^{-30}$ times the electron charge.

Challenge 1360 ny

Ref. 817

We know that light can *hit* objects. Since the energy and the speed of photons is known, we guess that the photon momentum is given by

Challenge 1361 ny

$$p = \frac{E}{c} = \hbar \frac{2\pi}{\lambda} \quad \text{or} \quad \boldsymbol{p} = \hbar \boldsymbol{k} \,. \tag{590}$$

In other words, if light is made of particles, we should be able to play billiard with them. This is indeed possible, as Arthur Compton showed in a famous experiment in 1923. He directed X-rays, which are high-energy photons, onto graphite, a material in which electrons move almost freely. He found that whenever the electrons in the material are hit by the X-ray photons, the deflected X-rays change colour. As expected, the strength of the hit is related to the deflection angle of the photon. From the colour change and the reflection angle, Compton confirmed that the photon momentum indeed satisfies the expression $\boldsymbol{p} = \hbar \boldsymbol{k}$.

Ref. 818

All other experiments agree that photons have momentum. For example, when an atom *emits* light, the atom feels a *recoil*. The momentum again turns out to be given by the expression $\boldsymbol{p} = \hbar \boldsymbol{k}$. In short, the quantum of action determines the momentum of the photon.

The value of a photon's momentum respects the indeterminacy principle. Just as it is impossible to measure exactly both the wavelength of a wave and the position of its crest, so it is impossible to measure both the momentum and the position of a photon. Can you confirm this? In other words, the value of the photon momentum is a direct consequence of the quantum of action.

Challenge 1362 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

From our study of classical physics, we know that light has a property beyond its colour: light can be *polarized*. That is only a complicated way to say that light can *turn* the objects that it shines on. In other words, light has an angular momentum oriented along the axis of propagation. What about photons? Measurements consistently find that each light quantum carries an *angular momentum* given by $L = \hbar$. It is called its *helicity*. The quantity is similar to one found for massive particles: one therefore also speaks of the *spin* of a photon. In short, photons somehow 'turn' – in a direction either parallel or antiparallel to the direction of motion. Again, the magnitude of the photon helicity, or spin, is no surprise; it confirms the classical relation $L = E/\omega$ between energy and angular momentum that we found in the section on classical electrodynamics. Note that, counterintuitively, the angular momentum of a single photon is fixed, and thus independent of its energy. Even the most energetic photons have $L = \hbar$. Of course, the value of the helicity also respects the limit given by the quantum of action. The helicity value $\hbar$ – twice the minimum $\hbar/2$ – has important consequences, which will become clear shortly.

Page 747

Challenge 1363 ny

What is light? – Again

> La lumière est un mouvement luminaire de corps lumineux.
>
> Blaise Pascal*

In the seventeenth century, Blaise Pascal used the above statement about light to make fun of certain physicists, ridiculing the blatant use of a circular definition. Of course, he was right: in his time, the definition was indeed circular, as no meaning could be given to any of the terms. But whenever physicists study an observation with care, philosophers lose out. All those originally undefined terms now have a definite meaning and the circular definition is resolved. Light is indeed a type of motion; this motion can rightly be called 'luminary' because, in contrast to the motion of material bodies, it has the unique property $v = c$; the luminous bodies, today called photons, are characterized, and differentiated from all other particles, by their dispersion relation $E = cp$, their energy $E = \hbar\omega$, their spin $L = \hbar$, the vanishing of all other quantum numbers, and the property of being the quanta of the electromagnetic field.

In short, *light is a stream of photons*. It is indeed a 'luminary movement of luminous bodies'. Photons provide our first example of a general property of the world on small scales: *all waves and all flows in nature are made of quantum particles*. Large numbers of (coherent) quantum particles – or *quantons* – behave and form as waves. We will see shortly that this is the case even for matter. Quantons are the fundamental constituents of *all* waves, without exception. Thus, the everyday continuum description of light is similar in many respects to the description of water as a continuous fluid: photons are the atoms of light, and continuity is an approximation valid for large numbers of particles. Small numbers of quantons often behave like classical particles.

Physics books used to discuss at length a so-called *wave–particle duality*. Let us be clear from the start: quantons, or quantum particles, are *neither* classical waves *nor* classical particles. In the microscopic world, quantons are the fundamental objects.

* 'Light is the luminary movement of luminous bodies.' Blaise Pascal (b. 1623 Clermont, d. 1662 Paris), important French mathematician and physicist up to the age of 26, after which he became a theologian and philosopher.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

However, there is much that is still unclear. Where, inside matter, do these monochromatic photons come from? Even more interestingly, if light is made of quantons, all electromagnetic fields, even static ones, must be made of photons as well. However, in static fields nothing is flowing. How is this apparent contradiction resolved? And what implications does the particle aspect have for these static fields? What is the difference between quantons and classical particles? The properties of photons require more careful study. Let us go on.

The size of photons

First of all, we might ask: what are these photons made of? All experiments so far, performed down to the present limit of about 10^{-20} m, give the same answer: 'we can't find anything'. This is consistent with both a vanishing mass and a vanishing size of photons. Indeed, one would intuitively expect a body with a finite size to have a finite mass. Thus, although experiments can give only an upper limit, it is consistent to claim that a photon has *zero size*.

A particle with zero size cannot have any constituents. Thus a photon cannot be divided into smaller entities: photons are not composite. For this reason, they are called *elementary* particles. We will soon give some further strong arguments for this result.

Challenge 1364 ny

(Can you find one?) It is a strange result. How can a photon have vanishing size, have no constituents, and still be *something*? This is a hard question; the answer will appear only later on. At the moment we simply have to accept the situation as it is. We therefore turn to an easier question.

Are photons countable? – Squeezed light

> Also gibt es sie doch.
>
> Max Planck*

We saw above that the simplest way to count photons is to distribute them across a large screen and then to absorb them. But this method is not entirely satisfactory, as it destroys the photons. How can one count photons without destroying them?

One way is to reflect photons in a mirror and measure the recoil of the mirror. It seems almost unbelievable, but nowadays this effect is becoming measurable even for small numbers of photons. For example, it has to be taken into account in relation to the laser mirrors used in gravitational wave detectors, whose position has to be measured

Page 532

with high precision.

Another way of counting photons without destroying them involves the use of special high-quality laser cavities. It is possible to count photons by the effect they have on atoms cleverly placed inside such a cavity.

In other words, light intensity can indeed be measured without absorption. However, the next difficulty appears straight away. Measurements show that even the best light beams, from the most sophisticated lasers, *fluctuate* in intensity. There are no steady

* 'Thus they do exist after all.' Max Planck, in his later years, said this after standing silently, for a long time, in front of an apparatus that counted single photons by producing a click for each photon it detected. For a large part of his life, Planck was sceptical of the photon concept, even though his own experiments and conclusions were the starting point for its introduction.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

beams. This comes as no surprise: if a light beam did *not* fluctuate, observing it twice would yield a vanishing value for the action. However, there is a minimum action in nature, namely $\hbar/2$. Thus any beam and any flow in nature must fluctuate. But there is more.

A light beam is described by its intensity and its phase. The change – or action – that occurs while a beam moves is given by the variation in the product of intensity and phase. Experiments confirm the obvious deduction: the intensity and phase of a beam behave like the momentum and position of a particle, in that they obey an indeterminacy relation. You can deduce it yourself, in the same way as we deduced Heisenberg's relations. Using as characteristic intensity $I = E/\omega$, the energy divided by the angular frequency, and calling the phase φ, we get*

$$\Delta I \, \Delta\varphi \geqslant \frac{\hbar}{2} \,. \tag{592}$$

For light emitted from an ordinary lamp, the product on the left-hand side of the above inequality is much larger than the quantum of action. On the other hand, laser beams can (almost) reach the limit. Laser light in which the two indeterminacies differ greatly from each other is called *non-classical light* or *squeezed light*; it is used in many modern research applications. Such light beams have to be treated carefully, as the smallest disturbances transform them back into ordinary laser beams, in which the two indeterminacies have the same value. Extreme examples of non-classical light are beams with a given, fixed, photon number, and thus with an extremely high phase indeterminacy.

The observation of non-classical light highlights a strange fact, valid even for classical light: the number of photons in a light beam is not a well-defined quantity. In general, it is undetermined, and it *fluctuates*. The number of photons at the beginning of a beam is not necessarily the same as the number at the end of the beam. Photons, unlike stones, cannot be counted precisely – as long as they are moving and not absorbed. In flight, it is only possible to determine an approximate number, within the limits set by indeterminacy.

An extreme example is a light beam with an (almost) fixed phase. In such a beam, the photon number fluctuates from zero to infinity. In order to produce a *coherent* laser beam that approximates a pure sine wave as perfectly as possible, one must build a source in which the photon number is as undetermined as possible.

At the other extreme is a beam with a fixed number of photons: in such a beam, the phase fluctuates erratically. The light that we encounter in most everyday situations – such as the light from an incandescent lamps – lies somewhere in between, the phase and intensity indeterminacies being of similar magnitude.

As an aside, it turns out that even in deep, dark intergalactic space, far from any star, there are about 400 photons per cubic centimetre. This number, like the number of photons in a light beam, also has a measurement indeterminacy. Can you estimate it?

Challenge 1365 ny

* A large photon number is assumed in the expression. This is obvious, as $\Delta\varphi$ cannot grow beyond all bounds. The exact relations are

$$\Delta I \, \Delta \cos\varphi \geqslant \frac{1}{2}|\langle \sin\varphi \rangle|$$
$$\Delta I \, \Delta \sin\varphi \geqslant \frac{1}{2}|\langle \cos\varphi \rangle| \tag{591}$$

where $\langle x \rangle$ denotes the expectation value of the observable x.

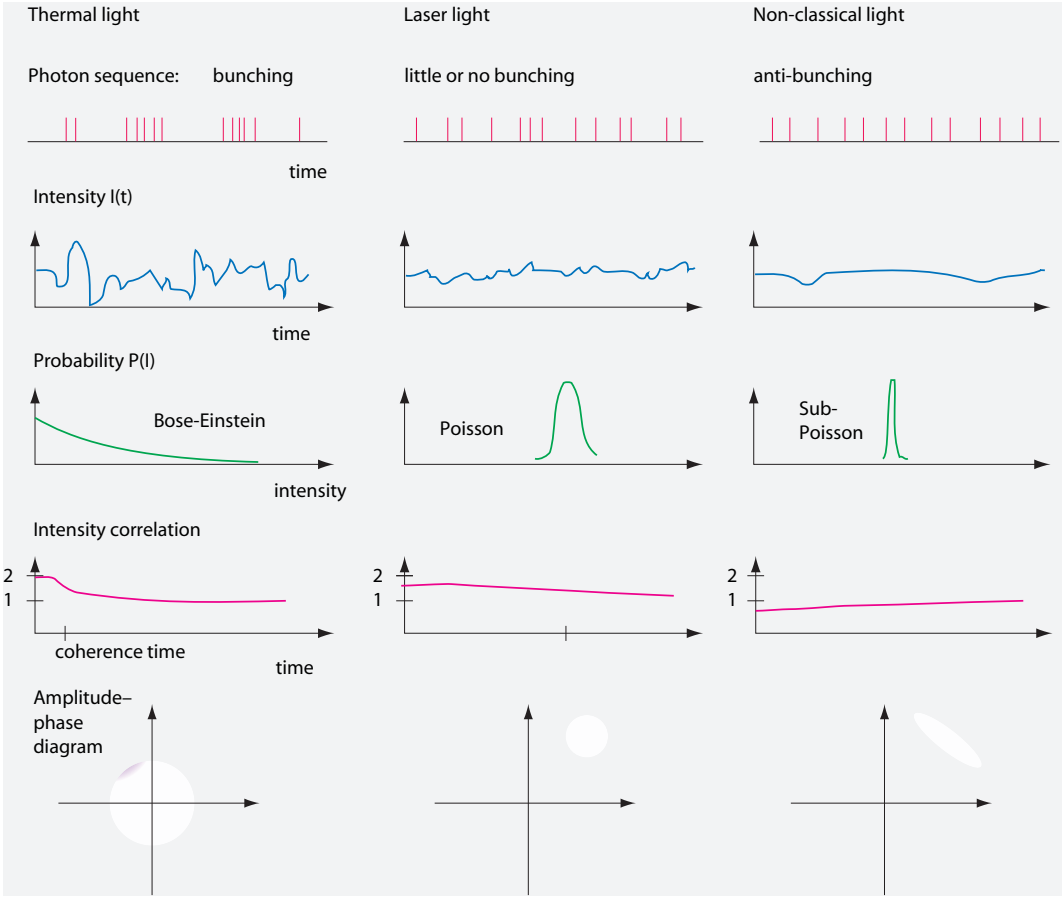

FIGURE 443 Various types of light

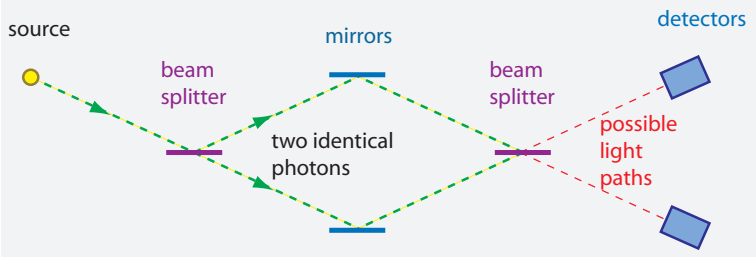

FIGURE 444 An interferometer

In summary, unlike pebbles, *photons are not countable*. And this it not the only difference between photons and pebbles.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

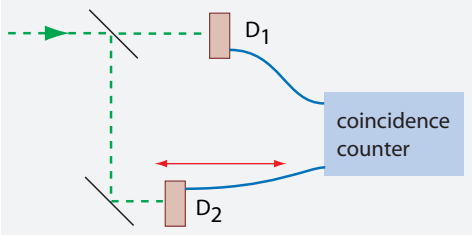

FIGURE 445 How to measure photon statistics with an electronic coincidence counter, the variation being measured by varying the position of a detector

The positions of photons

Where is a photon when it moves in a beam of light? Quantum theory gives a simple answer: nowhere in particular. This is proved most spectacularly by experiments with interferometers; they show that even a beam made of a *single* photon can be split, led along two different paths, and then recombined. The resulting interference shows that the single photon cannot be said to have taken either of the two paths. If one of the two paths is blocked, the pattern on the screen changes. In other words, somehow the photon must have taken both paths at the same time. Photons cannot be localized: they have no position.*

This impossibility of localizing photons can be quantified. It is impossible to localize photons in the direction *transverse* to the motion. It is less difficult to localize photons *along* the direction of motion. In the latter case, the quantum of action implies that the indeterminacy in the longitudinal position is given by the wavelength of the light. Can you confirm this?

Challenge 1366 ny

In particular, this means that photons *cannot* be simply visualized as short wave trains. Photons are truly *unlocalizable* entities, specific to the quantum world.

Now, if photons can *almost* be localized along their direction of motion, we can ask how photons are lined up in a light beam. Of course, we have just seen that it does not make sense to speak of their *precise* position. But do photons in a perfect beam arrive at almost-regular intervals?

To the shame of physicists, the study of this question was initiated by two astronomers, Robert Hanbury Brown and Richard Twiss, in 1956. They used a simple method to measure the probability that the second photon in a light beam arrives at a given time after the first one. They simply split the beam, put one detector in the first branch, and varied the position of a second detector in the other branch.

Ref. 819

Hanbury Brown and Twiss found that, for coherent light, the clicks in the two counters – and thus the photons themselves – are *correlated*. This result is completely contrary to classical electrodynamics. Photons are indeed necessary to describe light. To be more precise, their experiment showed that whenever the first photon hits, the second one is most likely to hit just afterwards. Thus, photons in beams are *bunched*. (As we will see below, this also implies that photons are bosons.)

Page 1011

Every light beam has an upper time limit for bunching, called the *coherence time*. For times longer than the coherence time, the probability for bunching is low, and indepen-

* One cannot avoid this conclusion by saying that photons are *split* at the beam splitter: if a detector is placed in each arm, one finds that they never detect a photon at the same time. Photons cannot be divided.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

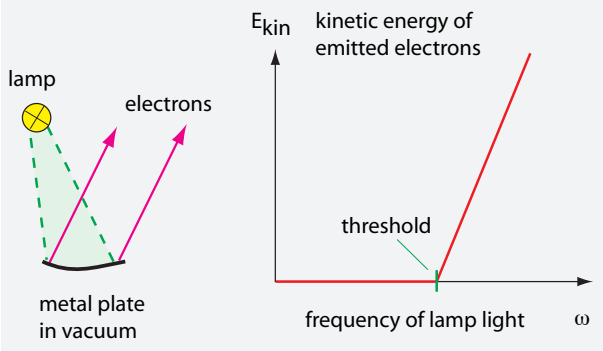

FIGURE 446 The kinetic energy of electrons emitted in the photoelectric effect

dent of the time interval, as shown in Figure 445. The coherence time characterizes every light beam, or rather every light source. In fact, it is often easier to think in terms of the *coherence length* of a light beam. For thermal lamps, the coherence length is only a few micrometres: a small multiple of the wavelength. The largest coherence lengths, of over 100 000 km, are obtained with research lasers. Interestingly, coherent light is even found in nature: several special stars have been found to emit it. Ref. 820

Although the intensity of a good laser beam is almost constant, the photons do not arrive at regular intervals. Even the best laser light shows bunching, though with different statistics and to a lesser degree than lamp light. Light whose photons arrive regularly, thus exhibiting so-called *(photon) anti-bunching*, is obviously non-classical in the sense defined above; such light can be produced only by special experimental arrangements. Extreme examples of this phenomenon are being investigated at present by several research groups aiming to construct light sources that emit one photon at a time, at regular time intervals, as reliably as possible.

In summary, experiments force us to conclude that light is made of photons, but that photons cannot be localized in light beams. It makes no sense to talk about the position of a photon in general; the idea makes sense only in some special situations, and then only approximately and as a statistical average.

Are photons necessary?

In light of the results uncovered so far, the answer to the above question is obvious. But the issue is tricky. In textbooks, the *photoelectric effect* is usually cited as the first and most obvious experimental proof of the existence of photons. In 1887, Heinrich Hertz observed that for certain metals, such as lithium or caesium, incident ultraviolet light leads to charging of the metal. Later studies of the effect showed that the light causes emission of electrons, and that that the energy of the ejected electrons does not depend on the intensity of the light, but only on the difference between $\hbar$ times its frequency and a material-dependent threshold energy. Figure 446 summarizes the experiment and the measurements. In classical physics, these measurement are difficult to explain. But in 1905, Albert Einstein deduced the measurements from the assumption that light is made of photons of energy $E = \hbar\omega$. He imagined that this energy is used partly to take the electron over the threshold, and partly to give it kinetic energy. More photons only lead Ref. 822

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to more electrons, not to faster ones.

In 1921, Einstein received the Nobel Prize for the explanation of the photoelectric effect. But Einstein was a *genius*: he deduced the correct result by a somewhat incorrect reasoning. The (small) mistake was the assumption that a classical, continuous light beam would produce a different effect. In fact it easy to see that a classical, continuous electromagnetic field interacting with discrete matter, made of discrete atoms containing discrete electrons, could lead to exactly the same result, if the motion of electrons is described by quantum theory. Several researchers confirmed this early in the twentieth century. The photoelectric effect by itself does *not* imply the existence of photons.

Ref. 823

Indeed, many researchers were unconvinced that the photoelectric effect shows the existence of photons. Historically, the most important argument for the *necessity* of light quanta was given by Henri Poincaré. In 1911 and 1912, aged 57 and only a few months before his death, he published two influential papers proving that the radiation law of black bodies – in which the quantum of action had been discovered by Max Planck – *requires* the existence of photons. He also showed that the amount of radiation emitted by a hot body is *finite* only because of the *quantum* nature of the processes leading to light emission. A description of these processes in terms of classical electrodynamics would lead to *infinite* amounts of radiated energy. Poincaré's two influential papers convinced most physicists that it was worthwhile to study quantum phenomena in more detail. Poincaré did not know about the action limit $S \geqslant \hbar/2$; yet his argument is based on the observation that light of a given frequency has a minimum intensity, namely a single photon. Such a one-photon beam may be split into two beams, for example by using a half-silvered mirror. However, one will never find more than one photon in those two beams together.

Ref. 824

Another interesting experiment that requires photons is the observation of 'molecules of photons'. In 1995, Jacobson et al. predicted that the de Broglie wavelength of a *packet* of photons could be observed. According to quantum theory, it is given by the wavelength of a single photon divided by the number of photons in the packet. The team argued that the packet wavelength could be observable if such a packet could be split and recombined without destroying the cohesion within it. In 1999, this effect was indeed observed by de Pádua and his research group in Brazil. They used a careful set-up with a nonlinear crystal to create what they call a *biphoton*, and observed its interference properties, finding a reduction in the effective wavelength by the predicted factor of two. Since then, packages with three and even four entangled photons have been created and observed.

Ref. 825

Ref. 826

Yet another argument for the necessity of photons is the above-mentioned recoil felt by atoms emitting light. The recoil measured in these cases is best explained by the emission of a photon in a particular direction. In contrast, classical electrodynamics predicts the emission of a spherical wave, with no preferred direction.

Page 996

Obviously, the observation of *non-classical light*, also called *squeezed light*, also argues for the existence of photons, as squeezed light proves that photons are indeed an *intrinsic* aspect of light, necessary even when interactions with matter play no role. The same is true for the Hanbury Brown–Twiss effect.

Page 1002

Ref. 827

Finally, the spontaneous decay of excited atomic states also requires the existence of photons. This cannot be explained by a continuum description of light.

In summary, the concept of a photon is indeed necessary for a precise description of light; but the details are often subtle, as the properties of photons are unusual and require a change in our habits of thought. To avoid these issues, most textbooks stop

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

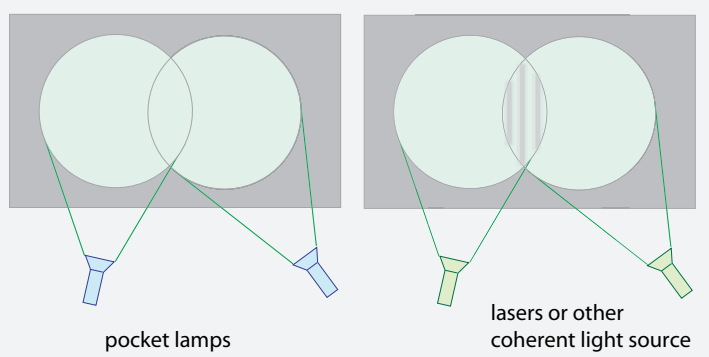

FIGURE 447 Light crossing light

discussing photons after coming to the photoelectric effect. This is a pity, as it is only then that things get interesting. Ponder the following. Obviously, all electromagnetic fields are made of photons. At present, photons can be counted for gamma rays, X-rays, ultraviolet light, visible light and infrared light. However, for lower frequencies, such as radio waves, photons have not yet been detected. Can you imagine what would be necessary to count the photons emitted from a radio station?

Challenge 1367 ny

This issue leads directly to the most important question of all:

How can a wave be made up of particles?

> Fünfzig Jahre intensiven Nachdenkens haben mich der Antwort auf die Frage 'Was sind Lichtquanten?' nicht näher gebracht. Natürlich bildet sich heute jeder Wicht ein, er wisse die Antwort. Doch da täuscht er sich.
>
> Albert Einstein, 1951 *

If a light wave is made of particles, one must be able to explain each and every wave property in terms of photons. The experiments mentioned above already hint that this is possible only because photons are *quantum* particles. Let us take a more detailed look at this.

Light can *cross* other light undisturbed. This observation is not hard to explain with photons; since photons do not interact with each other, and are point-like, they 'never' hit each other. In fact, there *is* an extremely small positive probability for their interaction, as will be found below, but this effect is not observable in everyday life.

But some problems remain. If two light beams of identical frequency and fixed phase relation cross, we observe alternating bright and dark regions: so-called *interference fringes*.** How do these interference fringes appear? How can it be that photons are not

Page 727

* 'Fifty years of intense reflection have not brought me nearer to the answer to the question 'What are light quanta?' Of course nowadays every little mind thinks he knows the answer. But he is wrong.' Einstein said this a few years before his death.

** This experiment is only possible if both beams are derived from a single beam by splitting, or if two expensive high-precision lasers are used. (Why?)

Challenge 1368 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

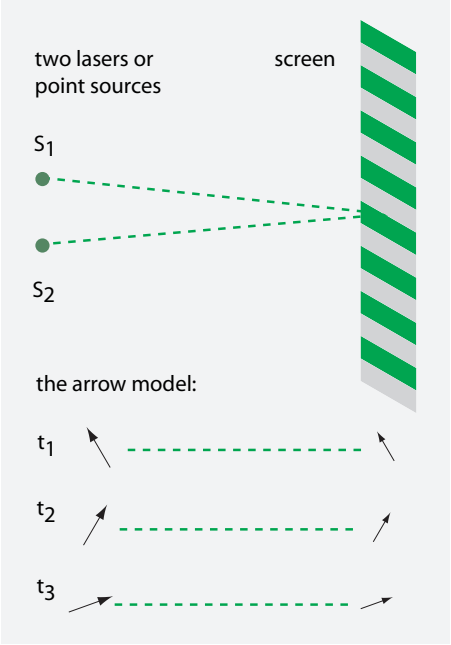

FIGURE 448 Interference and the description of light with arrows (at three instants of time)

detected in the dark regions? There is only one possible answer: the brightness at a given place corresponds to the *probability* that a photon will arrive there. The fringes imply that photons behave like little *arrows*. Some further thought leads to the following description:

— The probability of a photon arriving somewhere is given by the *square of an arrow*.
— The final arrow is the *sum* of all the arrows arriving there by all possible paths.
— The arrow's direction stays fixed in space when the photons move.
— The length of an arrow shrinks with the square of the distance travelled.
— Photons emitted by single-coloured sources are emitted with arrows of constant length pointing in the direction ωt; in other words, such sources spit out photons with a *rotating* mouth.
— Photons emitted by thermal sources, such as pocket lamps, are emitted with arrows of constant length pointing in *random* directions.

With this model* we can explain the stripes seen in laser experiments, such as those of Figure 447 and Figure 448. You can check that in some regions the two arrows travelling through the two slits add up to zero *for all times*. No photons are detected there. In other regions, the arrows always add up to the maximal value. These regions are always bright. Regions in between have intermediate shades. Obviously, in the case of pocket lamps, the brightness also behaves as expected: the averages simply add up, as in the common region shown in the left-hand diagram of Figure 447.

You may wish to calculate the distance between the lines, given the source distance, the colour and the distance to the screen. Challenge 1369 ny

* The model gives a correct description of light except that it neglects polarization.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

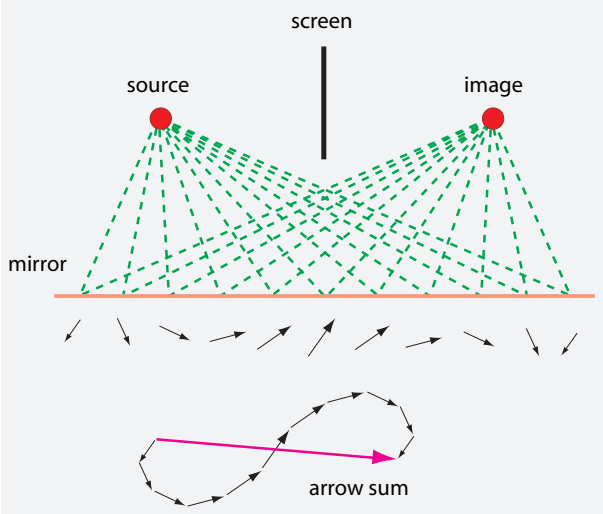

FIGURE 449 Light reflected by a mirror, and the corresponding arrows (at an instant of time)

Obviously, the photon model implies that an interference pattern like this is built up as the sum of a large number of single-photon hits. Using low-intensity beams, we should therefore be able to see how these little spots slowly build up an interference pattern by accumulating in the bright regions and never hitting the dark regions. This is indeed the case. All experiments have confirmed this description.

Page 996

It is important to note that interference between two light beams is *not* the result of two different photons cancelling each other out or being added together. Such cancellation would contradict conservation of energy and momentum. Interference is an effect applicable to each photon separately, because each photon is spread out over the whole set-up: each photon takes all possible paths. As Paul Dirac said, *each photon interferes only with itself*. Interference only works because photons are quantons, and not classical particles.

Ref. 828

Dirac's oft-quoted statement leads to a famous paradox: if a photon can interfere only with itself, how can two laser beams from two different lasers interfere with each other? The answer given by quantum physics is simple but strange: in the region where the beams interfere, it is impossible to say from which source a photon has come. The photons in the crossing region *cannot* be said to come from a specific source. Photons in the interference region are quantons, which indeed interfere only with themselves. In that region, one cannot truly say that light is a flow of photons. Despite regular claims to the contrary, Dirac's statement is correct. It is a strange consequence of the quantum of action.

Waves also show *diffraction*. To understand this phenomenon with photons, let us start with a simple mirror, and study *reflection* first. Photons (like all quantum particles) move from source to detector by *all* possible paths. As Richard Feynman,* who discov-

* Richard ('Dick') Phillips Feynman (b. 1918 New York City, d. 1988), US-American physicist. One of the founders of quantum electrodynamics, he also discovered the 'sum-over-histories' reformulation of quantum theory, made important contributions to the theory of the weak interaction and to quantum gravity,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

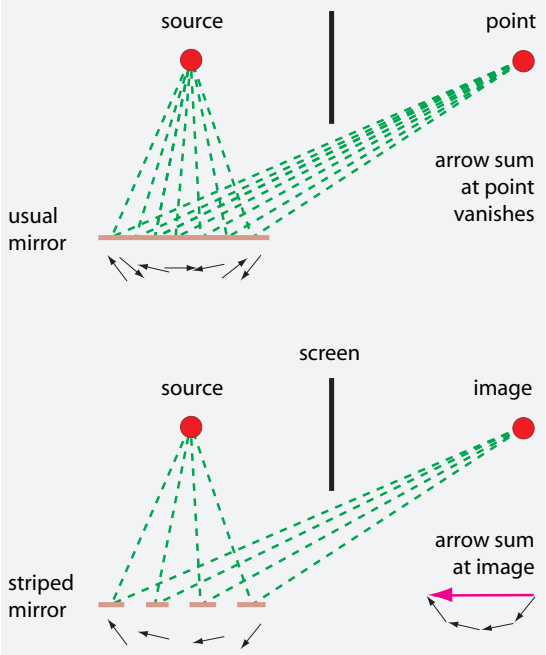

FIGURE 450 The light reflected by a badly-placed mirror and by a grating

ered this explanation, liked to stress, the term 'all' has to be taken literally. This is not a big deal in the explanation of interference. But in order to understand a mirror, we have to include all possibilities, however crazy they seem, as shown in Figure 449.

As stated above, a light source emits rotating arrows. To determine the probability that light arrives at a certain location within the image, we have to add up all the arrows arriving at the same time at that location. For each path, the arrow orientation at the image is shown – for convenience only – below the corresponding segment of the mirror. The angle and length of the arriving arrow depends on the path. Note that the sum of all the arrows does not vanish: light does indeed arrive at the image. Moreover, the largest contribution comes from the paths near to the middle. If we were to perform the same calculation for another image location, (almost) no light would get there. So the rule that reflection occurs with the incoming angle equal to the outgoing angle is an approximation, following from the arrow model of light.

In fact, a detailed calculation, with more arrows, shows that the approximation is quite precise: the errors are much smaller than the wavelength of the light.

and co-authored a famous textbook, the *Feynman Lectures on Physics*. He is one of those theoretical physicists who made his career mainly by performing complex calculations – but he backtracked with age, most successfully in his teachings and books. He helped building the nuclear bomb, wrote papers in topless bars, avoided to take any professional responsibility, and was famously arrogant and disrespectful of authority. Though he tried to surpass the genius of Wolfgang Pauli throughout his life, he failed in this endeavour. He was deeply dedicated to physics and to enlarging knowledge. A collector of surprising physical explanations, he wrote several popular books on his work and life. He shared the 1965 Nobel Prize in Physics for his work on quantum electrodynamics.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

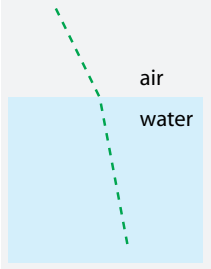

FIGURE 451 If light were made of little stones, they would move faster in water

The proof that light does indeed take all these strange paths is given by a more specialized mirror. As show in Figure 450, one can repeat the experiment with a mirror that reflects only along certain stripes. In this case, the stripes have been carefully chosen so that the corresponding path lengths lead to arrows with a bias in one direction, namely to the left. The arrow addition now shows that such a specialized mirror – usually called a *grating* – allows light to be reflected in unusual directions. Indeed, this behaviour is standard for waves: it is called *diffraction*. In short, the arrow model for photons allows us to describe this wave property of light, provided that photons follow the 'crazy' probability scheme. Do not get upset! As was said above, quantum theory is the theory for crazy people.

You may wish to check that the arrow model, with the approximations it generates by summing over all possible paths, automatically ensures that the quantum of action is indeed the smallest action that can be observed.

Challenge 1370 ny

All waves have a *signal velocity*. The signal velocity also depends on the medium in which they propagate. As a consequence, waves show *refraction* when they move from one medium into another with different signal velocity. Interestingly, the naive particle picture of photons as little stones would imply that light is faster in materials with high refractive indices: the so-called *dense* materials. Can you confirm this? However, experiments show that light in dense materials moves *slowly*. The wave picture has no difficulty explaining this observation. (Can you confirm this?) Historically, this was one of the arguments *against* the particle theory of light. Nevertheless, the arrow model of light presented above is able to explain refraction properly. It is not difficult: try it.

Challenge 1371 ny

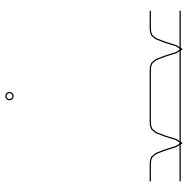
Challenge 1372 ny

Challenge 1373 ny

Waves also *reflect partially* from materials such as glass. This is one of the most difficult wave properties to explain with photons. This is one of the few effects that is *not* explained by a classical wave theory of light. However, it *is* explained by the arrow model, as we will find shortly. Partial reflection confirms rules 1367 and 1367 of the arrow model. It shows that photons indeed behave *randomly*: some are reflected and other are not, without any selection criterion. The distinction is purely statistical. More about this issue shortly.

In waves, the fields *oscillate in time and space*. One way to show how waves can be made of particles is to show how to build up a sine wave using a large number of photons. A sine wave is a coherent state of light. The way to build them up was explained by Roy Glauber. In fact, to build a pure sine wave, one needs a superposition of a beam with one photon, a beam with two photons, a beam with three photons, and so on. Together, they give a perfect sine wave. As expected, its photon number fluctuates to the highest possible degree.

Ref. 829



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

If we repeat the calculation for non-ideal beams, we find that the indeterminacy relation for energy and time is respected: every emitted beam will possess a certain spectral width. Purely monochromatic light does not exist. Similarly, no system that emits a wave *at random* can produce a monochromatic wave. All experiments confirm these results.

Waves can be *polarized*. So far, we have disregarded this property. In the photon picture, polarization is the result of carefully superposing beams of photons spinning clockwise and anticlockwise. Indeed, we know that linear polarization can be seen as a result of superposing circularly-polarized light of both signs, using the proper phase. What seemed a curiosity in classical optics turns out to be a fundamental justification for quantum theory.

Photons are *indistinguishable*. When two photons of the same colour cross, there is no way to say afterwards which of the two is which. The quantum of action makes this impossible. The indistinguishability of photons has an interesting consequence. It is impossible to say which emitted photon corresponds to which arriving photon. In other words, there is no way to follow the path of a photon, as we are used to following the path of a billiard ball. In addition, the experiment by Hanbury Brown and Twiss, implies that photons are bosons. Particles with this property are called bosons. We will discover more details about the indistinguishability of bosons later in.

Page 1003
Ref. 830
Page 1052

In summary, we find that light waves *can* indeed be built of particles. However, this is only possible with the proviso that photons are not precisely countable, that they are not localizable, that they have no size, no charge and no mass, that they carry an (approximate) phase, that they carry spin, that they are indistinguishable bosons, that they can take any path whatsoever, that one cannot pinpoint their origin, and that their probability of arriving somewhere is determined by the square of the sum of amplitudes for all possible paths. In other words, light can be made of particles only if these particles have very special *quantum* properties. These quantum properties allow them to behave like waves when they are present in large numbers.

Quantons are thus quite different from ordinary particles. In fact, one can argue that the only (classical) particle aspects of photons are their quantized energy, momentum and spin. In all other respects, photons are *not* like little stones. It is more accurate to say that *photons are calculating devices to precisely describe observations about light*. These calculating devices are often called *quantons*. In summary, *all waves are streams of quantons*. In fact, all waves are *correlated* streams of quantons. This is true for light, for any other form of radiation, and for all forms of matter.

Ref. 831

The strange properties of quantons are the reason why earlier attempts to describe light as a stream of (classical) particles, such as the attempt of Newton, failed miserably, and were rightly ridiculed by other scientists. Indeed, Newton upheld his theory against all experimental evidence – especially with regard to light's wave properties – which is something that a physicist should never do. Only after people had accepted that light is a wave, and then discovered and understood that quantum particles are different from classical particles, was the approach successful.

The indeterminacy relations show that even a single quanton can be regarded as a wave; however, whenever it interacts with the rest of the world, it behaves as a particle. In fact, it is *essential* that all waves be made of quantons; but if they are not, then interactions are non-local, and objects, contrary to experience, cannot be localized at all. To decide between the wave and particle descriptions, we can use the following criterion. Whenever

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

matter and light interact, it is more appropriate to describe electromagnetic radiation as a wave if the wavelength λ satisfies

$$\lambda \gg \frac{\hbar c}{kT} , \tag{593}$$

where $k = 1.4 \cdot 10^{-23}$ J/K is Boltzmann's constant. If the wavelength is much *smaller* than the quantity on the right-hand side, the particle description is most appropriate. If the two sides are of the same order of magnitude, both descriptions play a role.

Can light move faster than light? – Virtual photons

In a vacuum, light can move faster than c, as well as slower than c. The quantum principle provides the details. As long as this principle is obeyed, the speed of a short light flash can differ – though only by a tiny amount – from the 'official' value. Can you estimate the allowable difference in arrival time for a light flash coming from the dawn of time?

Challenge 1374 ny

The arrow explanation gives the same result. If one takes into account the crazy possibility that photons can move with any speed, one finds that all speeds very different from c cancel out. The only variation that remains, translated into distances, is the indeterminacy of about one wavelength in the longitudinal direction, which we mentioned above.

Challenge 1375 ny

More bizarre consequences of the quantum of action appear when one studies *static* electric fields, such as the field around a charged metal sphere. Obviously, such a field must also be made of photons. How do they move? It turns out that static electric fields are made of *virtual* photons. Virtual photons are photons that do not appear as free particles: they only appear for an extremely short time before they disappear again. In the case of a static electric field, they are *longitudinally* polarized, and do not carry energy away.

Virtual photons, like other virtual particles, are 'shadows' of particles that obey

$$\Delta x \Delta p \leqslant \hbar/2 . \tag{594}$$

Rather than obeying this indeterminacy relation, they obey the opposite relation, which expresses their very brief appearance. Despite their intrinsically short life, and the impossibility of detecting them directly, they have important effects. We will explore virtual particles in detail shortly.

Page 1037

In fact, the vector potential A allows *four* polarizations, corresponding to the four coordinates (t, x, y, z). It turns out that for the photons one usually talks about – the free or *real* photons – the polarizations in the t and z directions cancel out, so that one observes only the x and y polarizations in actual experiments.

For bound or *virtual* photons, the situation is different. All four polarizations are possible. Indeed, the z and t polarizations are the ones that can be said to be the building blocks of *static* electric and magnetic fields.

In other words, static electric and magnetic fields are continuous flows of virtual photons. Virtual photons can have mass, can have spin directions not pointing along the path of motion, and can have momentum opposite to their direction of motion. All these prop-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

erties are in contrast to real photons. Exchange of virtual photons leads to the *attraction* of bodies of different charge. In fact, virtual photons *necessarily* appear in any description of electromagnetic interactions. Later on we will discuss their effects further – including the famous attraction of neutral bodies.

In summary, light can indeed move faster than light, though only by an amount allowed by the quantum of action. For everyday situations, i.e., for high values of the action, all quantum effects average out, including light velocities different from c.

There is another point that we should mention here. Not only the position, but also
Ref. 832 the energy of a single photon can be undefined. For example, certain materials split one photon of energy $\hbar\omega$ into two photons, whose two energies add up to the original one. Quantum mechanics implies that the energy partitioning is known only when the energy of one of the two photons is measured. Only at that very instant is the energy of the second photon known. Before it, both photons have undefined energies. The process of energy fixing takes place *instantaneously*, even if the second photon is far away. We
Page 1082 will explain below the background to this and similar strange effects, which *seem* to be faster than light. In fact, they do not involve faster-than-light transmission of energy or
Challenge 1376 ny information.

Indeterminacy of electric fields

We have seen that the quantum of action implies an indeterminacy for light intensity. This implies a similar limit for electric and magnetic fields. This conclusion was first
Ref. 833 drawn in 1933 by Bohr and Rosenfeld. They started from the effects of the fields on a test particle of mass m and charge q, which are described by:

$$m\boldsymbol{a} = q(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{b}) \,. \tag{595}$$

Since it is impossible to measure both the momentum and the position of a particle, they
Challenge 1377 ny deduced an indeterminacy for the electrical field, given by

$$\Delta E = \frac{\hbar}{q\,\Delta x\,T} \,, \tag{596}$$

where T is the measurement time and Δx is the position indeterminacy. Thus every value of an electric field, and similarly of a magnetic field, possesses an indeterminacy. The physical state of the electromagnetic field behaves like the state of matter in this respect. This is the topic we explore now.

Curiosities and fun challenges about photons

Can one explain refraction with photons? Newton was not able to do so, but today we can. In refraction by a horizontal surface, as shown in Figure 452, the situation is translationally invariant along the horizontal direction. Therefore, the momentum component along this direction is also conserved: $p_1 \sin\alpha_1 = p_2 \sin\alpha_2$. The photon energy $E = E_1 = E_2$ is obviously conserved.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

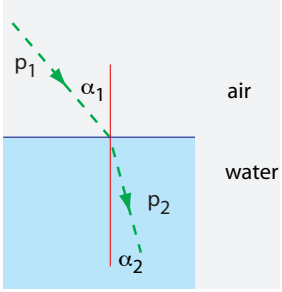


FIGURE 452 Refraction and photons

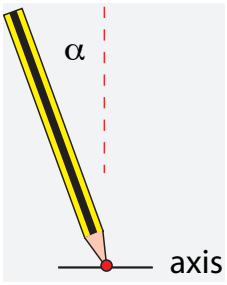

FIGURE 453 A falling pencil

The index of refraction n is defined in terms of momentum and energy as

$$n = \frac{cp}{E} \,. \tag{597}$$

The 'law' of refraction follows.

There is an important issue here. The velocity of a photon $v = \delta E/\delta p$ in a light ray is *not* the same as the phase velocity $u = E/p$ that enters into the calculation.

* *

If en electromagnetic wave has amplitude A, the photon density d is

$$d = \frac{A^2}{\hbar\omega} \,. \tag{598}$$

Challenge 1378 ny Can you show this?

* *

A typical effect of the quantum 'laws' is the yellow colour of the lamps used for street illumination in most cities. They emit pure yellow light of a single frequency; that is why no other colours can be distinguished in their light. According to classical electrodynamics, harmonics of that light frequency should also be emitted. Experiments show, however, that this is not the case; so classical electrodynamics is thus wrong. Is this argument correct? Challenge 1379 ny

* *

What happens to photons that hit an object but are not absorbed or transmitted? Generally speaking, they are *scattered*. The details of the scattering depend on the object, as Table 92 shows.

Chapter 35

MOTION OF MATTER – BEYOND CLASSICAL PHYSICS

> All great things begin as blasphemies.
> George Bernard Shaw

The existence of a smallest action has numerous consequences for the motion of matter. We start with a few experimental results that show that the quantum of action is indeed the smallest measurable action.

Wine glasses and pencils – no rest

> Otium cum dignitate.*
> Cicero, *De oratore*.

A simple consequence of the quantum of action is the impossibility of completely filling a glass of wine. If we call a glass at maximum capacity (including surface tension effects, to make the argument precise) 'full', we immediately see that the situation requires the liquid's surface to be completely at rest. But a completely quiet surface would admit two successive observations that differ by less than $\hbar/2$. We could try to reduce all motions by reducing the temperature of the system. But absolute rest would imply reaching absolute zero temperature. Experiments show that this is impossible. (Indeed, this impossibility, the so-called *third 'law' of thermodynamics*, is equivalent to the existence of a minimum action.) *There is no rest in nature.* In other words, the quantum of action proves the old truth that a glass of wine is always partially empty *and* partially full.

The absence of microscopic rest, predicted by the quantum of action, is confirmed in many experiments. For example, a pencil standing on its tip *cannot* remain vertical, even if it is isolated from all disturbances, such as vibrations, air molecules and thermal motion. This follows from the indeterminacy relation. In fact, it is even possible to calculate the time after which a pencil must have fallen over.**

* 'Rest with dignity.'

Ref. 834 ** This is not easy, but not too difficult either. For an initial orientation *close* to the vertical, the fall time T turns out to be

$$T = \frac{1}{2\pi} T_0 \ln \frac{8}{\alpha} \tag{599}$$

where α is the starting angle, and a fall through angle π is assumed. Here T_0 is the oscillation time of the pencil for small angles. (Can you determine it?) Challenge 1380 ny

The indeterminacy relation for the tip of the pencil yields a minimum starting angle, because the momentum indeterminacy cannot be made arbitrarily large. You should be able to provide an upper limit. Once this angle is known, you can calculate the maximum time. Challenge 1381 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The absence of rest for the electrons inside atoms also prevents them from falling into the nuclei. The size of atoms, and thus of all matter, is therefore a direct consequence of the absence of microscopic rest.

Cool gas

Rest is impossible in nature. In fact, even at extremely low temperatures, the particles inside matter are in motion. This fundamental lack of rest is said to be due to the so-called *zero-point fluctuations*. A good example is provided by the recent measurements of Bose–Einstein condensates, systems with a small number of atoms (between ten and a few million) at extremely low temperatures (around 1 nK). These cool gases can be observed with high precision. Using elaborate experimental techniques, Bose–Einstein condensates can be put into states for which $\Delta p \Delta x$ is almost exactly equal to $\hbar/2$ – though never lower than this value.

This leads to an interesting puzzle. In a normal object, the distance between the atoms is much larger than their de Broglie wavelength. (Can you confirm this?) But today it is possible to cool objects to extremely low temperatures. At sufficiently low temperatures, less than 1 nK, the wavelength of the atoms may be larger than their separation. Can you imagine what happens in such cases?

Challenge 1382 s
Ref. 835
Challenge 1383 s

No infinite precision

The quantum of action prevents the observation of rest in many ways. In order to determine the position of a system with high precision, we need a high-energy probe: only a high-energy probe has a wavelength small enough to allow very precise position measurements. As a result of this high energy, however, the system is disturbed. Worse, the disturbance itself is not precisely measurable; so there is no way to determine the original position even by taking the disturbance into account. In short, perfect rest cannot be observed even in principle. Indeed, all experiments in which systems have been observed with high precision confirm that perfect rest does not exist. For example, this result has been confirmed for electrons, neutrons, protons, ions, atoms, molecules, atomic condensates, crystals, and objects with a mass of up to a tonne, as used in certain gravitational wave detectors.

Flows and the quantization of matter

> “Die Bewegung ist die Daseinsform der Materie.”
> Friedrich Engels, *Anti-Dühring*.*

Not only does the quantum of action make rest impossible, but it makes any situation that does not change in time impossible. The most important examples of (apparently) stationary situations are *flows*. The quantum of action implies that *no* flow can be stationary. More precisely, a smallest action implies that no flow can be continuous. All flows are made of smallest entities. Flows are made of quantum particles. Apart from light, there are two types of flow from our everyday experience for which we should confirm this directly: flows of electricity and flows of liquids.

Ref. 813

* ‘Motion is matter’s way of being.’

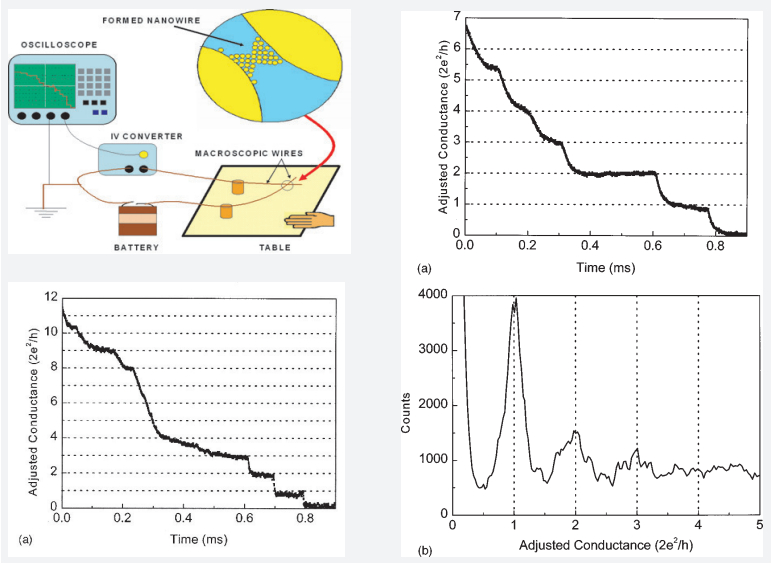

FIGURE 455 Steps in the flow of electricity in metal wire crossings: the set-up, the nanowires at the basis of the effect, and three measurement results (© José Costa-Krämer, AAPT from Ref. 837)

Knocking tables and quantized conductivity

If electrical current were a continuous flow, it would be possible to observe action values as small as desired. The simplest counter-example was discovered in 1996, by José Costa-Krämer and his colleagues. They put two metal wires on top of each other on a kitchen table and attached a battery, a current-voltage converter (or simply a resistor) and a storage oscilloscope to them. Then they measured the electrical current while *knocking* on the table. In the last millisecond before the wires detach, the conductivity and thus the electrical current diminished in regular steps of a 7 μA, as can easily be seen on the oscilloscope (see Figure 455). This simple experiment could have beaten, if it had been performed a few years earlier, a number of earlier, enormously expensive experiments which discovered this quantization at costs of several million euro each, using complex set-ups at extremely low temperatures.

Ref. 836, Ref. 837

In fact, the quantization of conductivity appears in any electrical contact with a small cross-section. In such situations the quantum of action implies that the conductivity can only be a multiple of $2e^2/\hbar \approx 1/12\,906\,1/\Omega$. Can you confirm this result? Note that electrical conductivity can be as small as required; only the *quantized* electrical conductivity has the minimum value of $2e^2/\hbar$.

Challenge 1384 ny

Many more elaborate experiments confirm the observation of conductance steps. They force us to conclude that there is a *smallest charge* in nature. This smallest charge has the same value as the charge of an electron. Indeed, electrons turn out to be part of every atom, in a construction to be explained shortly. In metals, a large number of electrons can move freely: that is why metals conduct electricity so well.

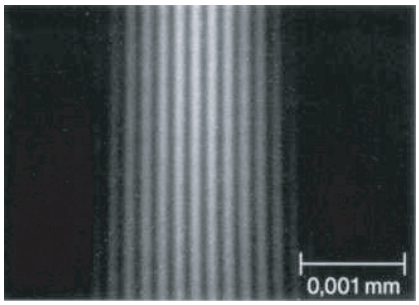

FIGURE 456 Electrons beams diffract and interfere at multiple slits (© Claus Jönsson)

Quantized liquid flow

The flow of matter also exhibits smallest units. We mentioned in the first part that a consequence of the particulate structure of liquids is that oil or any other smooth liquid produces *noise* when it flows through even the smoothest of pipes. We mentioned that the noise we hear in our ears in situations of absolute silence – for example, in a snowy landscape in the mountains – is due to the granularity of blood flow in the veins. Experiments show that all flows of matter produce vibrations. This is a consequence of the quantum of action, and of the resulting granularity of matter.

In short, matter and electricity flow in smallest units. Depending on the material, the smallest flowing units of matter may be 'molecules', 'atoms', 'ions', or 'electrons'.

Matter quantons and their motion – matter waves

Electrons, ions, atoms and molecules are *quantum* particles, or *quantons*. Like photons, matter quantons share some properties with ordinary stones, but also differ from them in many ways. A stone has position and momentum, mass and acceleration, orientation and angular momentum, size, shape, structure and colour. Let us explore each of these properties for quantons.

Ref. 838 In 1923 and 1924, the French physicist Louis de Broglie pondered the concept of the photon and the possible consequences of the quantum of action for matter particles. In the case of light, the quantum of action connects wave behaviour to particle behaviour. He reasoned that the same should apply to matter. It dawned to him that streams of matter particles with the same momentum should behave as waves, just as light quanta do. He thus predicted that coherent matter flows should have a wavelength and angular frequency given by

$$\lambda = \frac{2\pi\hbar}{p} \quad \text{and} \quad \omega = \frac{E}{\hbar}\,, \tag{600}$$

where p and E are the momentum and the energy, respectively, of the single particles. Soon after this prediction, experiments began to confirm the idea. It is indeed observed that matter streams can diffract, refract and interfere, with the values predicted by de Broglie. Because of the smallness of the wavelength, careful experiments are needed to detect these effects. But one by one, all experimental confirmations of the wave properties of light were repeated for matter beams. For example, just as light is diffracted when

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

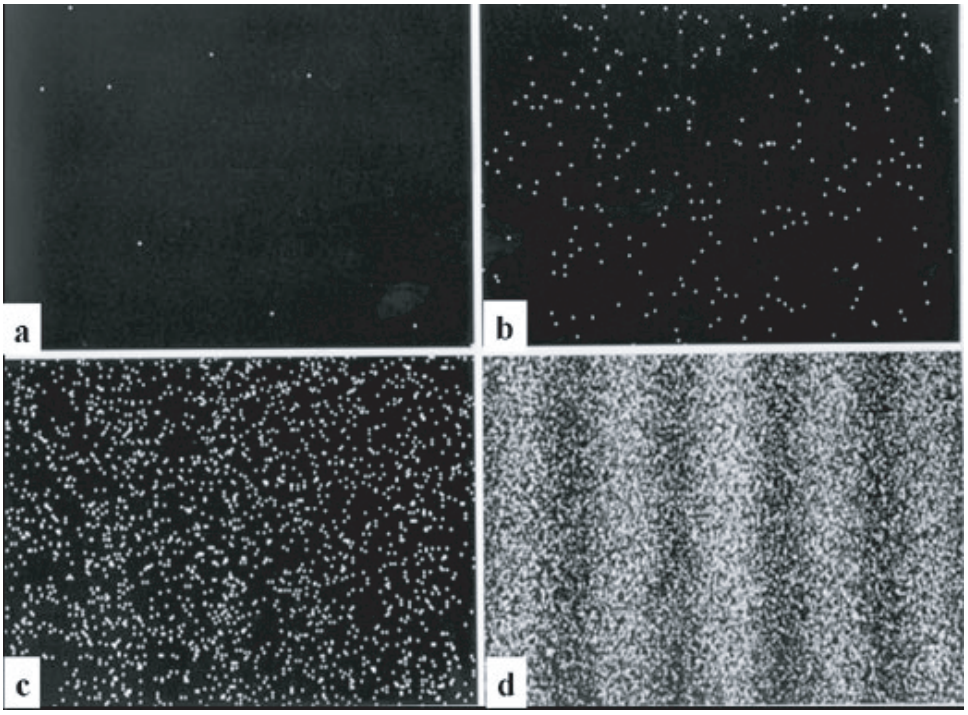

FIGURE 457 Formation of an interference pattern in a low-intensity double-slit experiment: (a) 8 electrons, (b) 270 electrons, (c) 2000 electrons, (d) 6000 electrons, after 20 minutes of exposure (© Tonomura Akira/Hitachi)

it passes around an edge or through a slit, matter is also diffracted in these situations. Ref. 839 This is true even for electrons, the simplest particles of matter, as shown in Figure 456. (The experiment with electrons, performed by Claus Jönsson in Tübingen in 1961, was voted the most beautiful experiment in all of physics in 2002.)

Inspired by light interferometers, researchers began to build *matter* interferometers. Ref. 840 Today these work with beams of electrons, nucleons, nuclei, atoms, or even large Page 726 molecules. Just as observations of light interference prove the wave character of light, so the interference patterns observed with these instruments prove the wave character of matter.

Like light, matter is also made of particles; like light, matter behaves as a wave when large numbers of particles with the same momentum are involved. But although beams of large molecules behave as waves, everyday objects – such as cars on a motorway – do not seem to. There are two main reasons for this. First, for cars on a motorway the relevant wavelength is extremely small. Secondly, the speeds of the cars vary too much: streams of cars with the same speed could be coherent, but these are extremely rare in everyday life.

If matter behaves like a wave, we can draw a strange conclusion. For any wave, the position and the wavelength cannot both be sharply defined simultaneously: the indeter-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

minacies of the wave number $k = 2\pi/\lambda$ and of the position X obey the relation

$$\Delta k \Delta X \geq \frac{1}{2} \,. \tag{601}$$

Similarly, for every wave the angular frequency $\omega = 2\pi f$ and the instant T of its peak amplitude cannot both be sharply defined. Their indeterminacies are related by

$$\Delta \omega \Delta T \geq \frac{1}{2} \,. \tag{602}$$

Using the wave properties of matter, we get

$$\Delta p \Delta X \geqslant \frac{\hbar}{2} \qquad \text{and} \qquad \Delta E \Delta T \geqslant \frac{\hbar}{2} \,. \tag{603}$$

These famous relations are called *Heisenberg's indeterminacy relations*. They were discovered by the German physicist Werner Heisenberg in 1925. They state that there is no way to simultaneously ascribe a precise momentum and position to a material system, nor to simultaneously ascribe a precise energy and age. The more accurately one quantity is known, the less accurately the other is.* Matter quantons – rather like stones, but unlike photons – *can* be localized, but only approximately.

Both these indeterminacy relations have been checked experimentally in great detail. In fact, every experiment proving that matter behaves like a wave is a confirmation of the indeterminacy relation – and vice versa.

Incidentally, Niels Bohr called the relation between two variables linked in this way *complementarity*. He then systematically explored all possible such pairs. You can search for such pairs yourself. Bohr was deeply fascinated by the existence of a complementarity principle, and he later extended it in philosophical directions. In a famous story, somebody asked him what was the quantity complementary to precision. He answered: 'clarity'.

Challenge 1385 ny

In short, the quantum of action means that values of position and momentum cannot both be exactly defined for quantons. The values are fuzzy – position and momentum are undetermined. In addition, the more precisely one of the two is known, the less precisely the other is known.

Mass and acceleration of quantons

Matter quantons, like stones, have mass. Hits by single electrons, atoms or molecules can be detected. Quantons can also be slowed down or accelerated. We have already explored some of these experiments in the section on electrodynamics. However, quantons differ from pebbles. Using the time–energy indeterminacy relation, you can deduce that

Page 680

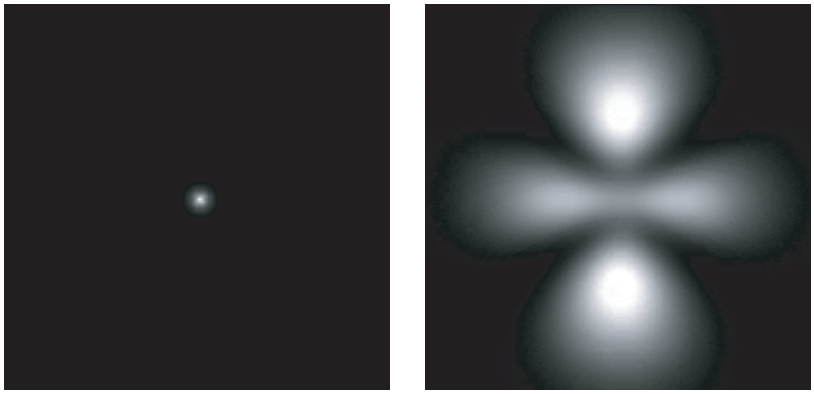

FIGURE 458 Probability clouds: a hydrogen atom in its spherical ground state (left) and in a non-spherical excited state (right) as seen by an observer travelling around it (QuickTime film produced with Dean Dauger's software package 'Atom in a Box', available at daugerresearch.com)

Thus there is a maximum acceleration for quantons.* Indeed, no particle has ever been observed with a higher acceleration than this value. In fact, no particle has ever been observed with an acceleration anywhere near this value.

Ref. 841

Velocities of quantons

The usual, *real*, matter quantons always move more slowly than light. However, the quantum of action allows the existence of particles that move faster than light – so-called *virtual* particles – which we will meet later on.

Page 1037

Why are atoms not flat? Why do shapes exist?

Experiments show that composed quantons have structures with finite sizes and often complex shapes. Obviously, the size and shape of quantons is due to the motion of their constituents.

In 1901, Jean Perrin, and independently in 1904 Nagaoka Hantaro, proposed that atoms are small 'solar systems'. In 1913, Niels Bohr used this idea, combining it with the quantum of action, and found that he could predict a number of properties of the hydrogen atom that had not until then been understood. These calculations, though often found in textbooks, are only of historical interest today. Even Bohr knew that they were not correct, because they assumed that hydrogen atoms were flat. This is observed not to be the case; moreover, it contradicts the quantum of action. Since the motion of quantum

Challenge 1388 e

* We note that this acceleration limit is different from the acceleration limit due to general relativity:

$$a \leqslant \frac{c^4}{4Gm} \,. \tag{605}$$

In particular, the quantum limit (604) applies to microscopic particles, whereas the general-relativistic limit applies to macroscopic systems. Can you confirm that in each domain the relevant limit is the smaller of the two?

Challenge 1387 e

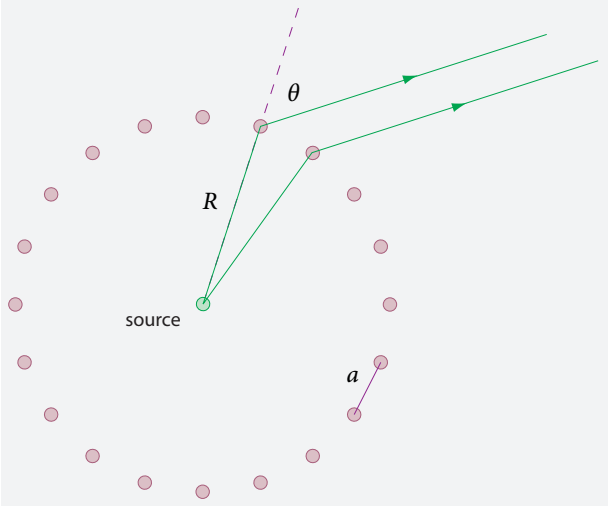

FIGURE 459 The quantization of angular momentum

constituents is fuzzy, all composed quantons must be made of *clouds* of constituents.

While atoms are spherical, molecules have more complex shapes. Experiment and theory show that the shape of any atom or molecule is due to the cloud, or probability distribution, of its electrons. Quantum theory states that atoms or molecules are not hard balls, as Democritus or Dalton believed, but that they are clouds. Atomic electron clouds are not infinitely hard, but can to a certain degree mix and interpenetrate. This mixing leads to molecules, liquids, solids, flowers and people.

Of course, the quantum of action also implies that shapes fluctuate. For example, if a long molecule is held fixed at its two ends, it cannot remain at rest in between. Such experiments are easy to perform, for example with DNA; they again confirm that perfect rest does not exist.

Rotation of quantons – the lack of north poles

> Tristo è quel discepolo che non avanza il suo maestro.
>
> Leonardo da Vinci*

Stones can rotate. The quantum of action also has important consequences for rotational motion. Action and angular momentum have the same physical dimensions. It only takes a little thought to show that if matter or radiation has a momentum and wavelength related by the quantum of action, then angular momentum is fixed in multiples of the quantum of action. This famous argument is due to Dicke and Wittke. Ref. 844

Imagine a circular fence, made of N steel bars spaced apart at a distance $a = 2\pi R/N$, as shown in Figure 459. At the centre of the fence, imagine a source of matter or radiation that can emit particles towards the fence in any chosen direction. The linear momentum

* 'Sad is that disciple who does not surpass his master.' This statement is sculpted in large letters in the chemistry aula of the University of Rome *La Sapienza*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of such a particle is $p = \hbar k = 2\pi\hbar/\lambda$. At the fence slits, the wave will interfere. Outside the fence, the direction of the motion of the particle is determined by the condition of positive interference. In other words, the angle θ, describing the direction of motion outside the fence, is given by $a \sin\theta = M\lambda$, where M is an integer. Through the deflection due to the interference process, the fence receives a linear momentum $p \sin\theta$, or an angular momentum $L = pR \sin\theta$. Using all these expressions, one finds that the angular momentum transferred to the fence is

$$L = NM\hbar \,. \tag{606}$$

In other words, the angular momentum of the fence is an integer multiple of $\hbar$. Fences can only have integer intrinsic angular momenta (in units of $\hbar$). Of course, this is only a hint, not a proof. Nevertheless, the generalization of argument to all bodies is correct. The measured intrinsic angular momentum of bodies is always a multiple of $\hbar$. Quantum theory thus states that every object's angular momentum increases in steps. Angular momentum is quantized.

But rotation has more interesting aspects. Thanks to the quantum of action, just as linear momentum is usually fuzzy, so is angular momentum. There is an indeterminacy relation for angular momentum L. The complementary variable is the phase angle φ of the rotation. The indeterminacy relation can be expressed in several ways. The simplest – though not the most precise – is

Ref. 845 Ref. 846 Page 1001

$$\Delta L \, \Delta\varphi \geqslant \frac{\hbar}{2} \,. \tag{607}$$

(This is obviously an approximation: the relation is only valid for large angular momenta. It cannot be valid for small values, as $\Delta\varphi$ by definition cannot grow beyond 2π. In particular, angular-momentum eigenstates have $\Delta L = 0$.*) The indeterminacy of angular momentum appears for all macroscopic bodies, or alternatively, for all cases when the angular phase of the system can be measured.

The quantization and indeterminacy of angular momentum have important consequences. Classically speaking, the poles of the Earth are the places that do not move when observed by a non-rotating observer. Therefore, at those places matter would have a defined position and a defined momentum. However, the quantum of action forbids this. There cannot be a North Pole on Earth. More precisely, the idea of a rotational axis is an approximation, not valid in general.

Even more interesting are the effects of the quantum of action on microscopic particles, such as atoms, molecules or nuclei. To begin with, we note that action and angular momentum have the same units. The precision with which angular momentum can be

* An *exact* formulation of the indeterminacy relation for angular momentum is

$$\Delta L \, \Delta\varphi \geqslant \frac{\hbar}{2} |1 - 2\pi P(\pi)| \,, \tag{608}$$

where $P(\pi)$ is the normalized probability that the angular position has the value π. For an angular-momentum eigenstate, one has $\Delta\varphi = \pi/\sqrt{3}$ and $P(\pi) = 1/2\pi$. This expression has been tested and confirmed by experiments. Ref. 847

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

measured depends on the precision of the rotation angle. But if a *microscopic* particle rotates, this rotation might be unobservable: a situation in fundamental contrast with the case of *macroscopic* objects. Experiments indeed confirm that many microscopic particles have unobservable rotation angles. For example, in many (but not all) cases, an atomic nucleus rotated by half a turn cannot be distinguished from the unrotated nucleus.

If a microscopic particle has a *smallest* unobservable rotation angle, the quantum of action implies that the angular momentum of that particle *cannot* be zero. It must always be rotating. Therefore we need to check, for each particle, what its smallest unobservable angle of rotation is. Physicists have checked all particles in nature in experiments, and found smallest unobservable angles (depending on the particle type) of 0, 4π, 2π, $4\pi/3$, π, $4\pi/5$, $2\pi/3$, etc.

Let us take an example. Certain nuclei have a smallest unobservable rotation angle of *half* a turn. This is the case for a prolate nucleus (one that looks like a rugby ball) turning around its short axis. Both the largest observable rotation and the indeterminacy are thus a *quarter* turn. Since the change, or action, produced by a rotation is the number of turns multiplied by the angular momentum, we find that the angular momentum of this nucleus is $2 \cdot \hbar$.

As a general result, we deduce from the minimum angle values that the angular momentum of a microscopic particle can be 0, $\hbar/2$, $\hbar$, $3\hbar/2$, $2\hbar$, $5\hbar/2$, $3\hbar$, etc. In other words, the intrinsic angular momentum of a particle, usually called its *spin*, is an integer multiple of $\hbar/2$. Spin describes how a particle behaves under rotations. (It turns out that all spin-0 particles are composed of other particles, thus respecting the quantum of action as the limit for rotational motion in nature.)

How can a particle rotate? At this point, we do not yet know how to *picture* the rotation. But we can *feel* it – just as we showed that light is made of rotating entities: all matter, including electrons, can be *polarized*. This is shown clearly by the famous Stern–Gerlach experiment.

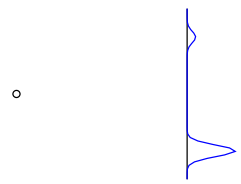
Silver, Stern and Gerlach – polarization of quantons

After a year of hard work, in 1922, Otto Stern and Walther Gerlach* completed an experiment to investigate the polarization of matter quantons. They knew that inhomogeneous magnetic fields act as polarizers for rotating charges. Rotating charges are present in every atom. Therefore they let a beam of silver atoms, extracted from an oven by evaporation, pass an inhomogeneous magnetic field. They found that the beam splits into two *separate* beams, as shown in Figure 460. No atoms leave the magnetic field region in intermediate directions. This is in full contrast to what would be expected from classical physics.

Ref. 848

The splitting into two beams is an intrinsic property of silver atoms; today we know that it is due to their spin. Silver atoms have spin $\hbar/2$, and depending on their orientation in space, they are deflected either in the direction of the field inhomogeneity or against it. The splitting of the beam is a pure quantum effect: there are no intermediate

* Otto Stern (1888–1969) and Walther Gerlach (1889–1979), both German physicists, worked together at the University of Frankfurt. For his subsequent measurement of the anomalous magnetic moment of the proton, Stern received the Nobel Prize for physics in 1943, after he had had to flee Germany.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

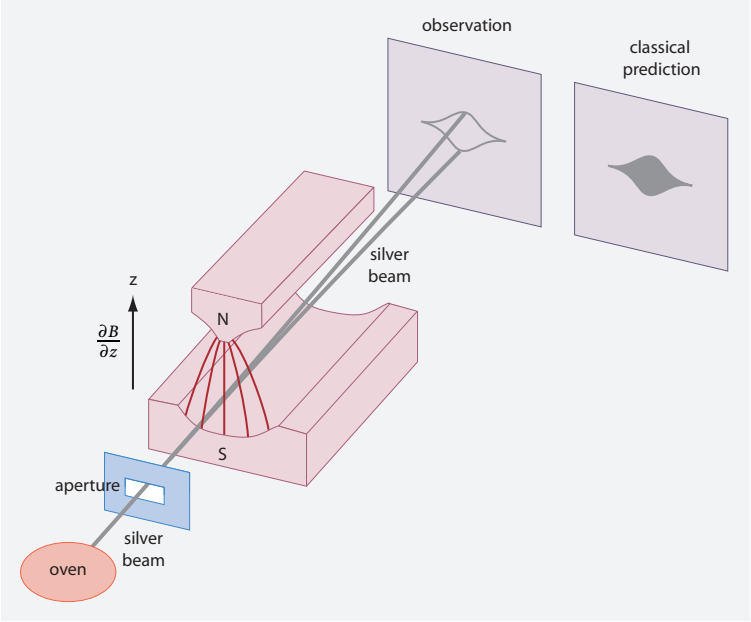


FIGURE 460 The Stern–Gerlach experiment

options. Indeed, the Stern–Gerlach experiment provides one of the clearest demonstrations that classical physics does not work well in the microscopic domain. In 1922, the result seemed so strange that it was studied in great detail all over the world.

When one of the two beams – say the 'up' beam – is passed through a second set-up, all the atoms end up in the 'up' beam. The other possible exit, the 'down' beam, remains unused in this case. In other words, the up and down beams, in contrast to the original beam, cannot be split. This is not surprising.

But if the second set-up is rotated by $\pi/2$ with respect to the first, again two beams – 'right' and 'left' – are formed, and it does not matter whether the incoming beam is directly from the oven or from the 'up' part of the beam. A partially-rotated set-up yields a partial, uneven split. The proportions depend on the angle.

Challenge 1389 e

We note directly that if we split the beam from the oven first vertically and then horizontally, we get a different result from splitting the beam in the opposite order. Splitting processes do not commute. (When the order of two operations makes a difference to the net result, physicists call them 'non-commutative'.) Since all measurements are also processes, we deduce that, in general, measurements in quantum systems are non-commutative.

Beam splitting is direction-dependent. Matter beams behave almost in the same way as polarized light beams. Indeed, the inhomogeneous magnetic field acts on matter somewhat like a polarizer acts on light. The up and down beams, taken together, define a polarization direction. In fact, the polarization direction can be rotated (with the help of a *homogeneous* magnetic field). Indeed, a rotated beam in a unrotated magnet behaves like an unrotated beam in a rotated magnet.

The 'digital' split forces us to rethink our description of motion. In special relativity,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the existence of a maximum speed forced us to introduce the concept of space-time, and then to refine our description of motion. In general relativity, the maximum force obliged us to introduce the concepts of horizon and curvature, and then again to refine our description of motion. At this point, the existence of the quantum of action forces us to take two similar steps. We will first introduce the concept of a Hilbert space, and then we will refine our description of motion yet again.

The quantum description of physical systems

In everyday life and in classical physics, a system is said to *have* momentum, to *have* position, and to *have* an axis of rotation. The quantum of action makes it impossible for us to continue using this language. In classical physics, the state (the quantities a system 'has') and the result of a measurement coincide: this is because measurements can be imagined to have a negligible effect on the system. But because of the existence of a smallest action, the interaction necessary to perform the measurement *cannot* be made arbitrarily small.

Indeed, the Stern–Gerlach experiment shows that the measured values of spin orientation are *not* intrinsic, but result from the measurement process itself (in this case, the interaction with the inhomogeneous field). This is in contrast to the spin *magnitude*, which is intrinsic and state-independent.

Therefore, the quantum of action forces us to distinguish three entities:

— the state of the system;
— the operation of measurement;
— the result of the measurement.

Thus, in contrast to the classical case, the general state of a quantum system is *not* described by the outcomes of measurements. The simplest illustration of this difference is the system made of a single particle in the Stern–Gerlach experiment. The experiment shows that a spin measurement on a general (oven) particle state sometimes gives 'up' (say +1), and sometimes gives 'down' (say –1). So a general atom, in an oven state, has no intrinsic orientation. It is also found that feeding 'up' states into the measurement apparatus gives 'up' states: thus certain special states ('eigenstates') do remain unaffected by measurement. Finally, the experiment shows that states can be rotated by applied fields: they have an abstract direction.

These details can be formulated in a straightforward way. Since measurements are operations that take a state as input and produce as output a measurement result and an output state, we can say:

— States are described by small rotating arrows; in other words, they are complex *vectors* in an abstract space. The space of all possible states is a *Hilbert space*.
— Measurements of observables are operations on the state vectors. Measurements are said to be described by self-adjoint, or *Hermitean*, operators (or matrices).
— Measurement results are *real numbers*.
— Changes of viewpoint are described by *unitary* operators (or matrices) that act on states and measurement operators.

Thus we have distinguished three quantities that are not distinguished in classical physics:

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

states, measurement of observables and measurement results. Given this distinction, quantum theory follows quite simply, as we shall see.

Quantum theory describes observables as operators, and thus as *transformations* in Hilbert space, because any measurement is an interaction with a system and thus a transformation of its state. The Stern–Gerlach experiment shows this clearly: the interaction with the field transforms some atoms in one way, and other atoms in another way.

Quantum-mechanical experiments also show that a measurement of an observable can only give a result that is an eigenvalue of this transformation. The resulting states, the 'special' states just mentioned, are the eigenvectors. Therefore every expert on motion must know what an eigenvalue and an eigenvector is.

For any linear transformation T, those special vectors $|\psi\rangle$ that are transformed into multiples of themselves,

$$T|\psi\rangle = \lambda|\psi\rangle \tag{609}$$

are called *eigenvectors* (or *eigenstates*), and the multiplication factor λ is called the associated *eigenvalue*. Experiments show that the state of the system *after* a measurement is given by the eigenvector corresponding to the measured eigenvalue. In the Stern–Gerlach experiment, the eigenstates are the 'up' and the 'down' states. Eigenvalues of Hermitean operators are always real, so that consistency is ensured.

In summary, the quantum of action obliges us to distinguish between three concepts that are mixed together in classical physics: the state of a system, a measurement on the system, and the measurement result. The quantum of action forces us to change the vocabulary with which we describe nature, and obliges to use more differentiated concepts. Now follows the main step: the description of *motion* with these concepts. This is what is usually called 'quantum theory'.

The quantum description of motion

In nature, motion happens in a way that minimizes change. Indeed, in classical physics, Page 198 the principle of least action states that in nature, all motion happens along that particular path – out of all possible paths with the same endpoints – for which the action is minimal. This principle of cosmic laziness was stated mathematically by saying that in nature, the *variation* δS of the action is zero. We now transfer this idea to the quantum domain.

For quantum systems, we need to redefine both the concept of action and the concept of variation: first of all, we to find a description of action that is based on operators; secondly, we need to define the action variation without paths, as the concept of 'path' does not exist for quantum systems; thirdly, since there is a smallest action in nature, a vanishing variation is not a clearly defined concept, and we must overcume this hurdle.

In classical physics, we defined the action (or change) as the integral of the Lagrangian between the initial and final points in time, and the Lagrangian itself as the difference Page 194 between kinetic and potential energy. In quantum theory, the action (or change) is best defined using the *quantum action*, as defined by Julian Schwinger. We call the initial and final states of the system ψ_i and ψ_f. The action S between these two states is defined as

$$S = \langle \psi_i \,|\, \int L \,\mathrm{d}t \,|\, \psi_f \rangle \,, \tag{610}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where L is the *Lagrangian (operator)*. The angle brackets represent the 'multiplication' of states and operators as defined in quantum theory. More about this, including the difference between left and right angle brackets, will be clarified below. In simple words, also in quantum theory, action is the integral of the Lagrangian.

The Lagrangian operator L is defined in the same way as in classical physics: the Lagrangian $L = T - V$ is the difference between the kinetic energy T and the potential energy V operators. The only difference is that, in quantum theory, the momentum and position *variables* of classical physics are replaced by the corresponding *operators* of quantum physics.*

To transfer the concept of action variation δS to the quantum domain, we use Julian Schwinger's approach and use the straightforward expression

$$\delta S = \langle \psi_i \,|\, \delta \int L \mathrm{d}t \,|\, \psi_f \rangle \ . \tag{611}$$

The concept of path is not needed in this expression, as it is based on varying wave functions instead of varying particle paths.

The last classical requirement to be transferred to the quantum domain is that the variation of the action must vanish. In the quantum domain, the variation of the action cannot be zero, as the smallest observable action is the quantum of action. As Julian Schwinger discovered, there is only one possible way to express the required minimality of action:

$$\delta S = \langle \psi_i \,|\, \delta \int L \mathrm{d}t \,|\, \psi_f \rangle = -i\hbar \, \delta \langle \psi_i | \psi_f \rangle \ . \tag{612}$$

This so-called *quantum action principle* describes all motion in the quantum domain. Classically, the right-hand side is zero – since $\hbar$ is taken to be zero – and we then recover the minimum-action principle $\delta S = 0$ of classical physics. But in quantum theory, the variation of the action is proportional to the variation at the end points.

In simple words, all quantum motion, i.e., the quantum evolution of a state $|\psi\rangle$, happens in such a way that the action variation is the same as $-i$ times the quantum of action $\hbar$ times the variation of the scalar product between initial and final states. In other words, in the actual motion, the intermediate states do *not* play a role at all. The variation of the action is indeed zero under variations of the intermediate 'path'.

In the quantum action principle, the factor $-i$ plays an important role. We recall that states are vectors. The factor $-i$ encodes the idea that state vectors rotate during motion. Indeed, the factor $-i$ implies that the *complex* variation on the right-hand side is rotated (in the complex plane) by a right angle. As a result, even if the variation at the endpoints is small, no action change below $\hbar/2$ can be observed.

To convince ourselves of the correctness of the quantum action principle, we proceed in the following way. We first deduce the evolution equation; then we deduce all the experimental phenomena presented so far; and finally we deduce some new predictions and compare these to experiments.

* More precisely, there is also a condition governing the ordering of operators in a mixed product, so that the non-commutativity of operators is taken into account. We do not explore this issue here.

The state evolution – dispersion of quantons

The quantum action principle determines how all quantum systems move. Usually, we describe motion as the change of state with time. If we use the usual method – the calculus of variations – to deduce how a *state* $|\psi\rangle$ changes with time, we find:

Ref. 808

$$i\hbar \frac{\partial}{\partial t}|\psi\rangle = H|\psi\rangle \,, \tag{613}$$

where $H = T + V$ is the Hamiltonian of the system, the sum of kinetic and potential energy. This famous equation is *Schrödinger's equation of motion*.* This evolution equation applies to all quantum systems and is one of the high points of modern physics.

Ref. 849

In fact, Erwin Schrödinger had found his equation in two different ways. In his first paper, he deduced it from a variational principle, though one slightly different from the one just given. In the second paper, he deduced the evolution equation directly, by asking a simple question: how does the state evolve? He knew that the state of a quanton behaves both like a wave and like a particle. A wave is described by a field, which he denoted $\psi(t, x)$. If the state ψ behaves like a wave, then it must be described by a function (a 'wave function') with amplitude W multiplied by a phase factor $e^{i\boldsymbol{kx}-\omega t}$. The state can thus be written as

Ref. 850

$$|\psi\rangle = \psi(t, x) = W(t, x)e^{i\boldsymbol{kx}-\omega t} \,. \tag{614}$$

At the same time, the state must also behave like a particle. In particular, the non-relativistic particle relation between energy and momentum $E = \boldsymbol{p}^2/2m + V(\boldsymbol{x}) - V\boldsymbol{x}$ being the potential at position $\boldsymbol{x}$ – must remain valid for these waves. Thus, from the two relations for matter wavelength and frequency, we must have

$$i\hbar \frac{\partial \psi}{\partial t} = H\psi = \frac{\Delta \psi}{2m} + V(\boldsymbol{x})\psi \,. \tag{615}$$

In 1926, this *wave equation* for the complex field ψ became instantly famous when Schrödinger used it, by inserting the potential felt by an electron near a proton, to calculate the energy levels of the hydrogen atom. Light is emitted by electrons; therefore a precise description of the motion of electrons in atoms allows us to describe the light frequencies they emit. (We will perform the calculation and the comparison with experiment below.) The Schrödinger equation explained the discrete colours of all radiation emitted by hydrogen: the frequencies of the light emitted by hydrogen gas were found to be in agreement with the prediction of the equation to five decimal places. This was an important result, especially if we keep in mind that classical physics cannot event explain

Page 1042

* Erwin Schrödinger (b. 1887 Vienna, d. 1961 Vienna) was famous for being a *physicien bohémien*, always living in a household with two women. In 1925 he discovered the equation that brought him international fame, and the Nobel Prize for physics in 1933. He was also the first to show that the radiation discovered by Victor Hess in Vienna was indeed coming from the cosmos. He left Germany, and then again Austria, out of dislike for National Socialism, and was a professor in Dublin for many years. There he published his famous and influential book *What is life?*. In it, he came close to predicting the then-unknown nucleic acid DNA from theoretical insight alone.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 461 Erwin Schrödinger (1887–1961)

the existence of atoms! The description of the motion of matter had arrived at a new high point.

The most precise description of matter is found when the *relativistic* energy–momentum relation is taken into account. We explore this approach below. No deviations between relativistic calculations and experiments have ever been found. Even today, predictions and measurements of atomic spectra remain the most precise and accurate in the whole study of nature: in some cases, the calculated values agree with experiments to 13 decimal places.

Page 1046

Let us delve a little into the details of the description given by the Schrödinger equation (615). The equation expresses a simple connection: the classical speed of matter is the group velocity of the field ψ. We know from classical physics that the group velocity is not always well defined: in cases where the group dissolves in several peaks, the concept of group velocity is not of much use. These are the cases in which quantum motion is very different from classical motion, as we will soon discover. But for the other, more well-behaved cases, we find that the wave function moves in the same way as a classical particle does.

As an example, the left corner pictures in these pages show the evolution of a wave function (actually its purely real, squared modulus $|\psi|^2$) for the case of an exploding two-particle system.

The squared modulus $|\psi|^2$ represents a probability distribution. In an atom, the probability distribution of the electrons determines the shape of the electron clouds. That is why it is said that the Schrödinger equation contains not only most of physics, but all of chemistry and biology. We will return to these sciences later on.

Page 1146

The Schrödinger equation makes another point: velocity and position of matter are not independent variables, and cannot be chosen at will. Indeed, the initial condition of a system is given by the initial value of the wave function alone. No derivatives have to be (or can be) specified. In other words, quantum systems are described by a *first-order* evolution equation, in stark contrast to classical systems.

We write the wave function ψ or $|\psi\rangle$, with no difference in meaning. The wave function is a *complex-valued* function: it assigns a complex number to every point in space. This reflects the fact that quantum states behave like arrows. Indeed, we know that complex numbers can be described by arrows. The orientation of the arrow in this abstract plane is called the *phase* of the wave function.

Page 877

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

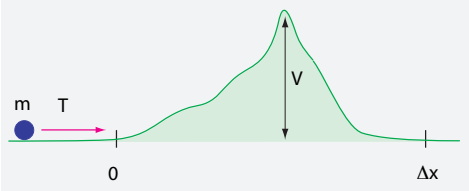

FIGURE 462 Climbing a hill

Even though the wave function can be seen as defining an arrow at every point in space, the wave function as a whole can also described as one, single vector, this time in a Hilbert space. The scalar product of two wave functions is the spatial integral of the product of the complex conjugate of the first function and the (unconjugated) second function. With this definition, all vector concepts (unit vectors, null vectors, basis vectors, etc.) can be meaningfully applied to wave functions.

For free quantum particles, the evolution equation has a simple consequence. Imagine a wavefunction that is localized around a given starting position. This wave function describes a quantum system at rest. When time passes, this wave function will *spread out* in space. Indeed, the evolution equation is similar, mathematically, to a diffusion equation. In the same way that a drop of ink in water spreads out, also a localized quantum particle will spread out in space. The most probable position stays unchanged, but the probability to find the particle at large distances from the strating position increases over time. For quantum particles, this spreading effect is indeed observed. For macroscopic objects, the spreading effect is not observed, however: cars rarely move away from parking spaces. Indeed, quantum theory predicts that for macroscopic systems, the effect of spreading is negligibly small. Can you show why?

Challenge 1390 ny

Many quantum particles are not free but move in an external potential. In these cases the quantum action principle, or equivalently, the Schrödinger equation, have a number of intriguing consequences.

Tunnelling and limits on memory – damping of quantons

'Common sense' says that a slow ball cannot roll over a high hill. More precisely, classical physics says that if the kinetic energy T is smaller than the potential energy V that the ball would have at the top of the hill, then the ball cannot reach the top of the hill. In contrast, according to quantum theory, there is a positive probability of passing the hill for *any* energy of the ball.

In quantum theory, hills and obstacles are described by potential barriers, and objects by wave functions. Any initial wave function will spread *beyond* any potential barrier of finite height and width. The wave function will also be non-vanishing at the location of the barrier. In short, any object can overcome any hill or barrier. This effect is called the *tunnelling effect*. It is in complete contrast to everyday experience – and to classical mechanics.

The tunnelling effect results from a new aspect contained in the quantum description of hills: the statement that all obstacles in nature can be overcome with a *finite* effort. No obstacle is infinitely difficult to surmount. Indeed, only for a potential of infinite height would the wave function vanish and fail to spread to the other side. But such potentials

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

exist only as approximations; in nature potentials are always of finite value.

Challenge 1391 ny How large is the tunnelling effect? Calculation shows that the transmission probability P is given approximately by

$$P \approx \frac{16T(V-T)}{V^2}\, \mathrm{e}^{\frac{-2w}{\hbar}\sqrt{2m(V-T)}} \tag{616}$$

where w is the width of the hill, v its height, and m and T the mass and the kinetic energy of the particle. For a system of large number of particles, the probability is the product of the probabilities for the different particles.

Let us take the case of a car in a garage, and assume that it is made of 10^{28} atoms at room temperature. A typical garage wall has a thickness of 0.1 m and a potential height of $V = 1\,\mathrm{keV} = 160\,\mathrm{aJ}$ for the passage of an atom. We get that the probability of finding the car outside the garage is

$$P \approx \left(10^{-(10^{12})}\right)^{(10^{28})} \approx 10^{-(10^{40})} \,. \tag{617}$$

Challenge 1392 e The smallness of this value (just try to write it down, to be convinced) is the reason why it is never taken into account by the police when a car is reported missing. (Actually, the probability is considerably smaller. Can you name at least one effect that has been Challenge 1393 ny forgotten in this simple calculation?)

Obviously, tunnelling can be important only for small systems, made of a few particles, and for thin barriers, with a thickness of the order of $\hbar/\sqrt{2m(V-T)}$. For example, tunnelling of single atoms is observed in solids at high temperature, but is not important in daily life. For electrons, the effect is larger: the barrier width w for an appreciable tunnelling effect is

$$w \approx \frac{0.5\,\mathrm{nm}\,\sqrt{\mathrm{aJ}}}{\sqrt{V-T}} \,. \tag{618}$$

At room temperature, the kinetic energy T is of the order of 6 zJ; increasing the temperature obviously increases the tunnelling. As a result, electrons tunnel quite easily through barriers that are a few atoms in width. Indeed, every TV tube uses tunnelling at high temperature to generate the electron beam producing the picture. The necessary heating is the reason why television tubes take some time to switch on.

The tunnelling of electrons also limits the physical size of computer memories. Memory chips cannot be made arbitrary small. Silicon integrated circuits with one terabyte Challenge 1394 s (TB) of random-access memory (RAM) will probably never exist. Can you imagine why? In fact, tunnelling limits the working of any type of memory, including that of our brain. Indeed, if we were much hotter than 37 °C, we could not remember anything!

Since light is made of particles, it can also tunnel through potential barriers. The best – or highest – potential barriers for light are mirrors; mirrors have barrier heights of the order of one attojoule. Tunnelling implies that light *can* be detected behind any mirror. These so-called evanescent waves have indeed been detected; they are used in various high-precision experiments.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

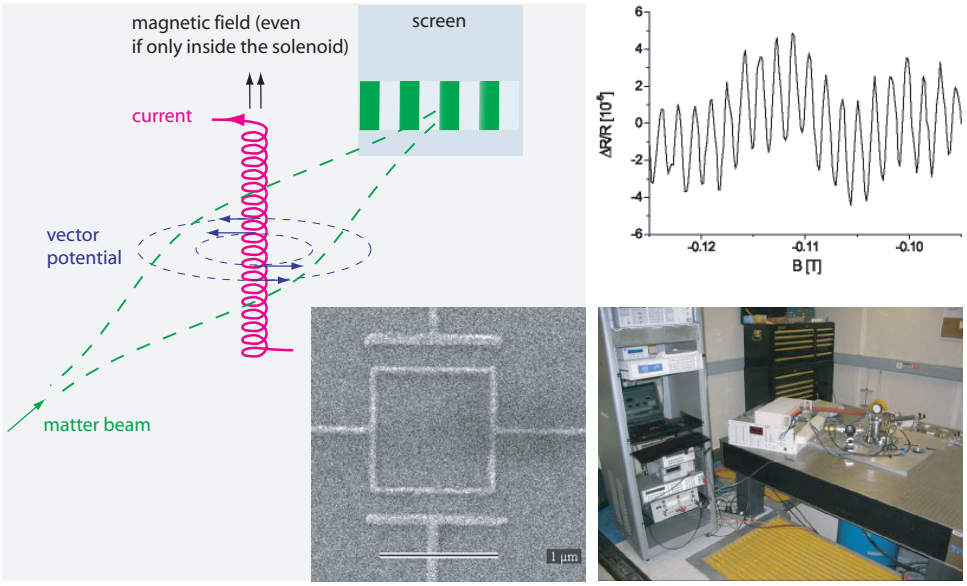

FIGURE 463 The Aharonov–Bohm effect: the influence of the magnetic vector potential on interference (left) and a measurement confirmation (right), using a microscopic sample that transports electrons in thin metal wires (© Doru Cuturela)

Phase and the Aharonov–Bohm effect

The motion of the cloud for a single microscopic particle is described by two quantities: the *density* and the *phase*. whereas the density is easy to picture – just think of a real cloud – the phase takes more effort. States or wave functions are clouds with a phase: they are clouds that can be rotated. In case of an everyday, spherical water cloud, rotation has no effect. In contrast, in quantum theory, the rotation of the cloud, its phase, has a measurable effect.

The phase is that aspect of the wave function that leads to the wave effects of matter. Most importantly, the phase of the wave function plays a role in interference effects. When two partial wave functions are separated and recombined after a relative phase change, the phase change will determine the interference. This is the origin of the electron beam interference results shown in Figure 456.

Page 1006

The phase of matter waves behaves like the phase of photons: it evolves with time, and thus increases along the path of a moving particle. The angular velocity with which it rotates is given by the famous relation $\omega = E/\hbar$. In summary, we can picture the wave function of a free particle as a moving clouds that rotates and disperses.

Ref. 851

A famous experiment shows the importance of the phase in a surprising way: the *Aharonov-Bohm* effect. The effect is famous because it is somewhat counterintuitive and because it was predicted before it was observed. Look at the set-up shown in Figure 463. A matter wave of charged particles is split into two by a cylinder – positioned at a right angle to the matter's path – and the matter wave recombines behind it. Inside the cylinder there is a magnetic field; outside, there is none. (A simple way to realize such a cylinder is a long solenoid.) The prediction is that an interference pattern will be observed, and that

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the position of the stripes will depend on the value of the magnetic field. This happens even though the wave never enters the region with the field!

The reason for the surprising effect is that for a charged particle, the phase of a wave function is determined by the vector potential $\boldsymbol{A}$, not by the magnetic field $\boldsymbol{B}$. The vector potential around a solenoid does not vanish, as we know from the section on Page 710 electrodynamics, but circulates around the solenoid. This circulation distinguishes the two sides of the solenoid and leads to a phase shift – one that indeed depends on the magnetic field value – and thus produces interference.

In summary, the phase of a wave function is an essential aspect of it: the phase is the reason for calling it 'wave' function. Like in any wave, the phase evolves over time. For charged particles, it can be influenced by the vector potential.

We note that all experiments confirm that, to be precise, the absolute phase of a wave function cannot be measured. But phase differences or phase changes – the relative phase Challenge 1395 e – *can* be measured. Can you confirm this?

The motion of quantons with spin

> Everything turns.
>
> Anonymous

Spin describes how a particle behaves under rotations. The full details of electron spin were deduced from experiments by two Dutch students, George Uhleneck and Samuel Ref. 852 Goudsmit. They had the guts to publish what Ralph Kronig had also suspected: that electrons rotate around an axis with a (z-component of the) angular momentum of $\hbar/2$. In fact, this value is correct for all elementary matter particles. (In contrast, radiation particles have spin values that are integer multiples of $\hbar$.) In particular, Uhlenbeck and Goudsmit proposed a g-value of 2 for the electron in order to explain the optical spectra. Ref. 853 This factor was explained by Llewellyn Thomas as a relativistic effect a few months later.

By 2004, experimental techniques had become so sensitive that the magnetic effect of a single electron spin attached to an impurity (in an otherwise non-magnetic material) could be detected. Researchers now hope to improve these so-called 'magnetic-resonance-force microscopes' until they reach atomic resolution.

In 1927, the Austrian physicist Wolfgang Pauli* discovered how to include spin in a quantum-mechanical description: instead of a state function with a single component, one needs a state function with *two* components. Nowadays, Pauli's equation is mainly of conceptual interest, because – like that of Schrödinger – it does not comply with special

* Wolfgang Ernst Pauli (b. 1900 Vienna, d. 1958 Zürich), at the age of 21, wrote one of the best texts on special and general relativity. He was the first to calculate the energy levels of hydrogen using quantum theory, discovered the exclusion principle, incorporated spin into quantum theory, elucidated the relation between spin and statistics, proved the CPT theorem, and predicted the neutrino. He was admired for his intelligence, and feared for his biting criticisms, which led to his nickname, 'conscience of physics'. Despite this, he helped many people in their research, such as Heisenberg with quantum theory, without claiming any Ref. 854 credit for himself. He was seen by many, including Einstein, as the greatest and sharpest mind of twentieth-century physics. He was also famous for the 'Pauli effect', i.e., his ability to trigger disasters in laboratories, machines and his surroundings by his mere presence. As we will see shortly, one can argue that Pauli actually received the Nobel Prize for physics in 1945 (officially 'for the discovery of the exclusion principle') for finally settling the question of how many angels can dance on the tip of a pin.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

relativity. However, the idea of doubling the necessary components was taken up by Dirac when he introduced the relativistic description of the electron, and the idea is used for all other particle equations.

Relativistic wave equations

A few years after Max Planck had discovered the quantum of action, Albert Einstein published the theory of special relativity. The first question Planck asked himself was whether the value of the quantum of action would be independent of the speed of the observer. It was his interest in this question that led him to invite Einstein to Berlin. By doing so, he made the patent-office clerk famous in the world of physics.

Experiments show that the quantum of action is indeed independent of the speed of the observer. All observers find the same minimum value. To include special relativity into quantum theory, we therefore only need to find the correct quantum Hamiltonian operator.

Given that the classical Hamiltonian of a free particle is given by

$$H = \beta\sqrt{c^4m^2 + c^2\boldsymbol{p}^2} \quad \text{with} \quad \boldsymbol{p} = \gamma m\boldsymbol{v}\,, \tag{619}$$

one might ask: what is the corresponding Hamilton operator? The simplest answer was
Ref. 855 given, only in 1950, by L.L. Foldy and S.A. Wouthuysen. The operator is almost the same one:

$$H = \beta\sqrt{c^4m^2 + c^2\boldsymbol{p}^2} \quad \text{with} \quad \beta = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix}. \tag{620}$$

The signs appearing in the operator β distinguish between particles and antiparticles. There are two +1s and two −1s, to take care of the two possible spin directions. With this Hamiltonian operator, a wave function for a particle has vanishing antiparticle components, and vice versa. The Hamilton operator yields the velocity operator $\boldsymbol{v}$ through the same relation that is valid in classical physics:

$$\boldsymbol{v} = \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{x} = \beta\frac{\boldsymbol{p}}{\sqrt{c^4m^2 + c^2\boldsymbol{p}^2}}\,. \tag{621}$$

This velocity operator shows a continuum of eigenvalues, from minus to plus the speed of light. The velocity $\boldsymbol{v}$ is a constant of motion, as are $\boldsymbol{p}$ and $\sqrt{c^4m^2 + c^2\boldsymbol{p}^2}$.

The orbital angular momentum $\boldsymbol{L}$ is also defined as in classical physics, through

$$\boldsymbol{L} = \boldsymbol{x} \times \boldsymbol{p}\,. \tag{622}$$

Ref. 856 The orbital angular momentum $\boldsymbol{L}$ and the spin $\boldsymbol{\sigma}$ are separate constants of motion. A particle (or antiparticle) with positive (or negative) component has a wave function with only one non-vanishing component; the other three components vanish.

But alas, the representation of relativistic motion given by Foldy and Wouthuysen is

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

not the simplest when it comes to take electromagnetic interactions into account. The simple identity between the classical and quantum-mechanical descriptions is lost when electromagnetism is included. We will solve this problem below.

Page 1047

– CS – the rest of quantum theory will appear soon – CS –

Virtual particles

Despite what was said above, actions smaller than the minimal action do have a role to play. We have already encountered one example: in a collision between two electrons, there is an exchange of virtual photons. We know that the exchanged virtual photon cannot be observed. Indeed, the action S for this exchange obeys

Page 1012

$$S \leqslant \frac{\hbar}{2} \,. \tag{623}$$

In short, *virtual* particles appear only as mediators in interactions. They cannot be observed. Virtual particles, in contrast to ordinary, real particles, do not obey the relation $E^2 - p^2c^2 = m^2c^4$. Indeed, virtual particles are the opposite of 'free' or real particles. They may be observed in a vacuum if the measurement time is very short. They are intrinsically short-lived.

– CS – more to come – CS –

In summary, all particle–antiparticles pairs of virtual matter and radiation together form what we call the vacuum. In addition, virtual radiation particles form static fields. Virtual particles are needed for a full description of all interactions. In particular, they are responsible for every decay process.

We will shortly describe a few more successes of quantum theory. But before doing that, we settle an important question.

Page 1119, page 1189

Compositeness

When is an object composite, and not elementary? Quantum theory gives several pragmatic answers. The first one is somewhat strange: an object is composite when its gyromagnetic ratio is different from the one predicted by QED. The *gyromagnetic ratio* γ is defined as the ratio between the magnetic moment $\boldsymbol{M}$ and the angular momentum $\boldsymbol{L}$:

$$\boldsymbol{M} = \gamma \boldsymbol{L} \,. \tag{624}$$

The gyromagnetic ratio γ is measured in units of $\mathrm{s}^{-1}\mathrm{T}^{-1}$, i.e., C/kg, and determines the energy levels of magnetic spinning particles in magnetic fields; it will reappear later in the context of magnetic resonance imaging. All candidates for elementary particles have spin 1/2. The gyromagnetic ratio for spin-1/2 particles of magnetic moment M and mass

Page 1222

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

m can be written as

$$\gamma = \frac{M}{\hbar/2} = g\frac{e}{2m} \,. \tag{625}$$

The criterion for being elementary can thus be reduced to a condition on the value of the dimensionless number g, the so-called *g-factor*. (The expression $e\hbar/2m$ is often called the *magneton* of the particle. Confusingly, the dimensionless factor $g/2$ is often called the gyromagnetic ratio as well.) If the g-factor *differs* from the value predicted by QED for point particles – about 2.0 – the object is *composite*. For example, a $^4He^+$ helium ion has spin 1/2 and a g value of $14.7 \cdot 10^3$. Indeed, the radius of the helium ion is $3 \cdot 10^{-11}$ m, obviously a finite value, and the ion is a composite entity. For the proton, one measures a g-factor of about 5.6. Indeed, experiments yield a finite proton radius of about 0.9 fm and show that it contains several constituents.

Challenge 1396 ny

The neutron, which has a magnetic moment despite being electrically neutral, must therefore be composite. Indeed, its radius is approximately the same as that of the proton. Similarly, molecules, mountains, stars and people must be composite. According to this first criterion, the only elementary particles are *leptons* (i.e., electrons, muons, tauons and neutrinos), *quarks*, and *intermediate bosons* (i.e., photons, W-bosons, Z-bosons and gluons). More details on these particles will be revealed in the chapters on the nucleus.

Page 1222

Another simple criterion for compositeness has just been mentioned: *any object with a measurable size is composite*. This criterion yields the same list of elementary particles as the first. Indeed, the two criteria are related. The simplest model for composite structures predicts that the g-factor obeys

Ref. 869

$$g - 2 = \frac{R}{\lambda_C} \tag{626}$$

where R is the radius and $\lambda_C = h/mc$ is the Compton wavelength of the system. This expression is surprisingly precise for helium-4 ions, helium-3, tritium ions and protons, as you may wish to check. The tables in Appendix E make the same point.

Challenge 1397 e

A third criterion for compositeness is more general: *any object larger than its Compton length is composite*. The argument is simple. An object is composite if one can detect *internal* motion, i.e., motion of some components. Now the action of any part with mass m_{part} moving inside a composed system of size r obeys

$$S_{part} < 2\pi\, r\, m_{part}\, c < \pi\, r\, m\, c \tag{627}$$

where m is the mass of the *composite* object. On the other hand, following the principle of quantum theory, this action, to be observable, must be larger than $\hbar/2$. Inserting this condition, we find that for any composite object*

$$r > \frac{\hbar}{2\pi\, m\, c} \,. \tag{628}$$

Challenge 1398 ny

* Can you find the missing factor of 2? And is the assumption that the components must always be lighter than the composite a valid one?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The right-hand side differs only by a factor $4\pi^2$ from the so-called *Compton (wave)length*

$$\lambda = \frac{h}{m\,c} \tag{629}$$

of an object. Thus any object *larger* than its own Compton wavelength is composite; and any object *smaller* than the right-hand side of expression (628) is elementary. Again, only leptons, quarks and intermediate bosons pass the test. All other objects are composite. This third criterion produces the same list as the previous ones. Can you explain why? Challenge 1399 ny

Interestingly, we are not yet finished with this topic. Even stranger statements about compositeness will appear when gravity is taken into account. Just be patient: it is worth it.

Curiosities and fun challenges about quantum matter

> It is possible to walk while reading, but not to read while walking.
>

Chapter 36

COLOURS AND OTHER INTERACTIONS BETWEEN LIGHT AND MATTER

> Rem tene; verba sequentur.*
>
> Cato

Stones have colours. So do quantons. Having separately described the motion of matter and of radiation, the next step is to describe their interactions. In other words, how do charged quantons react to electromagnetic fields, and vice versa? Interactions lead to surprising effects, especially when special relativity is taken into account.

What are stars made of?

Near the beginning of the eighteenth century, the English physicist William Wollaston and the Bavarian instrument-maker Joseph Fraunhofer** noted that the rainbow *lacks* certain colours. These colours appear as black lines when the rainbow is spread out in sufficient breadth. Figure 464 shows the lines in detail; they are called *Fraunhofer lines* today. In 1860, Gustav Kirchhoff and Robert Bunsen showed that the *missing* colours were exactly those colours that certain elements *emit* when heated. In this way they managed to show that sodium, calcium, barium, nickel, magnesium, zinc, copper and iron are present in the Sun. However, of the 476 lines they observed, they were unable to attribute 13. In 1868, Jules Janssen and Joseph Lockyer independently predicted that these unknown lines were from a new element. It was eventually found on Earth, in an uranium mineral called cleveite, in 1895. This new element was called *helium*, from the Greek word ἥλιος 'helios' – Sun. Today we know that it is the second most widespread ingredient of the Sun and of the universe, after hydrogen. Despite being so common, helium

* 'Know the subject and the words will follow.' Marcus Porcius Cato, (234–149 BCE) or Cato the elder, Roman politician famous for his speeches and his integrity.

** Joseph Fraunhofer (b. 1787 Straubing, d. 1826 München). Bavarian. Having been orphaned at the age of 11, he learned lens-polishing. He taught himself optics from books. He entered an optical company at the age of 19, ensuring the success of the business by producing the best available lenses, telescopes, micrometers, optical gratings and optical systems of his time. He invented the spectroscope and the heliometer. He discovered and counted 476 lines in the spectrum of the Sun; these lines are now named after him. (Today, Fraunhofer lines are still used as measurement standards: the second and the metre are defined in terms of them.) Physicists from all over the world would buy their equipment from him, visit him, and ask for copies of his publications. Even after his death, his instruments remained unsurpassed for generations. With his telescopes, in 1837 Bessel was able to make the first measurement of parallax of a star, and in 1846 Johann Gottfried Galle discovered Neptune. Fraunhofer became a professor in 1819. He died young, from the consequences of the years spent working with lead and glass powder.

FIGURE 465 A hydrogen discharge

is rare on Earth because it is a light noble gas that does not form chemical compounds. Helium thus tends to rise in the atmosphere and escape into space.

Understanding the colour lines produced by each element had started to become interesting already before the discovery of helium; but afterwards the interest increased further, thanks to the increasing number of applications of colour knwoledge in chemistry, physics, technology, crystallography, biology and lasers. It is obvious that classical electrodynamics cannot explain the existence of sharp colour lines. Indeed, only quantum theory can explain them – or any other colour.

What determines the colours of atoms?

The simplest atom to study is that of hydrogen. Hydrogen gas emits light consisting of a handfull of sharp spectral lines, as shown in Figure 466. Already in 1885, the Swiss schoolteacher Johann Balmer (1828–1898) had discovered that the wavelengths of visible hydrogen lines obey the formula:

$$\frac{1}{\lambda_m} = R\left(\frac{1}{4} - \frac{1}{m^2}\right) . \tag{631}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

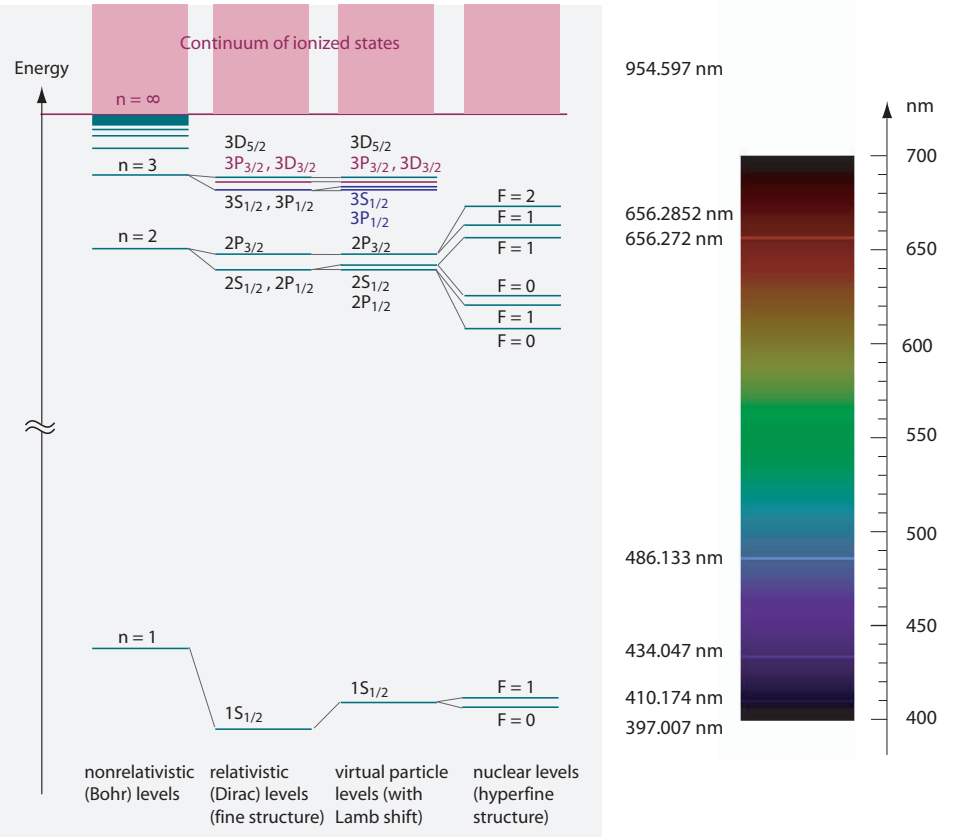

FIGURE 466 The visible spectrum of hydrogen (NASA) and its energy levels, in four approximations of increasing precision. Can you associate the visible lines to the correct level transitions?

Careful measurements, which included the hydrogen's spectral lines in the infrared and in the ultraviolet, allowed Johannes Rydberg (1854–1919) to generalize this formula to:

$$\frac{1}{\lambda_{mn}} = R\left(\frac{1}{n^2} - \frac{1}{m^2}\right) , \tag{632}$$

where n and $m > n$ are positive integers, and the so-called *Rydberg constant* R has the value $10.97\,\mu m^{-1}$; easier to remember, the inverse value is $1/R = 91.16\,nm$. All the colour lines emitted by hydrogen satisfy this simple formula. Thus, quantum theory has a clearly defined challenge here: to explain the formula and the value of R.

Incidentally, the transition λ_{21} for hydrogen is called the *Lyman-alpha line*. Its wavelength, 121.6 nm, lies in the ultraviolet. It is easily observed with telescopes, since most of the visible stars consist of excited hydrogen. The Lyman-alpha line is routinely used to determine the speed of distant stars or galaxies, since the Doppler effect changes the wavelength when the speed is large. The record so far is a galaxy found in 2004, with a Lyman-alpha line shifted to 1337 nm. Can you calculate the speed with which it is moving

Ref. 862

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1407 ny away from the Earth?

There are many ways to deduce Balmer's formula from the minimum action. The first way was due to Bohr. Then, in 1926, Schrödinger solved his equation of motion for the electrostatic potential $V(r) = e^2/4\pi\varepsilon_0 r$ of a point-like proton and by doing so, deduced Balmer's formula; however, this famous calculation is long and complex. In order to understand hydrogen colours, it is not necessary to solve an equation of motion; it is sufficient to compare the energies of the initial and final states. This can be done most easily by noting that a specific form of the action must be a multiple of $\hbar/2$. This approach was developed by Einstein, Brillouin and Keller, and is now named after them. It relies on Ref. 863 the fact that the action S of any quantum system obeys

$$S = \frac{1}{2\pi} \oint \mathrm{d}q_i p_i = \left(n_i + \frac{\mu_i}{4}\right)\hbar \tag{633}$$

for every coordinate q_i and its conjugate momentum p_i. Here, n_i can be zero or any positive integer, and μ_i is the so-called *Maslov index*, an even integer, which in the case of atoms has the value 2 for the radial and azimuthal coordinates r and θ, and 0 for the rotation angle φ. The integral is to be taken along a full orbit. In simple words, the action S is a half-integer multiple of the quantum of action.

Any rotational motion in a spherical potential $V(r)$ is characterized by a constant energy E and constant angular momenta L and L_z. Therefore the conjugate momenta for Challenge 1408 ny the coordinates r, θ and φ are

$$\begin{aligned} p_r &= \sqrt{2m(E - V(r)) - \frac{L^2}{r^2}} \\ p_\theta &= \sqrt{L^2 - \frac{L_z^2}{\sin^2\theta}} \\ p_\varphi &= L_z \,. \end{aligned} \tag{634}$$

Using these expressions in equation (633) and setting $n = n_r + n_\theta + n_\varphi + 1$ yields* the result

$$E_n = -\frac{1}{n^2}\frac{me^4}{2(4\pi\varepsilon_0)^2\hbar^2} = -\frac{R}{n^2} \approx -\frac{2.19\,\mathrm{aJ}}{n^2} \approx -\frac{13.6\,\mathrm{eV}}{n^2} \,. \tag{637}$$

Using the idea that a hydrogen atom emits a single photon when its electron changes from state E_n to E_m, one gets exactly the formula deduced by Balmer and Rydberg from

* The calculation is straightforward. After insertion of $V(r) = e/4\pi\varepsilon_0 r$ into equation (634) one needs to Challenge 1409 ny perform the (tricky) integration. Using the general result

$$\frac{1}{2\pi}\oint \frac{\mathrm{d}z}{z}\sqrt{Az^2 + 2Bz - C} = -\sqrt{C} + \frac{B}{\sqrt{-A}} \tag{635}$$

one gets

$$\left(n_r + \frac{1}{2}\right)\hbar + L = n\hbar = \frac{e^2}{4\pi\varepsilon_0}\sqrt{\frac{m}{-2E}} \,. \tag{636}$$

This leads to the energy formula (637).

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

observations. The quantum of action thus explains the colours of hydrogen. (This whole discussion assumes that the electrons in hydrogen atoms are in eigenstates. Can you argue why this is the case?)

Challenge 1410 e

Challenge 1411 ny

The lowest energy level, for $n = 1$, is called the ground state. The energy value 2.19 aJ is the *ionization energy* of hydrogen; if that energy is added to the ground state, the electron is no longer bound to the nucleus. The ionization energy thus plays the same role for electrons around atoms as does the escape velocity for satellites around planets.

The calculation also yields the effective radius of the electron orbit in hydrogen. It is given by

$$r_n = n^2 \frac{\hbar^2 4\pi\varepsilon_0}{m_e e^2} = \frac{\hbar}{m_e c\alpha} = n^2 a_0 \approx n^2\, 52.918\,937\,\text{pm} \,. \tag{638}$$

In contrast to classical physics, quantum theory allows only certain specific orbits around the nucleus. (For more details about the fine structure constant α, see below.) The smallest value, 53 pm for $n = 1$, is called the *Bohr radius*, and is denoted by a_0. To be more precise, these radii are the average sizes of the electron clouds surrounding the nucleus. Quantum theory thus implies that a hydrogen atom excited to the level $n = 500$ is about 12 μm in size: larger than many bacteria! Such blown-up atoms, usually called *Rydberg atoms*, have indeed been observed in the laboratory, although they are extremely sensitive to perturbations.

Page 1046, page 1050

Ref. 864

The orbital frequency of electrons in hydrogen is

$$f_n = \frac{1}{n^3} \frac{e^4 m_e}{4\varepsilon_0^2 h^3} = \frac{1}{n^3} \frac{m_e c^2 \alpha^2}{h} \approx \frac{6.7\,\text{PHz}}{n^3} \tag{639}$$

and the electron speed is

$$v_n = \frac{1}{n} \frac{e^2}{4\pi\varepsilon_0 \hbar} = \frac{\alpha c}{n} \approx \frac{2.2\,\text{Mm/s}}{n} \approx \frac{0.007\ c}{n} \,. \tag{640}$$

As expected, the further the electron's orbit is from the nucleus, the more slowly it moves. This result can also be checked by experiment: exchanging the electron for a muon allows us to measure the time dilation of its lifetime. Measurements are in agreement with the calculations.

Ref. 865

In 1915, Arnold Sommerfeld understood that the analogy of electron motion with orbits could be continued in two ways. First of all, electrons can move in ellipses. The quantization of angular momentum implies that only selected eccentricities are possible. The higher the angular momentum, the larger the number of possibilities: the first are shown in Figure 467. The highest eccentricity corresponds to the minimum value $l = 0$ of the so-called azimuthal quantum number, whereas the case $l = n - 1$ correspond to circular orbits. In addition, the ellipses can have different orientations in space.

Ref. 866

The second point Sommerfeld noted was that the speeds of the electron in hydrogen are slightly relativistic. The above calculation did not take into account relativistic effects. However, high-precision measurements show slight differences between the non-relativistically calculated energy levels and the measured ones.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

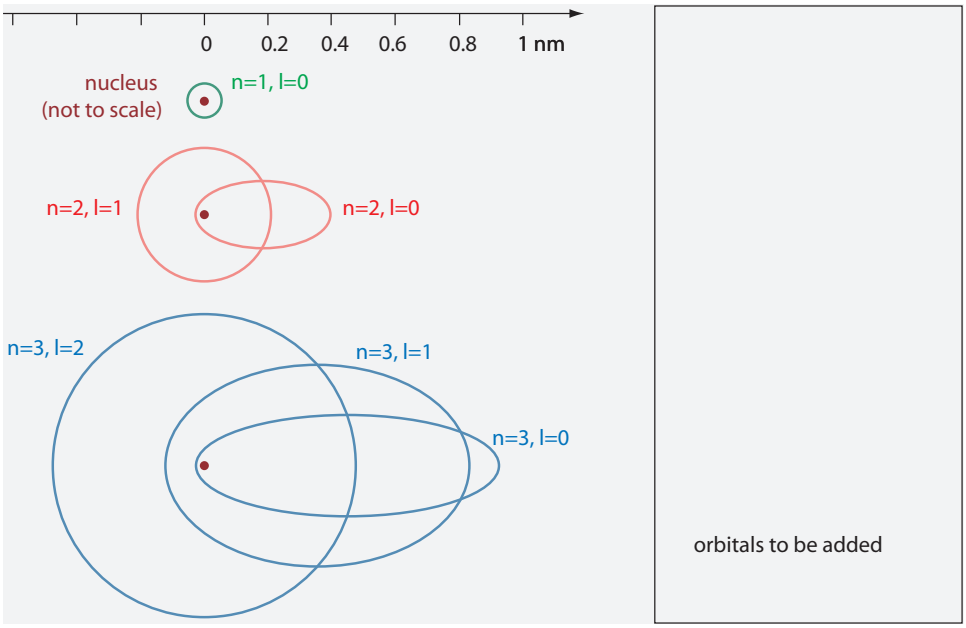

FIGURE 467 The orbits of the Bohr–Sommerfeld model of the hydrogen atom and the corresponding orbital wave functions

Relativistic hydrogen

In the relativistic case, too, the EBK action has to be a multiple of $\hbar/2$. From the relativistic
Ref. 863 expression for energy of the electron

$$E + mc^2 = \sqrt{p^2c^2 + m^2c^4} - \frac{e^2}{4\pi\varepsilon_0 r} \tag{641}$$

Challenge 1412 ny we get the expression

$$p_r^2 = 2mE\left(1 + \frac{E}{2mc^2}\right) + \frac{2me^2}{4\pi\varepsilon_0 r}\left(1 + \frac{E}{mc^2}\right) . \tag{642}$$

We now introduce, for convenience, the so-called *fine structure constant*, as $\alpha = e^2/(4\pi\varepsilon_0\hbar c) = \sqrt{4\pi\hbar R/mc^3} \approx 1/137.036$. ($\alpha$ is a dimensionless constant; $R =$
Challenge 1413 ny $10.97\,\mu m^{-1}$ is the Rydberg constant.) The radial EBK action then implies that

$$E_{nl} + mc^2 = \frac{mc^2}{\sqrt{1 + \frac{\alpha^2}{(n-l-\frac{1}{2}+\sqrt{(l+\frac{1}{2})^2-\alpha^2})^2}}} . \tag{643}$$

This result, first found by Arnold Sommerfeld in 1915, is correct for point-like electrons. In reality, the electron has spin 1/2; the correct relativistic energy levels thus appear when

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 468 Paul Dirac (1902–1984)

we set $l = j \pm 1/2$ in the above formula. The result can be approximated by

$$E_{nj} = -\frac{R}{n^2}\left(1 + \frac{\alpha^2}{n^2}\left(\frac{n}{j+\frac{1}{2}} - \frac{3}{4}\right) + \ldots\right) . \tag{644}$$

It reproduces the hydrogen spectrum to an extremely high accuracy. If one compares the result with the non-relativistic one, one notes that each non-relativistic level n is split in n different levels. This is shown in Figure 466. In practice, in precision experiments the lines of the hydrogen spectrum have a so-called *fine structure*. The magnitude of the fine structure depends on α, a fundamental constant of nature. Since the importance of this fundamental constant was discovered in this context, the name chosen by Arnold Sommerfeld, the *fine structure constant*, has been taken over across the world. The fine structure constant describes the *strength* of the electromagnetic interaction.

Of course, it is possible to do even better. The introduction of virtual-particle effects and the coupling of the proton spin gives additional corrections, as shown in Figure 466. But that is still not all, isotope effects, Doppler shifts and level shifts to environmental electric or magnetic fields also influence the hydrogen spectrum.

Relativistic wave equations – again

> The equation was more intelligent than I was.
> Paul Dirac, about his equation, repeating a statement made by Heinrich Hertz.

Unfortunately, it is not a simple matter to generalize the representation of relativistic motion given by Foldy and Wouthuysen to the case of particles with electromagnetic interactions. The simple identity between the classical and quantum-mechanical descriptions is lost if electromagnetism is included.

Charged particles are best described by another, equivalent representation of the Hamiltonian, which was discovered much earlier, in 1926, by the British physicist Paul Dirac.* Dirac found a neat trick to take the square root appearing in the relativistic en-

* Paul Adrien Maurice Dirac (b. 1902 Bristol, d. 1984 Tallahassee), British physicist, son of a Francophone Swiss immigrant. He studied electrotechnics in Bristol, then went to Cambridge, where he later became a professor, holding the chair that Newton had once held. In the years from 1925 to 1933 he published a stream of papers, of which several were worth a Nobel Prize; he received this in 1933. He unified special relativity

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ergy operator. In this representation, the Hamilton operator is given by

$$H_{\text{Dirac}} = \beta m + \boldsymbol{\alpha} \cdot p \,. \tag{645}$$

Its position operator x is not the position of a particle, but has additional terms; its velocity operator has only the eigenvalues plus or minus the velocity of light; the velocity operator is not simply related to the momentum operator; the equation of motion contains the famous 'Zitterbewegung' term; orbital angular momentum and spin are not separate constants of motion.

So why use this horrible Hamiltonian? It is the only one that can easily be used for charged particles. Indeed, it is transformed to the one coupled to the electromagnetic Page 712 field by the so-called minimal coupling, i.e., by the substitution

$$\boldsymbol{p} \to \boldsymbol{p} - q\boldsymbol{A} \,, \tag{646}$$

that treats electromagnetic momentum like particle momentum. With this prescription, Dirac's Hamiltonian describes the motion of charged particles interacting with an electromagnetic field $\boldsymbol{A}$. This substitution is not possible in the Foldy–Wouthuysen Hamiltonian. In the Dirac representation, particles are pure, point-like, structureless electric charges; in the Foldy–Wouthuysen representation they acquire a charge radius and a magnetic-Ref. 867 moment interaction. (We will come to the reasons below, in the section on QED.)

In more detail, the simplest description of an electron (or any other elementary, stable, electrically-charged particle of spin 1/2) is given by the action S and Lagrangian

$$\begin{aligned} S &= \int \mathcal{L}_{\text{QED}} d^4x \quad \text{where} \\ \mathcal{L}_{\text{QED}} &= \overline{\psi}\left(i\hbar c \not{D} - mc^2\right)\psi - \frac{1}{4\mu_0} F_{\mu\nu}F^{\mu\nu} \quad \text{and where} \\ \not{D}_\mu &= \gamma^\mu\left(\partial_\mu - ieA_\mu\right) \end{aligned} \tag{647}$$

The first, matter term in the Lagrangian leads to the Dirac equation; it describes how elementary, charged, spin 1/2 particles are moved by electromagnetic fields. The second, radiation term leads to Maxwell's equations, and describes how electromagnetic fields are moved by the charged particle wave function. Together, they describe what is usually called *quantum electrodynamics*, or QED for short.

As far as is known today, the relativistic description of the motion of charged matter and electromagnetic fields given by expression (647) is *perfect*: no differences between theory and experiment have ever been found, despite intensive searches and despite a high reward for anybody who would find one. All known predictions completely correspond with the measurements. In the most spectacular cases, the correspondence be-

and quantum theory, predicted antimatter, worked on spin and statistics, predicted magnetic monopoles, speculated on the law of large numbers, and more besides. His introversion, friendliness and shyness, and his deep insights into nature, combined with a dedication to beauty in theoretical physics, made him a legend all over the world during his lifetime. For the latter half of his life he tried, unsuccessfully, to find an alternative to quantum electrodynamics, of which he was the founder, as he was repelled by the problems of infinities. He died in Florida, where he lived and worked after his retirement from Cambridge.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tween theory and measurement extends to more than fourteen digits. But even more interesting than the precision of QED are certain of its features that are missing in classical electrodynamics. Let's have a quick tour.

– CS – more to come here – CS –

Antimatter

'Antimatter' is now a household term. Interestingly, the concept appeared *before* there was any experimental evidence for it. Indeed, the antimatter companion of the electron was predicted in 1926 by Paul Dirac from his equation. Unaware of this prediction, Carl Anderson discovered it in 1932, and called it the *positron*. (The correct name would have been 'positon', without the 'r'. Indeed, this correct form is used in the French language.) Anderson was studying cosmic rays, and noticed that some 'electrons' were turning the wrong way in the magnetic field he had applied to his apparatus. He checked his apparatus thoroughly, and finally deduced that he had found a particle with the same mass as the electron but with positive electric charge.

The existence of positrons has many strange implications. Already in 1928, before their discovery, the Swedish theorist Oskar Klein had pointed out that Dirac's equation for electrons makes a strange prediction: when an electron hits a sufficiently steep potential wall, the reflection coefficient is larger than unity. Such a wall will reflect *more* than is thrown at it. In 1935, after the discovery of the positron, Werner Heisenberg and Hans Euler explained the paradox. They found that the Dirac equation predicts that whenever an electric field exceeds the critical value of

Ref. 868

$$E_c = \frac{m_e c^2}{e\lambda_e} = \frac{m_e^2 c^3}{e\hbar} = 1.3\,\mathrm{EV/m}\,, \tag{648}$$

the vacuum will spontaneously generate electron–positron pairs, which are then separated by the field. As a result, the original field is reduced. This so-called *vacuum polarization* is the reason for the reflection coefficient greater than unity found by Klein, as steep potentials correspond to high electric fields.

Later on we will describe truly gigantic examples of vacuum polarization, around charged black holes.

Page 1211

Such effects show that, in contrast to everyday life, the *number* of particles is not a constant in the microscopic domain. Only the *difference* between particle number and antiparticle number turns out to be conserved. We will expand on this issue in the chapter on the nucleus.

Of course, the generation of electron–positron pairs is not a *creation* out of nothing, but a *transformation* of energy into matter. Such processes are part of every relativistic description of nature. Unfortunately, physicists have a habit of calling this transformation 'pair creation', thus confusing the issue somewhat.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Curiosities and fun challenges about colour

If atoms contain orbiting electrons, the rotation of the Earth, via the Coriolis acceleration, should have an effect on their motion. This beautiful prediction is due to Mark Silverman; Ref. 865 the effect is so small, however, that is has not yet been measured.

* *

Light is diffracted by material gratings. Can matter be diffracted by light gratings? Surprisingly, it actually can, as predicted by Dirac and Kapitza in 1937. This was accom- Ref. 870 plished for the first time in 1986, using atoms. For free electrons, the feat is more difficult; the clearest confirmation came in 2001, when new laser technology was used to perform a beautiful measurement of the typical diffraction maxima for electrons diffracted by a light grating.

* *

Light is totally reflected when it is directed to a dense material at a large enough angle so that it cannot enter the material. A group of Russian physicists have shown that if Ref. 865 the dense material is excited, the totally-reflected beam can be *amplified*. It is unclear whether this will ever lead to applications.

* *

Where is the sea bluest? Sea water is blue because it absorbs red and green light. Sea water can also be of bright colour if the sea floor reflects light. Sea water can also be green, when it contains small particles that scatter or absorb blue light. Most often, these particles are soil or plankton. (Satellites can determine plankton content from the 'greenness' of the sea.) Thus the sea is especially blue if it is deep, quiet and cold; in that case, the ground is distant, soil is not mixed into the water, and the plankton content is low. The Sargasso Sea is deep, quiet and cold for most of the year. It is often called the bluest of the Earth's waters.

The strength of electromagnetism

The great physicist Wolfgang Pauli used to say that after his death, the first thing he would ask the devil would be to explain Sommerfeld's fine-structure constant. (Others used to comment that after the devil had explained it to him, he would think a little, and then snap: 'Wrong!')

Page 1046 Ref. 871 The *fine-structure constant* was introduced by Arnold Sommerfeld. It is the dimensionless constant of nature given by

$$\alpha = \frac{e^2}{4\pi\varepsilon_0\hbar c} \approx \frac{1}{137.035\,999\,710(96)} \approx 0.007\,297\,352\,5359(51)\ . \tag{649}$$

This number first appeared in explanations of the fine structure of certain atomic colour spectra; hence its strange name. Sommerfeld was the first to understand its general importance. It is central to quantum electrodynamics for several reasons. First of all, it describes the *strength* of electromagnetism. Since all charges are multiples of the electron

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

charge, a higher value would mean a stronger attraction or repulsion between charged bodies. Thus the value of α determines the sizes of atoms, and indeed of all things, as well as all colours in nature.

Secondly, it is only because this number is so small that we are able to talk about particles at all. The argument is somewhat involved; it will be given in detail later on. In any case, the small value of the fine-structure constant makes it possible to distinguish particles from each other. If the number were near to or larger than one, particles would interact so strongly that it would not be possible to observe them or to talk about them at all.

This leads on to the third reason for the importance of the fine-structure constant. Since it is a dimensionless number, it implies some yet-unknown mechanism that fixes its value. Uncovering this mechanism is one of the challenges remaining in our adventure. As long as the mechanism remains unknown – as is the case in 2007– we do not understand the colour and size of a single thing around us.

Small changes in the strength of electromagnetic attraction between electrons and protons would have numerous important consequences. Can you describe what would happen to the size of people, to the colour of objects, to the colour of the Sun, or to the workings of computers, if the strength were to double? And what if it were to gradually drop to half its usual value?

Challenge 1414 ny

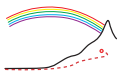
Since the 1920s, explaining the value of α has been seen as one of the toughest challenges facing modern physics. That is the reason for Pauli's request to the devil. In 1946, during his Nobel Prize lecture, he repeated the statement that a theory that does not determine this number cannot be complete. Since that time, physicists seem to have fallen into two classes: those who did not dare to take on the challenge, and those who had no clue. This fascinating story still awaits us.

Ref. 872

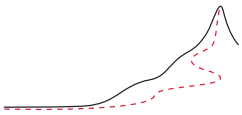
The problem of the fine-structure constant is so deep that it leads many astray. For example, it is sometimes said that it is impossible to change physical units in such a way that $\hbar$, c and e are all equal to 1 at the same time, because to do so would change the number $\alpha = 1/137.036\ldots$. Can you show that the argument is wrong?

Challenge 1415 s

To continue with the greatest efficiency on our path across quantum theory, we next look at two important topics: the issue of indistinguishability, and the issue of the interpretation of its probabilities.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 37

PERMUTATION OF PARTICLES – ARE PARTICLES LIKE GLOVES?

Why are we able to distinguish twins from each other? Why can we distinguish what looks alike, such as a copy from an original? Most of us are convinced that whenever we compare an original with a copy, we can find a difference. This conviction turns out to be correct. In fact, this conviction is in contrast with classical physics. The possibility to distinguish originals from copies is a pure quantum effect.

Indeed, quantum theory has a lot to say about copies and their differences. Think about any method that allows to distinguish objects: you will find that it runs into trouble for point-like particles. Therefore in the quantum domain something must change about our ability to distinguish particles and objects. Let us explore the issue.

Challenge 1416 s

Some usually forgotten properties of objects are highlighted by studying a pretty combinatorial puzzle: the *glove problem*. It asks:

> How many surgical gloves (for the right hand) are necessary if m doctors need to operate w patients in a hygienic way, so that nobody gets in contact with the body fluids of anybody else?

The same problem also appears in other settings. For example, it also applies to condoms, men and women – and is then called the *condom problem* – or to computers, interfaces and computer viruses. To be clear, the optimal number of gloves is *not* the product mw. In fact, the problem has three subcases.

Ref. 873

Challenge 1417 s

— The simple case $m = w = 2$ already provides the most important ideas needed. Are you able to find the optimal solution and procedure?

Challenge 1418 e

— In the case $w = 1$ and m odd or the case $m = 1$ and w odd, the solution is $(m+1)/2$ gloves. This is the optimal solution, as you can easily check yourself.

Ref. 874

— A solution with a simple procedure for all other cases is given by $\lceil 2w/3 + m/2 \rceil$ gloves, where $\lceil x \rceil$ means the smallest integer greater than or equal to x. For example, for two doctors and three patients this gives only three gloves. (However, this formula does not always give the optimal solution; better values exist in certain subcases.)

Challenge 1419 e

Two basic properties of gloves determine the solution to the puzzle. First, gloves have two sides, an interior and an exterior one. Secondly, gloves can be distinguished from each other. Do these two properties also apply to particles? We will discuss the issue of double-sidedness in the last part of the mountain ascent. In fact, the question whether particles can be turned inside out will be of importance for their description and their motion. (In fact, particles do behave like gloves in the sense that one can distinguish right-

Page 1445

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 1277 handed from left-handed ones.) In the present chapter we concentrate on the second issue, namely whether objects and particles can always be distinguished. We will find that *elementary* particles do not behave like gloves but in an even more surprising manner.

In everyday life, distinction of objects can be achieved in two ways. We are able to distinguish objects – or people – from each other because they differ in their *intrinsic properties*, such as their mass, colour, size or shape. In addition, we are also able to distinguish objects if they have the *same* intrinsic properties. Any game of billiard suggests that by following the path of each ball, we can distinguish it from the others. In short, objects with identical properties can also be distinguished using their *state*.

The state of a billiard ball is given by its position and momentum. In the case of billiard balls, the state allows distinction because the measurement error for the position of the ball is much smaller than the size of the ball itself. However, in the microscopic domain this is not the case. Let us take single atoms. Atoms of the same type have the same intrinsic properties. To distinguish them in collisions, we would need to keep track of their motion. But we have no chance to achieve this. Already in the nineteenth century it was shown experimentally that even nature itself is not able to do it! This profound result was discovered studying systems which incorporate a large number of colliding atoms of the same type: *gases*.

Page 282 The calculation of the entropy S of a simple gas, made of N simple particles of mass m moving in a volume V, gives

$$\frac{S}{kN} = \ln\left[\frac{V}{\Lambda^3}\right] + \frac{3}{2} + \frac{\ln \alpha}{N} \tag{650}$$

where k is the Boltzmann constant, ln the natural logarithm, T the temperature, and $\Lambda = \sqrt{2\pi\hbar^2/mkT}$ is the thermal wavelength (approximately the de Broglie wavelength of the particles making up the gas). In this formula, the pure number α is equal to 1 if the particles are distinguishable like billiard balls, and equal to $1/N!$ if they are not distinguishable at all. Measuring the entropy thus allows us to determine α and therefore whether particles are distinguishable. It turns out that only the second case describes nature. This can easily be checked without even performing the measurement: only in the second case, $\alpha = 1/N!$ does the entropy of two volumes of identical gas *add* up.* The result, often called *Gibbs' paradox*,** thus proves that the microscopic components of matter are *indistinguishable*: in a system of microscopic particles, there is no way to say which particle is which. Indistinguishability is an experimental property of nature.***

Challenge 1420 e

Ref. 875

Challenge 1421 d

* Indeed, the entropy values observed by experiment, for a monoatomic gas, are given by the so-called Sackur–Tetrode formula

$$\frac{S}{kN} = \ln\left[\frac{V}{N\Lambda^3}\right] + \frac{5}{2} \tag{651}$$

which follows when $\alpha = 1/N!$ is inserted above. It was deduced independently by the German physicist Otto Sackur (1880–1914) and the Dutch physicist Hugo Tetrode (1895–1931). Note that the essential parameter is the ratio between V/N, the volume per particle, and Λ^3, the de Broglie volume of a particle.

** Josiah Willard Gibbs (1839–1903), US-American physicist who was, with Maxwell and Planck, one of the three founders of statistical mechanics and thermodynamics; he introduced the concept of *ensemble* and the term *thermodynamic phase*.

*** When radioactivity was discovered, people thought that it contradicted the indistinguishability of atoms, as decay seems to single out certain atoms compared to others. But quantum theory then showed that this

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 469 Willard Gibbs (1839–1903)

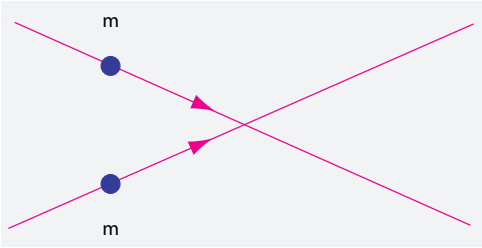


FIGURE 470 Identical objects with crossing paths

The properties of matter would be completely different without indistinguishability. For example, we will discover that without it, knifes and swords would not cut. In addition, the soil would not carry us; we would fall right through it. To illuminate the issue in more detail, we explore the following question.

Why does indistinguishability appear in nature?

Take two microscopic particles with the same mass, the same composition and the same shape, such as two atoms. Imagine that their paths cross, and that they approach each other to small distances at the crossing, as shown in Figure 470. In a gas, both a collision of atoms or a near miss are examples. Now, experiments show that at small distances it is impossible to say whether the two particles have switched roles or not. This is the main reason that makes it *impossible* in a gas to follow particles moving around and to determine which particle is which. This impossibility is a direct consequence of the quantum of action.

For a path that brings two approaching particles very close to each other, a role switch requires only a small amount of change, i.e., only a small (physical) action. However, we know that there is a smallest observable action in nature. Keeping track of each particle at small distances would require action values *smaller* than the minimal action observed in nature. The existence of a smallest action thus makes it impossible to keep track of microscopic particles when they come too near to each other. Any description of several particles must thus take into account that after a close encounter, it is impossible to say which particle is which.

is not the case and that atoms do remain indistinguishable.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

If we remember that quantum theory describes particles as clouds, the indistinguishability appears more natural. Whenever two clouds meet and depart again, it is impossible to say which one is which.

If two particles are kept distant enough, one does have an effective distinguishability; indistinguishability thus appears only when the particles come close. In short, indistinguishability is a consequence of the existence of a minimal action in nature. This result leads straight away to the next question:

Can particles be counted?

In everyday life, objects can be counted because they can be distinguished. Since quantum particles cannot always be distinguished, we need some care in determining how to count them. The first step in counting particles is the definition of what is meant by a situation without any particle at all. This seems an easy thing to do, but later on we will encounter situations where already this step runs into difficulties. In any case, the first step is thus the *specification of the vacuum*. Any counting method requires that the situation without particles is clearly separated from situations with particles.

The second step is the specification of an observable useful for determining particle number. The easiest way is to chose one of those quantum numbers which add up under composition, such as electric charge.* Counting is then performed by measuring the total charge and dividing by the unit charge.

This method has several advantages. First of all, it is not important whether particles are distinguishable or not; counting always works. Secondly, virtual particles are not counted. This is a welcome state of affairs, as we will see, because for virtual particles, i.e., particles for which $E^2 \neq p^2c^2 + m^2c^4$, there is *no way* to define a particle number anyway.

Page 1192

The side effect of the counting method is that antiparticles count negatively! Also this consequence is a result of the quantum of action. We saw above that the quantum of action implies that even in vacuum, particle–antiparticle pairs are observed at sufficiently high energies. As a result, an antiparticle must count as minus one particle. In other words, any way of counting particles can produce an error due to this effect. In everyday life this limitation plays no role, as there is no antimatter around us. The issue does play a role at higher energies, however. It turns out that there is no general way to count the exact number of particles and antiparticles separately; only the sum can be defined. In short, quantum theory shows that particle counting is never perfect.

In summary, nature does provide a way to count particles even if they cannot be distinguished, though only for everyday, low energy conditions; due to the quantum of action, antiparticles count negatively. Antiparticles thus provide a limit to the counting of particles at high energies, when the mass–energy relation becomes important.

What is permutation symmetry?

Since particles are countable but indistinguishable, there exists a symmetry of nature for systems composed of several identical particles. *Permutation symmetry*, also called

* In everyday life, the weight or mass is commonly used as observable. However, it cannot be used in the quantum domain, except for simple cases. Can you give at least two reasons, one from special relativity and one from general relativity?

Challenge 1422 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

exchange symmetry, is the property of nature that observations are unchanged under exchange of identical particles. Together with space-time symmetry, gauge symmetry and the not yet encountered renormalization symmetry, permutation symmetry forms one of the four pillars of quantum theory. Permutation symmetry is a property of *composed* systems, i.e., of systems made of many (identical) subsystems. Only for such systems does indistinguishability play a role.

In other words, 'indistinguishable' is not the same as 'identical'. Two particles are not the *same*; they are more like *copies* of each other. On the other hand, everyday life experience shows us that two copies can always be distinguished under close inspection, so that the term is not fully appropriate either. In the microscopic domain, particles are countable and completely indistinguishable.* Particles are perfect copies of each other.

We will discover shortly that permutation is partial rotation. Permutation symmetry thus is a symmetry under partial rotations. Can you find out why?

Challenge 1423 e

Indistinguishability and symmetry

The indistinguishability of particles leads to important conclusions about the description of their state of motion. This happens because it is impossible to formulate a description of motion that includes indistinguishability right from the start. (Are you able to confirm this?) We need to describe a n-particle state with a state $\Psi_{1\dots i\dots j\dots n}$ which assumes that distinction is possible, as expressed by the ordered indices in the notation, and we introduce the indistinguishability afterwards.

Challenge 1424 s

Indistinguishability means that the exchange of any two particles results in the same physical system.** Now, two quantum states have the same physical properties if they differ at most by a phase factor; indistinguishability thus requires

$$\Psi_{1\dots i\dots j\dots n} = \mathrm{e}^{i\alpha}\, \Psi_{1\dots j\dots i\dots n} \tag{652}$$

for some unknown angle α. Applying this expression twice, by exchanging the same couple of indices again, allows us to conclude that $\mathrm{e}^{2i\alpha} = 1$. This implies that

$$\Psi_{1\dots i\dots j\dots n} = \pm\, \Psi_{1\dots j\dots i\dots n}\,, \tag{653}$$

in other words, a wave function is either *symmetric* or *antisymmetric* under exchange of indices. (One can also say that the eigenvalue for the exchange operator is either +1 or −1.) *Quantum theory thus predicts that particles can be indistinguishable in one of two distinct ways.**** Particles corresponding to symmetric wave functions – those which transform with a '+' in equation (653) – are called *bosons*, those corresponding to antisymmetric wave functions – those which transform with a '−' in equation (653) – are called *fermions*.****

* The word 'indistinguishable' is so long that many physicists sloppily speak of 'identical' particles nevertheless. Take care.

** We therefore have the same situation that we encountered already several times: *an overspecification of the mathematical description*, here the explicit ordering of the indices, *implies a symmetry of this description*, which in our case is a symmetry under exchange of indices, i.e., under exchange of particles.

*** This conclusion applies to three-dimensional space only. In two dimensions there are more possibilities.

**** The term 'fermion' is derived from the name of the Italian physicist and Nobel Prize winner Enrico

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

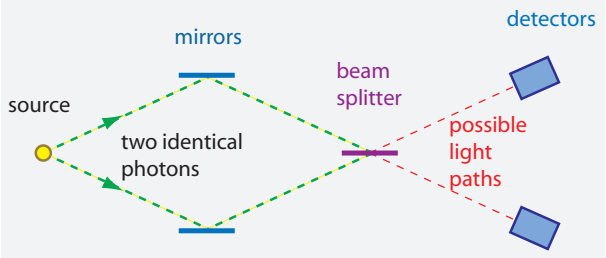

FIGURE 471 Two photons and interference

Experiments show that the exchange behaviour depends on the *type* of particle. Photons are found to be bosons. On the other hand, electrons, protons and neutrons are found to be fermions. Also about half of the atoms are found to behave as bosons (at moderate energies), the other half are fermions. In fact, a composite of an *even* number of fermions (at moderate energies) – or of any number of bosons (at any energy) – turns out to be a boson; a composite of an *odd* number of fermions is (always) a fermion.

For example, almost all of the known molecules are bosons (electronically speaking). Fermionic molecules are rather special and even have a special name in chemistry; they are called *radicals* and are known for their eagerness to react and to form normal bosonic molecules. Inside the human body, too many radicals can have adverse effects on health; it is well known that vitamin C is important because it is effective in reducing the number of radicals.

Challenge 1425 s To which class of particles do mountains, trees, people and all other macroscopic objects belong?

The behaviour of photons

A simple experiment allows to determine the behaviour of photons. Take a source that emits two photons of identical frequency and polarization at the same time, as shown in Figure 471. In the laboratory, such a source can be realized with a down-converter, a material that converts a photon of frequency 2ω into two photons of frequency ω. Both photons, after having travelled exactly the same distance, are made to enter the two sides of a beam splitter (for example, a half-silvered mirror). At the two exits of the beam splitter are two detectors. Experiments show that both photons are always detected together on the *same* side, and never separately on opposite sides. This result shows that photons are bosons. Fermions behave in exactly the opposite way; two fermions are always detected separately on *opposite* sides, never together on the same side.

Ref. 877

Fermi (b. 1901 Roma, d. 1954 Chicago) famous for his all-encompassing genius in theoretical and experimental physics. He mainly worked on nuclear and elementary particle physics, on spin and on statistics. For his experimental work he was called 'quantum engineer'. He is also famous for his lectures, which are still published in his own hand-writing, and his brilliant approach to physical problems. Nevertheless, his highly deserved Nobel Prize was one of the few cases in which the prize was given for a discovery which turned out to be incorrect.

'Bosons' are named after the Indian physicist Satyenra Nath Bose (b. 1894 Calcutta, d. 1974 Calcutta) who first described the statistical properties of photons. The work was later expanded by Albert Einstein.

Bunching and antibunching

A beautiful way to test the exchange character of a particle is the Hanbury Brown–Twiss experiment described earlier on. First of all, the experiment shows that quantum particles behave differently than classical particles. In addition, compared to classical particles, fermions show antibuching – because of Pauli's exclusion principle – and bosons show bunching. Hanbury Brown and Twiss performed the experiment with photons. In 2005, a French–Dutch research collaboration performed the experiment with atoms. By using an extremely cold helium gas at 500 nK and a clever detector principle, they were able to measure the correlation curves typical for the effect. The result, shown in Figure 472 shows that, as predicted by quantum theory, ^{3}He is a fermion and ^{4}He is a boson.

Page 1003

Ref. 878

The energy dependence of permutation symmetry

If experiments force us to conclude that nobody, not even nature, can distinguish any two particles of the same type, we deduce that they do not form two separate entities, but some sort of unity. Our naive, classical sense of particle as a separate entity from the rest of the world is thus an incorrect description of the phenomenon of 'particle'. Indeed, no experiment can track particles with identical intrinsic properties in such a way that they can be distinguished with certainty. This impossibility has been checked experimentally with all elementary particles, with nuclei, with atoms and with numerous molecules.

How does this fit with everyday life, i.e., with classical physics? Photons do not worry us much here. Let us focus the discussion on matter particles. We know to be able to distinguish electrons by pointing to the wire in which they flow, and we can distinguish

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 473 Particles as localized excitations or clouds

our fridge from that of our neighbour. While the quantum of action makes distinction impossible, everyday life allows it. The simplest explanation is to imagine a microscopic particle, especially an elementary one, as a bulge, i.e., as a localized excitation of the vacuum, or as a tiny cloud. Figure 473 shows two such bulges and two clouds representing particles. It is evident that if particles are too near to each other, it makes no sense to distinguish them; we cannot say any more which is which.

The bulge image shows that either for large distances or for high potential walls separating them, distinction of identical particles does become possible. In such situations, measurements allowing to track them independently do exist. In other words, we can specify a limit energy at which permutation symmetry of objects or particles separated by a distance d becomes important. It is given by

$$E = \frac{c\,\hbar}{d} \,. \tag{654}$$

Challenge 1426 ny Are you able to confirm the expression? For example, at everyday temperatures we *can* distinguish atoms inside a solid from each other, since the energy so calculated is much higher than the thermal energy of atoms. To have fun, you might want to determine at what energy two truly identical human twins become indistinguishable. Estimating at what energies the statistical character of trees or fridges will become apparent is then
Challenge 1427 ny straightforward.

The bulge image of particles thus purveys the idea that distinguishability exists for objects in everyday life but not for particles in the microscopic domain. To sum up, in daily life we are able to distinguish objects and thus people for two reasons: because they are made of *many* parts, and because we live in a *low energy* environment.

The energy issue immediately adds a new aspect to the discussion. How can we describe fermions and bosons in the presence of virtual particles and of antiparticles?

Indistinguishability in quantum field theory

Quantum field theory, as we will see shortly, simply puts the cloudy bulge idea of Figure 473 into mathematical language. A situation with no bulge is called *vacuum state*. Quantum field theory describes all particles of a given type as *excitations* of a single fundamental field. Particles are indistinguishable because each particle is an excitation of the same basic substrate and each excitation has the same properties. A situation with one particle is then described by a vacuum state acted upon by a *creation operator*. Adding

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

a second particle is described by adding a second creation operator, and subtracting a particle by adding a *annihilation operator*; the latter turns out to be the adjoint of the former.

Quantum field theory studies how creation and annihilation operators must behave to describe observations.* It arrives at the following conclusions:

— Fields with half-integer spin are fermions and imply (local) anticommutation.
— Fields with integer spin are bosons and imply (local) commutation.
— For all fields at spacelike separations, the commutator, respectively anticommutator, vanishes.
— Antiparticles of fermions are fermions, and antiparticles of bosons are bosons.
— Virtual particles behave under exchange like their real counterparts.

These connections are at the basis of quantum field theory. They describe how particles are identical. But why are they? Why are all electrons identical? Quantum field theory describes electrons as identical excitations of the vacuum, and as such as identical by construction. Of course, this answer is only partially satisfying. We will find a better one only in the final part of our mountain ascent.

How accurately is permutation symmetry verified?

A simple but effective experiment testing the fermion behaviour of electrons was carried out by Ramberg and Snow. They sent an electric current of 30 A through a copper wire for one month and looked for X-ray emission. They did not find any. They concluded that electrons are always in an antisymmetric state, with a symmetric component of less than

Ref. 879

$$2 \cdot 10^{-26} \tag{657}$$

of the total state. In short, electrons are always in an antisymmetric state: they are fermions.

The reasoning behind this elegant experiment is the following. If electrons would not always be fermions, every now and then an electron could fall into the lowest energy level of a copper atom, leading to X-ray emission. The lack of such X-rays implies that electrons are fermions to a very high accuracy. X-rays could be emitted only if they were bosons, at least part of the time. Indeed, two electrons, being fermions, cannot be in the same quantum state: this restriction is called the Pauli exclusion principle. It applies to all fermions and is our next topic.

* Whenever the relation

$$[b, b^\dagger] = bb^\dagger - b^\dagger b = 1 \tag{655}$$

holds between the creation operator $b^\dagger$ and the annihilation operator b, the operators describe a *boson*. The dagger can thus be seen as describing the operation of adjoiningg; a double dagger is equivalent to no dagger. If the operators for particle creation and annihilation anticommute

$$\{d, d^\dagger\} = dd^\dagger + d^\dagger d = 1 \tag{656}$$

they describe a *fermion*. The so defined bracket is called the *anticommutator bracket*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Copies, clones and gloves

Can classical systems be indistinguishable? They can: large molecules are examples – provided they are made of exactly the same isotopes. Can *large* classical systems, made of a mole or more particles be indistinguishable? This simple question effectively asks whether a perfect copy, or (physical) *clone* of a system is possible.

It could be argued that any factory for mass-produced goods, such as one producing shirt buttons or paper clips, shows that copies are possible. But the appearance is deceiving. On a microscope there is usually some difference. Is this always the case? In 1982, the Dutch physicist Dennis Dieks and independently, the US-American physicists Wootters and Zurek, published simple proofs that quantum systems cannot be copied. This is the famous *no-cloning theorem*.

Ref. 881

A copying machine is a machine that takes an original, reads out its properties and produces a copy, leaving the original unchanged. This seems definition seems straightforward. However, we know that if we extract information from an original, we have to interact with it. As a result, the system will change at least by the quantum of action. We thus expect that due to quantum theory, copies and originals can never be identical.*

Quantum theory proves this in detail. A copying machine is described by an operator that maps the state of an original system to the state of the copy. In other words, a copying machine is linear. This linearity leads to a problem. Simply stated, if a copying machine were able to copy originals either in state $|A\rangle$ or in state $|B\rangle$, it could not decide what to do if the state of the original were $|A\rangle+|B\rangle$. On one hand, the copy should be $|A\rangle+|B\rangle$; on the other hand, the linearity of the copier forbids this. Indeed, a copier is a device described by an operator U that changes the starting state $|s\rangle_c$ of the copy in the following way:

— If the original is in state $|A\rangle$, a copier acts as

$$U|A\rangle|s\rangle_c = |A\rangle|A\rangle_c \,. \tag{658}$$

— If the original is in state $|B\rangle$, a copier acts as

$$U|B\rangle|s\rangle_c = |B\rangle|B\rangle_c \,. \tag{659}$$

As a result of these two requirements, an original in the state $|A + B\rangle$ is treated by the copier as

$$U|A + B\rangle|s\rangle_c = |A\rangle|A\rangle_c + |B\rangle|B\rangle_c \,. \tag{660}$$

This is in contrast to what we want, which would be

$$U_{\text{wanted}}|A + B\rangle|s\rangle_c = (|A\rangle + |B\rangle)(|A\rangle_c + |B\rangle_c) \,. \tag{661}$$

In other words, a copy machine cannot copy a state completely.** This is the no-cloning theorem.

* This seems to provide a solution against banknote forgeries. In fact, Steve Wiesner proposed to use quantum theory already in 1970; he imagined to use polarizations of stored single photons as bits of serial numbers. Can you explain why this cannot work?

Challenge 1428 ny

** The no-cloning theorem puts severe limitations on quantum computers, as computations often need

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The impossibility of copying is implicit in quantum theory. If we were able to clone systems, we could to measure a variable of a system and a second variable on its copy. We would be thus able to beat the indeterminacy relation. This is impossible. Copies are and always must be imperfect.

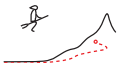
Other researchers then explored how near to perfection a copy can be, especially in the case of classical systems. To make a long story short, these investigations show that also the copying or cloning of macroscopic systems is impossible. In simple words, copying machines do not exist. Copies can always be distinguished from originals if observations are made with sufficient care. In particular, this is the case for biological clones; biological clones are identical twins born following separate pregnancies. They differ in their finger prints, iris scans, physical and emotional memories, brain structures, and in many other aspects. (Can you specify a few more?) In short, biological clones, like identical twins, are not copies of each other.

Ref. 882

Challenge 1429 s

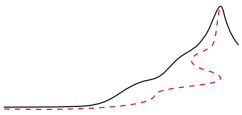
The lack of quantum mechanical copying machines is disappointing. Such machines, or teleportation devices, could be fed with two different inputs, such as a lion and a goat, and produce a superposition: a chimaera. Quantum theory shows that all these imaginary beings cannot be realized.

In summary, everyday life objects such as photocopies, billiard balls or twins are always distinguishable. There are two reasons: first, quantum effects play no role in everyday life, so that there is no danger of unobservable exchange; secondly, perfect clones of classical systems do not exist anyway, so that there always are tiny differences between any two objects, even if they look identical at first sight. Gloves, being classical systems, can thus always be distinguished.



copies of intermediate results. It also shows that faster-than-light communication is impossible in EPR experiments. In compensation, quantum cryptography becomes possible – at least in the laboratory. Indeed, the no-cloning theorem shows that nobody can copy a quantum message without being noticed. The specific ways to use this result in cryptography are the 1984 Bennett–Brassard protocol and the 1991 Ekert protocol.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 38

ROTATIONS AND STATISTICS – VISUALIZING SPIN

We saw above that spin is the observation that matter rays, like light rays, can be polarized. Spin thus describes how particles behave under rotations, and it proves that particles are not simple spheres shrunk to points. We also saw that spin describes a fundamental difference between quantum systems and gloves: spin specifies the indistinguishability of quantum systems. Let us explore this connection in more detail.

Ref. 883 The general background for the appearance of spin was clarified by Eugene Wigner in 1939.* He started by recapitulating that any quantum mechanical particle, if elementary, must behave like an irreducible representation of the set of all viewpoint changes. This set forms the symmetry group of flat space-time, the so-called *inhomogeneous Lorentz group*. We have seen in the chapter on classical mechanics how this connection between Page 213 elementarity and irreducibility arises. To be of physical relevance for quantum theory, representations have to be *unitary*. The full list of irreducible unitary representations of viewpoint changes thus provides the range of possibilities for any particle that wants to be *elementary*.

Cataloguing the possibilities, one finds first of all that every elementary particle is described by four-momentum – no news so far – and by an internal angular momentum, the *spin*. Four-momentum results from the translation symmetry of nature, and spin from its rotation symmetry. The momentum value describes how a particle behaves under translation, i.e., under position and time shift of viewpoints. The spin value describes how an object behaves under rotations in three dimensions, i.e., under orientation change of viewpoints.** As is well known, the magnitude of four-momentum is an invariant property, given by the mass, whereas its orientation in space-time is free. Similarly, the magnitude of spin is an invariant property, and its orientation has various possibilities with respect to the direction of motion. In particular, the spin of massive particles behaves differently from that of massless particles.

For *massive* particles, the inhomogeneous Lorentz group implies that the invariant magnitude of spin is $\sqrt{J(J+1)}\hbar$, often written, by oversimplification, as J. Since the value J specifies the magnitude of the angular momentum, it gives the representation under rotations of a given particle type. The spin magnitude J can be any multiple of $1/2$, i.e., it can take the values $0, 1/2, 1, 3/2, 2, 5/2$, etc. Experiments show that electrons,

* Eugene Wigner (b. 1902 Budapest, d. 1995 Princeton), Hungarian–US-American theoretical physicist, received the Nobel Prize for physics in 1963. He wrote over 500 papers, many about symmetry in physics. He was also famous for being the most polite physicist in the world.

** The group of physical rotations is also called SO(3), since mathematically it is described by the group of Special Orthogonal 3 by 3 matrices.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

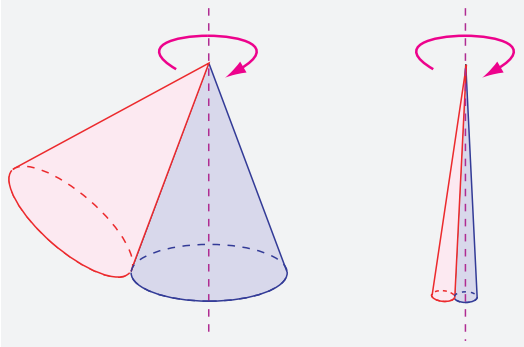


FIGURE 474 An argument showing why rotations by 4π are equivalent to no rotation at all

protons and neutrons have spin 1/2, the W and Z particles spin 1 and helium atoms spin 0. In addition, the representation of spin J is $2J + 1$ dimensional, meaning that the spatial orientation of the spin has $2J + 1$ possible values. For electrons there are thus two possibilities; they are usually called 'up' and 'down'.

Spin thus only takes *discrete* values. This is in contrast with linear momentum, whose representations are infinite dimensional and whose possible values form a *continuous* range.

Also *massless* particles are characterized by the value of their spin. It can take the same values as in the massive case. For example, photons and gluons have spin 1. For massless particles, the representations are one-dimensional, so that massless particles are completely described by their *helicity*, defined as the projection of the spin onto the direction of motion. Massless particles can have positive or negative helicity, often also called right-handed and left-handed. There is no other freedom for the orientation of spin in the massless case.

In short, symmetry investigations lead to the classification of particles by their mass, their momentum and their spin. To complete the list, the remaining symmetries must be included. These are motion inversion parity, spatial parity and charge inversion parity. Since these symmetries are parities, each elementary particle has to be described by three additional numbers, called T, P and C, each of which can take values of either +1 or −1. Being parities, they must be *multiplied* to yield the value for a composed system.

Page 1290 A list of the values observed for all elementary particles in nature is given below. Spin and parities together are called *quantum numbers*. As we will discover later on, additional interaction symmetries will lead to additional quantum numbers. But let us return to spin.

A central result of quantum theory is that spin 1/2 is a possibility in nature, even though it does not appear in everyday life. For a system to have spin 1/2 means that for such a system only a rotation of 720 degrees is equivalent to one of 0 degrees, while one of 360 degrees is not, as explained in Table 93. The mathematician Hermann Weyl used Page 52 a simple image explaining this connection.

Take two cones, touching each other at their tips as well as along a line. Hold one cone and roll the other around it, as shown in Figure 474. When the rolling cone, after a full turn around the other cone, has come back to the original position, it has rotated

TABLE 93 Particle spin as representation of the rotation group

Spin [$\hbar$]	System unchanged after rotation by	Massive examples elementary	composite	Massless examples elementary
0	any angle	none [a,b]	mesons, nuclei, atoms	none [b]
1/2	2 turns	e, μ, τ, q, ν_e, ν_μ, ν_τ	nuclei, atoms, molecules	none, as neutrinos have a tiny mass
1	1 turn	W, Z	mesons, nuclei, atoms, molecules, toasters	g, γ
3/2	2/3 turn	none [b]	baryons, nuclei, atoms	none [b]
2	1/2 turn	none	nuclei	'graviton' [c]
5/2	2/5 turn	none	nuclei	none
3	1/3 turn	none	nuclei [d]	none
etc.[d]	etc.[d]	etc.[d]	etc.[d]	etc.[d]

a. Whether the Higgs particle is elementary or not is still unknown.
b. Supersymmetry predicts particles in these and other boxes.
c. The graviton has not yet been observed.
d. Nuclei exist with spins values up to at least 101/2 and 51 (in units of $\hbar$). Ref. 885

by some angle. If the cones are wide, the rotation angle is small. If the cones are very thin, almost like needles, the moving cone has rotated by almost 720 degrees. A rotation of 720 degrees is thus similar to one by 0 degrees. If we imagine the cone angle to vary continuously, this visualization also shows that a 720 degree rotation can be continuously deformed into a 0 degree one, whereas a 360 degree rotation cannot.

To sum up, the list of possible representations thus shows that rotations *require* the existence of spin. But why then do experiments show that all fermions have half-integer spin and that all bosons have integer spin? Why do electrons obey the Pauli exclusion principle? At first, it is not clear what the spin has to do with the statistical properties of a particle.

In fact, there are several ways to show that rotations and statistics are connected. The first proof, due to Wolfgang Pauli, used the details of quantum field theory and was so Ref. 884 complicated that its essential ingredients were hidden. It took quite several decades to convince everybody that a simple observation about belts was the central part of the proof.

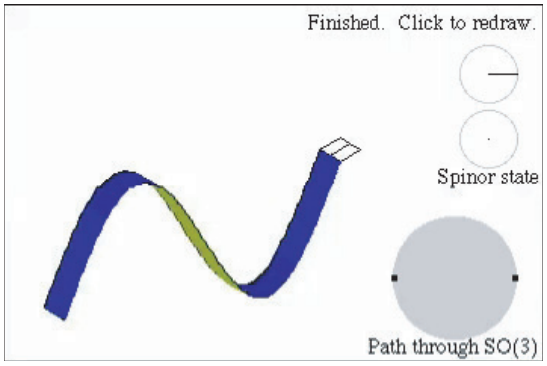

FIGURE 475 The belt trick (QuickTime film © Greg Egan)

FIGURE 476 A belt visualizing two spin 1/2 particles

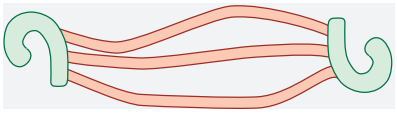

FIGURE 477 Another model for two spin 1/2 particles

The belt trick

The well-known *belt trick* (also called *scissor trick*) was often used by Dirac to explain the features of spin 1/2. Taking Figure 473, which models particles as indistinguishable excitations, it is not difficult to imagine a sort of sheet connecting them, similar to a belt connecting the two parts of the buckle, as shown in Figure 476. If one end of the belt is rotated by 2π along any axis, a twist is inserted into the belt. If the end is rotated for another 2π, bringing the total to 4π, the ensuing double twist can easily be undone without moving or rotating the ends. (See Figure 475.) You may need to experience this yourself in order to believe it.

Ref. 886

Challenge 1430 e

In addition, if you take the two ends and simply *swap* positions, a twist is introduced into the belt. Again, a second swap will undo the twist.

In other words, if we take each end to represent a particle and a twist to mean a factor -1, the belt exactly describes the phase behaviour of spin 1/2 wave functions under exchange and under rotations. In particular, we see that spin and exchange behaviour are related.

The human body has such a belt built in: the *arm*. Just take your hand, put an object on it for clarity such as a cup, and turn the hand and object by 2π by twisting the arm. After a second rotation the whole system will be untangled again.

The trick is even more impressive when many arms are used. You can put your two hands (if you chose the correct starting position) under the cup or you can take a friend or two who each keep a hand attached to the cup. The feat can still be performed: the whole system untangles after two full turns.

Challenge 1431 e

Challenge 1432 e

Another demonstration is to connect two buckles with *many* bands or threads, like in Figure 477. Both a rotation by 2π of one end or an exchange of the two ends produces

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

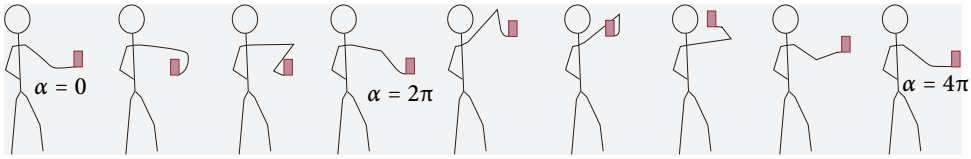

FIGURE 478 The human arm as spin 1/2 model

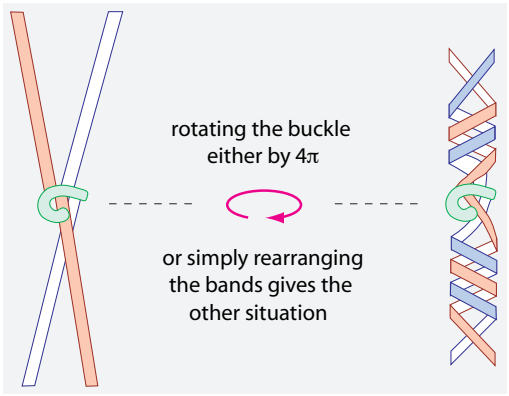

FIGURE 479 The extended belt trick, modelling a spin 1/2 particle: independently of the number of bands attached, the two situations can be transformed into each other, either by rotating the central object by 4π or by keeping the central object fixed and moving the bands around it

quite a tangle, even if one takes paths that 'in between' the bands; nevertheless, in both cases a second rotation leads back to the original situation.

There is still another way to show the connection between rotation and exchange. Just glue any number of threads or bands, say half a metre long, to an asymmetric object. Like the arm of a human being, the bands are supposed to go to infinity and be attached there. If any of the objects, which represent the particles, is rotated by 2π, twists appear in its strings. If the object is rotated by an additional turn, to a total of 4π, as shown in Figure 479, all twists and tangles can be made to disappear, without moving or turning the object. You really have to experience this in order to believe it. And the trick really works with *any* number of bands glued to the object.

Even more astonishing is the exchange part of the experiment. Take *two* particles of the type shown on the left side of Figure 479. If you exchange the positions of two such spin 1/2 particles, always keeping the ends at infinity fixed, a tangled mess is created. But incredibly, if you exchange the objects a second time, everything untangles neatly, independently of the number of attached strings. You might want to test yourself that the behaviour is also valid with sets of three or more particles.

Challenge 1433 e

All these observations together form the spin statistics theorem for spin 1/2 particles: *spin and exchange behaviour are related*. Indeed, these almost 'experimental' arguments can be put into exact mathematical language by studying the behaviour of the configuration space of particles. These investigations result in the following statements:

Ref. 887

▷ *Objects of spin 1/2 are fermions.**

* A mathematical observable behaving like a spin 1/2 particle is neither a vector nor a tensor, as you may

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

▷ *Exchange and rotation of spin 1/2 particles are similar processes.*

Note that all these arguments require three dimensions, because there are no tangles (or knots) in fewer dimensions.* And indeed, spin exists only in three or more spatial dimensions.

Here is a challenge. A spin 1/2 object can be modelled with one belt attached to it. If you want to model the spin behaviour with attached one-dimensional *strings* instead of *bands*, what is the minimum number required?

Challenge 1435 s

Angels, Pauli's exclusion principle and the hardness of matter

Why are we able to knock on a door? Why can stones not fly through tree trunks? How does the mountain we are walking on carry us? Why can't we walk across walls? In classical physics, we avoided this issue, by taking solidity as a defining property of matter. But doing so, we cheated: we have seen that matter consists mainly of empty space, so that we have to study the issue without any sneaky way out. The answer is now clear: penetration is made impossible by *Pauli's exclusion principle* between the electrons inside atoms. The exclusion principle states:

▷ *Two fermions cannot occupy the same quantum state.*

All experiments known confirm the statement.

Why do electrons and other fermions obey the Pauli exclusion principle? The answer can be given with a beautifully simple argument. We know that exchanging two fermions produces a minus sign in the total wave function. Imagine these two fermions being, as a classical physicist would say, located at the same spot, or as a quantum physicist would say, in the same state. If that could be possible, an exchange would change nothing in the system. But an exchange of fermions must produce a minus sign for the total state. Both possibilities – no change at all as well as a minus sign – cannot be realized at the same time. There is only one way out: two fermions must avoid to ever be in the same state. This is Pauli's exclusion principle.

Ref. 888

The exclusion principle is the reason that two pieces of matter in everyday life cannot penetrate each other, but have to repel each other. For example, bells only work because of the exclusion principle. A bell would not work if the colliding pieces that produce the sound would interpenetrate. But in any example of two interpenetrating pieces electrons from two atoms would have to be at the same spot: they would have to be in the same states. This is forbidden. Pauli's exclusion principle forbids interpenetration of matter.

Why don't we fall through the floor, even though gravity pulls us down, but remain on the surface? Again, the reason is Pauli's exclusion principle. Why does the floor not fall? It does not fall, because the matter of the Earth cannot be compressed further. Why? Pauli's exclusion principle does not allow atoms to be compressed. In other words, the

Challenge 1434 e

want to check. An additional concept is necessary; such an observable is called a *spinor*. We will introduce it later on.

Page 1047

* Of course, knots and tangles do exist in higher dimensions. Instead of considering knotted one-dimensional lines, one can consider knotted planes or knotted higher-dimensional hyperplanes. For example, deformable planes can be knotted in four dimensions and deformable 3-spaces in five dimensions.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

exclusion principle implies that matter cannot be compressed indefinitely, as at a certain stage an effective Pauli pressure appears, so that a compression limit ensues. For this reason for example, planets or neutron stars do not collapse under their own gravity.

The exclusion principle is the reason that atoms are *extended* electron clouds. In fact, the exclusion principle forces the electrons to form shells, and when one shell is filled, the next one is started. The size of the atom is the size of the last shell. Without the exclusion principle, atoms would be point-like. The same argument applies to the protons (and the neutrons) in nuclei.

The exclusion principle also answers the question about how many angels can dance on the top of a pin. (Note that angels, if at all, must be made of fermions, as you might want to deduce from the information known about them.) Both theory and experiment confirm the answer already given by Thomas Aquinas in the Middle Ages: Only one! The fermion exclusion principle could also be called 'angel exclusion principle'. To stay in the topic, the principle also shows that *ghosts* cannot be objects, as ghosts are supposed to be able to traverse walls.

Challenge 1436 s
Ref. 880

Whatever the interpretation, the exclusion principle keeps things in shape; without it, there would be no three-dimensional objects. Only the exclusion principle keeps the cloudy atoms of nature from merging, holding them apart. This repulsion keeps the size of planets to a finite value, and that of neutron stars. All shapes of solids and fluids are a direct consequence of the exclusion principle. In other words, when we knock on a table or on a door, we prove experimentally that both objects are made of fermions.

Since permutation properties and spin properties of fermions are so well described by the belt model, we could be led to the conclusion that these properties might really be consequence of such belt-like connections between particles and the outside world. Maybe for some reason we only observe the belt buckles, not the belts themselves. In the final part of this walk we will discover whether this idea is correct.

So far, we have only considered spin 1/2 particles. We will not talk much about systems with odd spin of higher value, such as 3/2 or 5/2. Such systems can be seen as being composed of spin 1/2 entities. Can you confirm this?

Challenge 1437 ny

We did not talk about lower spins than 1/2 either. A famous theorem states that a positive spin value below 1/2 is impossible, because the largest angle that can be measured in three dimensions is 4π. There is no way to measure a larger angle;* the quantum of action makes this impossible. Thus there cannot be any spin value between 0 and 1/2.

Spin, statistics and composition

Under rotations, integer spin particles behave differently from half-integer particles. Integer spin particles do not show the strange sign changes under rotations by 2π. In the belt imagery, integer spin particles need no attached strings. The spin 0 particle obviously corresponds to a sphere. Models for other spin values are shown in Figure 480. Exploring their properties in the same way as above, we arrive at the so-called *spin–statistics theorem*:

▷ *Exchange and rotation of objects are similar processes.*

* This statement, like all statements about spin 1/2, is tied to the three-dimensionality of space. In two dimensions, other largest angles and other 'spin' values are possible.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

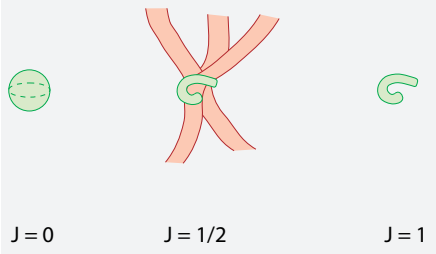

FIGURE 480 Some visualizations of spin representations

▷ *Objects of half-integer spin are fermions. They obey the Pauli exclusion principle.*

▷ *Objects of integer spin are bosons.*

Challenge 1438 ny You might prove by yourself that this suffices to show the following:

▷ *Composites of bosons, as well as composites of an even number of fermions (at low energy), are bosons; composites of an uneven number of fermions are fermions.*[*]

These connections express basic characteristics of the three-dimensional world in which we live.

Is spin a rotation about an axis?

The spin of a particle behaves experimentally like an intrinsic angular momentum, adds up like angular momentum, is conserved as part of angular momentum, is described like angular momentum and has a name synonymous with angular momentum. Despite all this, for many decades a strange myth was spread in many physics courses and textbooks around the world, namely that spin 1/2 is *not* a rotation about an axis. The myth maintains that any rotating object must have integer spin. Since half integer spin is not possible in classical physics, it is argued that such spin is not due to rotation. It is time to finish with this example of muddled thinking.

Electrons do have spin 1/2 and are charged. Electrons and all other charged particles with spin 1/2 do have a magnetic moment.[**] A magnetic moment is expected for any rotating charge. In other words, spin 1/2 does behave like rotation. However, assuming that a particle consists of a continuous charge distribution in rotational motion gives the wrong value for the magnetic moment. In the early days of the twentieth century, when physicists were still thinking in classical terms, they concluded that spin 1/2 particles thus cannot be rotating. This myth has survived through many textbooks. The correct deduction is that the assumption of continuous charge distribution is wrong. Indeed,

* This sentence implies that spin 1 and higher can also be achieved *with* tails; can you find such a representation? Challenge 1439 ny

Note that composite fermions can be bosons only up to that energy at which the composition breaks down. Otherwise, by packing fermions into bosons, we could have fermions in the same state.

** This can easily be measured in a an experiment; however, not one of the Stern–Gerlach type. Why not? Challenge 1440 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

charge is quantized; nobody today expects that elementary charge is continuously spread over space, as that would contradict its quantization.

Let us remember what rotation is. Both the belt trick for spin 1/2 as well as the integer spin case remind us: a *rotation* of one body around another is a fraction or a multiple of an exchange. What we call a rotating body in everyday life is a body continuously exchanging the positions of its parts. Rotation and exchange are the same.

Above we found that spin is exchange behaviour. Since rotation is exchange and spin is exchange, it follows that spin *is* rotation. Since we deduced, like Wigner, spin from rotation invariance, this consequence is not a surprise.

The belt model of a spin 1/2 particle tells us that such a particle can rotate continuously
Page 1066 without any hindrance. In short, we are allowed to maintain that spin is rotation about an axis, without any contradiction to observations, even for spin 1/2. The belt model helps to keep two things in mind: we must assume that in the belt model only the buckle can
Ref. 889 be observed and does interact, not the belt, and we must assume that elementary charge is pointlike.*

Why is fencing with laser beams impossible?

When a sword is approaching dangerously, we can stop it with a second sword. Many old films use such scenes. When a laser beam is approaching, it is impossible to fend it off with a second beam, despite all science fiction films showing so. Banging two laser beams against each other is impossible.

The above discussion shows why. The electrons in the swords are fermions and obey the Pauli exclusion principle. Fermions make matter impenetrable. On the other hand, photons are bosons. Two bosons *can* be in the same state; bosons allow interpenetration. Matter is impenetrable because at the fundamental level it is composed of fermions. Radiation is composed of bosons. The distinction between fermions and bosons thus explains why objects can be touched while images cannot. In the first part of our mountain ascent
Page 89 we started by noting this difference; now we know its origin.

Rotation requires antiparticles

The connection between rotation and antiparticles may be the most astonishing conclusion from the experiments showing the existence of spin. So far, we have seen that rotation requires the existence of spin, that spin appears when relativity is introduced into
Page 444 quantum theory, and that relativity requires antimatter. Taking these three statements together, the conclusion of the title is not surprising any more. Interestingly, there is a simple argument making the same point directly, without any help of quantum theory, when the belt model is extended from space alone to full *space-time*.

To learn how to think in space-time, let us take a particle spin 1, i.e., a particle looking like a detached belt buckle in three dimensions. When moving in a 2+1 dimensional
Challenge 1441 ny space-time, it is described by a ribbon. Playing around with ribbons in space-time, in-

* Obviously, the detailed structure of the electron still remains unclear at this point. Any angular momentum S is given classically by $S = \Theta\omega$; however, neither the moment of inertia Θ, connected to the rotation radius and electron mass, nor the angular velocity ω are known at this point. We have to wait quite a while, until the final part of our adventure, to find out more.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

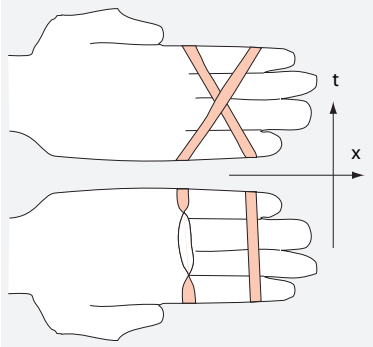

FIGURE 481 Equivalence of exchange and rotation in space-time

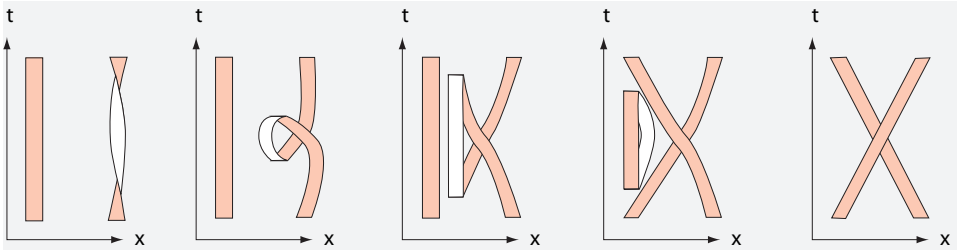

FIGURE 482 Belts in space-time: rotation and antiparticles

stead of belts in space, provides many interesting conclusions. For example, Figure 481 shows that wrapping a rubber ribbon around the fingers can show that a rotation of a body by 2π in presence of a second one is the same as exchanging the positions of the two bodies.* Both sides of the hand transform the same initial condition, at one edge of the hand, to the same final condition at the other edge. We have thus successfully extended a known result from space to space-time. Interestingly, we can also find a smooth sequence of steps realizing this equivalence.

If you think that Figure 481 is not a satisfying explanation, you are right. A more complete (yet equivalent) explanation is given by Figure 482. We assume that each particle is described by a segment; in the figure, they lie horizontally. The leftmost diagram shows two particles: one at rest and one being rotated by 2π. The deformation of the ribbons shows that this process is equivalent to the exchange in position of two particles, which is shown in the rightmost diagram. Again, one notes that the sequence that shows the equivalence between rotation and exchange requires the use of a particle–antiparticle pair. Without antiparticles, the equivalence of rotation and exchange would not hold. Rotation in space-time indeed requires antiparticles.

A summary on spin and indistinguishability

The quantum of action implies that physical systems are made of two types of indistinguishable particles: bosons and fermions. The two possible exchange behaviours are re-

* Obviously, the next step would be to check the full spin 1/2 model of Figure 479 in four-dimensional space-time. But this is not an easy task; there is no generally accepted solution yet.

Challenge 1442 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

lated to their spin value, because exchange is related to rotation.

Radiation is made of elementary particles that behave as bosons. They have integer spin. Two or more bosons, such as two photons, can share the same state. This sharing makes laser light possible.

Matter is made of elementary particles that behave as fermions. They have half-integer spin. They obey Pauli's exclusion principle: two fermions cannot be in the same state. The exclusion principle between electrons explains the structure and (partly) the size of atoms, as well as the chemical behaviour of atoms, as we will find out later on. Together with the electrostatic repulsion of electrons, the exclusion principle explains the incompressibility of matter and its lack of impenetrability.

Despite the indistinguishability of particles, the quantum of action also implies that exact copies of macroscopic objects cannot be produced, because quantum states for macroscopic objects cannot be copied.

Finally, the connection between spin and rotation implies that antiparticles exist. It also implies that spin is intrinsically a three-dimensional phenomenon.

Limits and open questions of quantum statistics

The topic of statistics is an important research field in theoretical and experimental physics. In particular, researchers have searched and still are searching for generalizations of the possible exchange behaviours of particles.

In two spatial dimensions, the result of an exchange of the wave function is not described by a sign, but by a continuous phase. Two-dimensional objects behaving in this way, called *anyons* because they can have 'any' spin, have experimental importance, since in many experiments in solid state physics the set-up is effectively two-dimensional. The fractional quantum Hall effect, perhaps the most interesting discovery of modern experimental physics, has pushed anyons onto the stage of modern research.

Page 1178

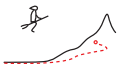
Other theorists generalized the concept of fermions in other ways, introducing parafermions, parabosons, plektons and other hypothetical concepts. Oscar Greenberg has spent most of his professional life on this issue. His conclusion is that in $3+1$ space-time dimensions, only fermions and bosons exist. (Can you show that this implies that the ghosts appearing in Scottish tales do not exist?)

Ref. 890

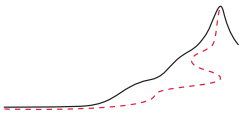
Challenge 1443 s

From a different viewpoint, the belt model of spin 1/2 invites to study the behaviour of braids, open links and knots. (In mathematics, braids and open links are made of strands extending to infinity.) This fascinating part of mathematical physics has become important with in modern unfied theories, which all state that particles, especially at high energies, are not point-like, but extended entities.

Still another generalization of statistical behaviour at high energies is the concept of quantum group. In all of these cases, the quest is to understand what happens to permutation symmetry in a unified theory of nature. A glimpse of the difficulties appears already above: how can Figures 473, 479 and 482 be reconciled and combined? We will settle this issue in the final part of our mountain ascent.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 39

SUPERPOSITIONS AND PROBABILITIES – QUANTUM THEORY WITHOUT IDEOLOGY

> The fact that an adequate philosophical presentation has been so long delayed is no doubt caused by the fact that Niels Bohr brainwashed a whole generation of theorists into thinking that the job was done fifty years ago.
>
> Murray Gell-Mann

Ref. 891

Why is this famous physical issue arousing such strong emotions? In particular, who is brainwashed, Gell-Mann, the discoverer of the quarks, or most of the world's physicists working on quantum theory who follow Niels Bohr's opinion? In the twentieth century, quantum mechanics has thrown many in disarray. Indeed, it radically changed the two most basic concepts of classical physics: state and system. The *state* is not described any more by the specific values taken by position and momentum, but by the specific wave function 'taken' by the position and momentum operators.* In addition, in classical physics a *system* was described as a set of permanent aspects of nature; permanence was defined as negligible interaction with the environment. Quantum mechanics shows that this definition has to be modified as well.

The description of nature with quantum theory is unfamiliar for two reasons: it allows superpositions and it leads to probablilities. Let us clarify these issues. A clarification is essential if we want to avoid getting lost on our way to the top of Motion Mountain, as happened to quite a number of people since quantum theory appeared, including Gell-Mann.

WHY ARE PEOPLE EITHER DEAD OR ALIVE?

The evolution equation of quantum mechanics is *linear* in the wave function; linearity implies the existence of superpositions. Therefore we can imagine and try to construct systems where the state ψ is a superposition of two radically distinct situations, such as those of a dead and of a living cat. This famous fictional animal is called *Schrödinger's cat* after the originator of the example. Is it possible to produce it? And how would it evolve in time? We can ask the same two questions in other situations. For example, can

* It is equivalent, but maybe conceptually clearer, to say that the state is described by a complete set of commuting operators. In fact, the discussion is somewhat simplified in the Heisenberg picture. However, here we study the issue in the Schrödinger picture, using wave functions.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

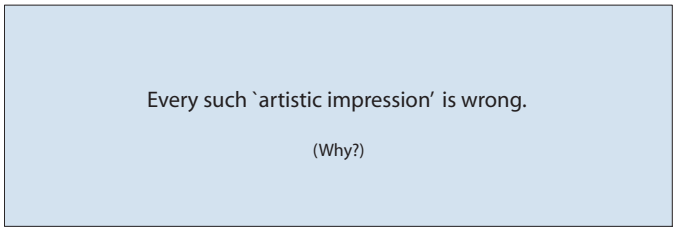


FIGURE 483 An artist's impression of a macroscopic superposition is impossible

we produce a superposition of a state where a car is inside a closed garage with a state where the car is outside? What happens then?

Such strange situations are not usually observed in everyday life. The reason for this rareness is an important aspect of what is often called the 'interpretation' of quantum mechanics. In fact, such strange situations *are* possible, and the superposition of macroscopically distinct states has actually been observed in a few cases, though not for cats, people or cars. To get an idea of the constraints, let us specify the situation in more detail.*

The object of discussion are linear superpositions of the type $\psi = a\psi_a + b\psi_b$, where ψ_a and ψ_b are macroscopically distinct states of the system under discussion, and where a and b are some complex coefficients. States are called *macroscopically distinct* when each state corresponds to a different macroscopic situation, i.e., when the two states can be distinguished using the concepts or measurement methods of classical physics. In particular, this means that the physical action necessary to transform one state into the other must be much larger than $\hbar$. For example, two different positions of any body composed of a large number of molecules are macroscopically distinct.

A 'strange' situation is thus a superposition of macroscopically distinct states. Let us work out the essence of macroscopic superpositions more clearly. Given two macroscopically distinct states ψ_a and ψ_b, a superposition of the type $\psi = a\psi_a + b\psi_b$ is called a *pure state*. Since the states ψ_a and ψ_b can interfere, one also talks about a *(phase) coherent superposition*. In the case of a superposition of macroscopically distinct states, the scalar product $\psi_a^\dagger \psi_b$ is obviously vanishing. In case of a coherent superposition, the coefficient product $a^* b$ is different from zero. This fact can also be expressed with the help of the *density matrix* ρ of the system, defined as $\rho = \psi \otimes \psi^\dagger$. In the present case it is given by

$$\begin{aligned}\rho_{\text{pure}} = \psi \otimes \psi^\dagger &= |a|^2 \psi_a \otimes \psi_a^\dagger + |b|^2 \psi_b \otimes \psi_b^\dagger + a\, b^* \psi_a \otimes \psi_b^\dagger + a^*\, b\, \psi_b \otimes \psi_a^\dagger \\ &= (\psi_a, \psi_b) \begin{pmatrix} |a|^2 & a\, b^* \\ a^*\, b & |b|^2 \end{pmatrix} \begin{pmatrix} \psi_a^\dagger \\ \psi_b^\dagger \end{pmatrix} . \end{aligned} \tag{662}$$

We can then say that whenever the system is in a pure state, its density matrix, or *density functional*, contains off-diagonal terms of the same order of magnitude as the diagonal

* Most what can be said about this topic has been said by two people: John von Neumann, who in the nineteen-thirties stressed the differences between evolution and decoherence, and by Hans Dieter Zeh, who in the nineteen-seventies stressed the importance of baths and the environment in the decoherence process.
Ref. 892
Ref. 893

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ones.* Such a density matrix corresponds to the above-mentioned strange situations that we do not observe in daily life.

We now have a look at the opposite situation, a density matrix for macroscopic distinct states with *vanishing* off-diagonal elements. For two state, the example

$$\begin{aligned}\rho &= |a|^2 \psi_a \otimes \psi_a^\dagger + |b|^2 \psi_b \otimes \psi_b^\dagger \\ &= (\psi_a, \psi_b) \begin{pmatrix} |a|^2 & 0 \\ 0 & |b|^2 \end{pmatrix} \begin{pmatrix} \psi_a^\dagger \\ \psi_b^\dagger \end{pmatrix}\end{aligned} \tag{664}$$

describes a system which possesses *no* phase coherence at all. (Here, $\otimes$ denotes the non-commutative dyadic product or tensor product which produces a tensor or matrix starting from two vectors.) Such a diagonal density matrix cannot be that of a pure state; it describes a system which is in the state ψ_a with probability $|a|^2$ and which is in the state ψ_b with probability $|b|^2$. Such a system is said to be in a *mixed state*, because its state is *not known*, or equivalently, to be in a *(phase) incoherent superposition*, because interference effects cannot be observed in such a situation. A system described by a mixed state is always *either* in the state ψ_a *or* in the state ψ_b. In other words, a diagonal density matrix for macroscopically distinct states is not in contrast, but in agreement with everyday experience. In the picture of density matrices, the non-diagonal elements contain the difference between normal, i.e., incoherent, and unusual, i.e., coherent, superpositions.

The experimental situation is clear: for macroscopically distinct states, only diagonal density matrices are observed in everyday life. Any system in a coherent macroscopic superposition somehow loses its off-diagonal matrix elements. How does this process of *decoherence*** take place? The density matrix itself shows the way.

Ref. 894 In thermodynamics, the density matrix for a large system is used for the definition of its entropy and of all its other thermodynamic quantities. These studies show that

Challenge 1444 ny

$$S = -k \operatorname{tr}(\rho \ln \rho) \tag{665}$$

where tr denotes the *trace*, i.e., the sum of all diagonal elements. We also remind ourselves that a system with a large and constant entropy is called a *bath*. In simple physical terms, a bath is a system to which we can ascribe a temperature. More precisely, a *(physical) bath*, or *(thermodynamic) reservoir*, is any large system for which the concept of *equilibrium* can be defined. Experiments show that in practice, this is equivalent to the condition that a bath consists of many interacting subsystems. For this reason, all macroscopic quantities describing the state of a bath show small, irregular *fluctuations*, a fact that will be of central importance shortly.

* Using the density matrix, we can rewrite the evolution equation of a quantum system:

$$\dot{\psi} = -iH\psi \quad \text{becomes} \quad \frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{i}{\hbar}[H, \rho] \,. \tag{663}$$

Both are completely equivalent. (The new expression is sometimes also called the *von Neumann equation*.) We won't actually do any calculations here. The expressions are given so that you recognize them when you encounter them elsewhere.

** In certain settings, decoherence is called *disentanglement*, as we will see below.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

An everyday bath is also a thermodynamic bath in the physical sense: indeed, a thermodynamic bath is similar to an extremely large warm water bath, one for which the temperature does not change even if one adds some cold or warm water to it. Examples of physical baths are an intense magnetic field, a large amount of gas, or a large solid. (The meanings of 'intense' and 'large' of course depend on the system under study.) The physical concept of bath (or *reservoir*) is thus an abstraction and a generalization of the everyday concept of bath.

Challenge 1445 s

It is easy to see from the definition (665) of entropy that the loss of off-diagonal elements corresponds to an increase in entropy. And it is known that any increase in entropy of a reversible system, such as the quantum mechanical system in question, is due to an interaction with a bath.

Where is the bath interacting with the system? It obviously must be outside the system one is talking about, i.e., in its *environment*. Indeed, we know experimentally that any environment is large and characterized by a temperature. Some examples are listed in Table 94. Any environment therefore contains a bath. We can even go further: for every experimental situation, there is a bath *interacting* with the system. Indeed, every system which can be observed is not isolated, as it obviously interacts at least with the observer; and every observer by definition contains a bath, as we will show in more detail shortly. Usually however, the most important baths we have to take into consideration are the atmosphere around a system, the radiation or electromagnetic fields interacting with the system, or, if the system itself is large enough to have a temperature, those degrees of freedom of the system which are not involved in the superposition under investigation.

Since every system is in contact with baths, every density matrix of a macroscopic superposition will lose its diagonal elements eventually. At first sight, this direction of thought is not convincing. The interactions of a system with its environment can be made extremely small by using clever experimental set-ups; that would imply that the time for decoherence can be made extremely large. Thus we need to check how much time a superposition of states needs to decohere. It turns out that there are two standard ways to estimate the *decoherence time:* either by modelling the bath as large number of colliding particles, or by modelling it as a continuous field.

Challenge 1446 ny

If the bath is described as a set of particles randomly hitting the microscopic system, it is best characterized by the effective wavelength λ_{eff} of the particles and by the average interval t_{hit} between two hits. A straightforward calculation shows that the decoherence time t_d is in any case smaller than this time interval, so that

$$t_d \leqslant t_{\text{hit}} = \frac{1}{\varphi\sigma} \,, \tag{666}$$

where φ is the flux of particles and σ the cross-section for the hit.* Typical values are

* The decoherence time is derived by studying the evolution of the density matrix $\rho(x, x')$ of objects localized at two points x and x'. One finds that the off-diagonal elements follow $\rho(x, x', t) = \rho(x, x', 0)\mathrm{e}^{-\Lambda t(x-x')^2}$, where the localization rate Λ is given by

$$\Lambda = k^2 \varphi \sigma_{\text{eff}} \tag{667}$$

where k is the wave number, φ the flux and σ_{eff} the cross-section of the collisions, i.e., usually the size of the macroscopic object.

a. Values are rough estimates. The macroscopic ball is assumed to have a 1 mm size.

given in Table 94. We easily note that for macroscopic objects, decoherence times are extremely short. (We also note that nuclear and gravitational effects lead to large decoherence times and can thus all be neglected.) Scattering leads to fast decoherence. However, for atoms or smaller systems, the situation is different, as expected.

A second method to estimate the decoherence time is also common. Any interaction of a system with a bath is described by a relaxation time t_r. The term *relaxation* designates any process which leads to the return to the equilibrium state. The terms *damping* and *friction* are also used. In the present case, the relaxation time describes the return to equilibrium of the combination bath and system. Relaxation is an example of an irreversible evolution. A process is called *irreversible* if the reversed process, in which every component moves in opposite direction, is of very low probability.* For example, it is usual that

One also finds the surprising result that a system hit by a particle of energy E_{hit} collapses the density matrix roughly down to the de Broglie (or thermal de Broglie) wavelength of the hitting particle. Both results together give the formula above. Ref. 896

* Beware of other definitions which try to make something deeper out of the concept of irreversibility, such

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

a glass of wine poured into a bowl of water colours the whole water; it is very rarely observed that the wine and the water separate again, since the probability of all water and wine molecules to change directions together at the same time is rather low, a state of affairs making the happiness of wine producers and the despair of wine consumers.

Now let us simplify the description of the bath. We approximate it by a single, unspecified, scalar field which interacts with the quantum system. Due to the continuity of space, such a field has an infinity of degrees of freedom. They are taken to model the many degrees of freedom of the bath. The field is assumed to be in an initial state where its degrees of freedom are excited in a way described by a temperature T. The interaction of the system with the bath, which is at the origin of the relaxation process, can be described by the repeated transfer of small amounts of energy E_{hit} until the relaxation process is completed.

The objects of interest in this discussion, like the mentioned cat, person or car, are described by a mass m. Their main characteristic is the maximum energy E_r which can be transferred from the system to the environment. This energy describes the interactions between system and environment. The superpositions of macroscopic states we are interested in are solutions of the Hamiltonian evolution of these systems.

The initial coherence of the superposition, so disturbingly in contrast with our every-
Ref. 897 day experience, disappears exponentially within a *decoherence time* t_d given by*

$$t_d = t_r \frac{E_{\text{hit}}}{E_r} \frac{e^{E_{\text{hit}}/kT} - 1}{e^{E_{\text{hit}}/kT} + 1} \tag{670}$$

where k is the *Boltzmann constant* and like above, E_r is the maximum energy which can be transferred from the system to the environment. Note that one always has $t_d \leqslant t_r$. After the decoherence time t_d is elapsed, the system has evolved from the coherent to the incoherent superposition of states, or, in other words, the density matrix has lost its off-diagonal terms. One also says that the phase coherence of this system has been destroyed. Thus, after a time t_d, the system is found either in the state ψ_a or in the state ψ_b, respectively with the probability $|a|^2$ or $|b|^2$, and not any more in a coherent superposition which is so much in contradiction with our daily experience. Which final state is selected depends on the precise state of the bath, whose details were eliminated from the calculation by taking an *average* over the states of its microscopic constituents.

---

as claims that 'irreversible' means that the reversed process is *not at all* possible. Many so-called 'contradictions' between the irreversibility of processes and the reversibility of evolution equations are due to this mistaken interpretation of the term 'irreversible'.

* This result is derived as in the above case. A system interacting with a bath always has an evolution given
Ref. 898 by the general form

$$\frac{d\rho}{dt} = -\frac{i}{\hbar}[H, \rho] - \frac{1}{2t_o}\sum_j [V_j\rho, V_j^\dagger] + [V_j, \rho V_j^\dagger] \,, \tag{668}$$

where ρ is the density matrix, H the Hamiltonian, V the interaction, and t_o the characteristic time of the
Challenge 1447 ny interaction. Are you able to see why? Solving this equation, one finds for the elements far from the diagonal $\rho(t) = \rho_0 e^{-t/t_0}$. In other words, they disappear with a characteristic time t_o. In most situations one has a relation of the form

$$t_0 = t_r \frac{E_{\text{hit}}}{E_r} = t_{\text{hit}} \tag{669}$$

or some variations of it, as in the example above.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The important result is that for all macroscopic objects, the decoherence time t_d is extremely small. In order to see this more clearly, we can study a special simplified case. A macroscopic object of mass m, like the mentioned cat or car, is assumed to be at the same time in two locations separated by a distance l, i.e., in a superposition of the two corresponding states. We further assume that the superposition is due to the object moving as a quantum mechanical oscillator with frequency ω between the two locations; this is the simplest possible system that shows superpositions of an object located in two different positions. The energy of the object is then given by $E_r = m\omega^2 l^2$, and the smallest transfer energy $E_{\text{hit}} = \hbar\omega$ is the difference between the oscillator levels. In a macroscopic situation, this last energy is much smaller than kT, so that from the preceding expression
Ref. 899 we get

$$t_d = t_r \frac{E_{\text{hit}}^2}{2E_r\, kT} = t_r \frac{\hbar^2}{2mkTl^2} = t_r \frac{\lambda_T^2}{l^2} \tag{671}$$

in which the frequency ω has disappeared. The quantity $\lambda_T = \hbar/\sqrt{2mkT}$ is called the *thermal de Broglie wavelength* of a particle.

It is straightforward to see that for practically all macroscopic objects the typical decoherence time t_d is extremely short. For example, setting $m = 1\,\text{g}$, $l = 1\,\text{mm}$ and $T = 300\,\text{K}$ we get $t_d/t_r = 1.3 \cdot 10^{-39}$. Even if the interaction between the system and the environment would be so weak that the system would have as relaxation time the age of the universe, which is about $4 \cdot 10^{17}\,\text{s}$, the time t_d would still be shorter than $5 \cdot 10^{-22}\,\text{s}$, which is over a million times faster than the oscillation time of a beam of light (about 2 fs for green light). For Schrödinger's cat, the decoherence time would be even shorter. These times are so short that we cannot even hope to *prepare* the initial coherent superposition, let alone to observe its decay or to measure its lifetime.

For microscopic systems however, the situation is different. For example, for an electron in a solid cooled to liquid helium temperature we have $m = 9.1 \cdot 10^{-31}\,\text{kg}$, and typically $l = 1\,\text{nm}$ and $T = 4\,\text{K}$; we then get $t_d \approx t_r$ and therefore the system can stay in a coherent superposition until it is relaxed, which confirms that for this case coherent effects can indeed be observed if the system is kept isolated. A typical example is the behaviour
Ref. 900 of electrons in superconducting materials. We will mention a few more below.

In 1996 the first actual measurement of decoherence times was published by the Paris
Ref. 901 team around Serge Haroche. It confirmed the relation between the decoherence time and the relaxation time, thus showing that the two processes have to be distinguished at microscopic scale. In the meantime, other experiments confirmed the decoherence
Ref. 902 process with its evolution equation, both for small and large values of t_d/t_r. A particularly
Ref. 903 beautiful experiment has been performed in 2004, where the disappearance of two-slit interference for C_{70} molecules was observed when a bath interacts with them.

Summary on decoherence, life and death

Our exploration showed that *decoherence results from coupling to a bath in the environment.* Decoherence is a statistical, thermodynamic effect.

The estimates of decoherence times in everyday life told us that both the preparation and the survival of superpositions of macroscopically different states is made impossible by the interaction with any bath found in the environment. This is the case even if the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

usual measure of this interaction, given by the friction of the motion of the system, is very small. Even if a macroscopic system is subject to an extremely low friction, leading to a very long relaxation time, its decoherence time is still vanishingly short. Only carefully designed and expensive laboratory systems can reach substantial decoherence times.

Our everyday environment is full of baths. Therefore, *coherent superpositions of macroscopically distinct states never appear in everyday life.* Cars cannot be in and out of a garage at the same time. In short, we cannot be dead and alive at the same time.

WHAT IS A SYSTEM? WHAT IS AN OBJECT?

In classical physics, a system is a part of nature which can be isolated from its environment. However, quantum mechanics tells us that isolated systems do not exist, since interactions cannot be made vanishingly small. The results above allow us to define the concept of system with more accuracy. A *system* is any part of nature which interacts *incoherently* with its environment. In other words, an *object* is a part of nature interacting with its environment only through baths.

In particular, a system is called *microscopic* or *quantum mechanical* and can described by a wave function ψ whenever

— it is almost isolated, with $t_{\text{evol}} = \hbar/\Delta E < t_{\text{r}}$, and
Ref. 904 — it is in *incoherent* interaction with its environment.

In short, a microscopic or quantum mechanical system that is described by a wave function interacts incoherently and weakly with its environment. (For such a system, the energy indeterminacy ΔE is larger than the relaxation energy.) In contrast, a bath is never isolated in the sense just given, because the evolution time of a bath is always much larger than its relaxation time. Since all macroscopic bodies are in contact with baths – or even contain one – they cannot be described by a wave function. In particular, it is impossible to describe any measuring apparatus with the help of a wave function.

We thus conclude that a *macroscopic system* is a system with a decoherence time much shorter than any other evolution time of its constituents. Obviously, macroscopic systems also interact incoherently with their environment. Thus cats, cars and television news speakers are all macroscopic systems.

One possibility is left over by the two definitions: what happens in the situation in which the interactions with the environment are *coherent*? We will encounter some examples shortly. Following the definition, they are neither microscopic and macroscopic systems; they are not described by a wave function, and strictly speaking, they are *not* systems. In these situations, when the interaction is coherent, one speaks of *entanglement* or of entangle 'systems'; such a particle or set of particles is said to be *entangled* with its environment.

Entangled, coherently interacting systems can be divided, but must be disentangled when doing so. The act of division leads to detached entities; detached entities interact incoherently. Quantum theory shows that nature is not made of detached entities, but that it is made of *detachable* entities. In quantum theory, the criterion of detachment is the incoherence of interaction. Coherent superpositions imply the surprising consequence

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

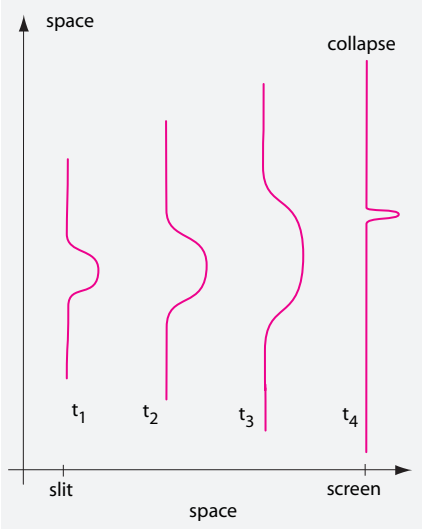

FIGURE 484 Quantum mechanical motion: an electron wave function (actually its module squared) from the moment it passes a slit until it hits a screen

that there are systems which, even though they look being made of detached parts, are not. Entanglement poses a limit to detachment. All surprising properties of quantum mechanics, such as Schrödinger's cat, are consequences of the classical prejudice that a system made of two or more parts can obviously be detached into two subsystems without disturbance. But coherent superpositions, or entangled systems, do not allow detachment without disturbance. Whenever we assume to be able to detach entangled systems, we get strange or incorrect conclusions, such as apparent faster-than-light propagation, or, as one says today, non-local behaviour. Let us have a look at a few typical examples.

Is quantum theory non-local? – A bit about the Einstein-Podolsky-Rosen paradox

> [Mr. Duffy] lived a little distance away from his body ...
>
> James Joyce, *A Painful Case*

We now explore non-locality in quantum mechanics.* To do this, we explore wave function collapse in some detail.

We imagine an electron hitting a screen after passing a slit. Following the description just deduced, the process proceeds schematically as depicted in Figure 484. A film of the same process can be seen in the lower left corners on these pages, starting at page 1074. The process has a surprising aspect: due to the short decoherence time, during this (and any other) wave function collapse the maximum of the wave function changes position faster than light. Is this reasonable?

A situation is called *acausal* or *non-local* if energy is transported faster than light. Using Figure 484 you can determine the energy velocity involved, using the results on sig-

Challenge 1448 s

* This continues a topic that we know already: we have explored a different type of non-locality, in general relativity, earlier on.

Page 622

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

nal propagation. The result is a value smaller than c. A wave function maximum moving faster than light does *not* imply energy moving faster than light.

Page 751

In other words, quantum theory has speeds greater than light, but no energy speeds greater than light. In classical electrodynamics, the same happens with the scalar and the vector potentials if the Coulomb gauge is used. We have also encountered speeds faster than that of light in the motion of shadows and in many other observations. Any physicist now has two choices: he can be straight, and say that there is no non-locality in nature; or he can be less straight, and claim there is. In the latter case, he has to claim that even classical physics is non-local. However, this never happens. On the other hand, there is a danger in this more provoking usage: a small percentage of those who say that the world is non-local after a while start to believe that there really are faster-than-light effects in nature. These people become prisoners of their muddled thinking; on the other hands, muddled thinking helps to get more easily into newspapers. In short, even though the definition of non-locality is not unanimous, here we stick to the stricter one, and define non-locality as energy transport faster than light.

Ref. 905

Page 435

An often cited Gedanken experiment that shows the pitfalls of non-locality was proposed by Bohm* in the discussion around the so-called Einstein–Podolsky–Rosen paradox. In the famous EPR paper the three authors try to find a contradiction between quantum mechanics and common sense. Bohm translated their rather confused paper into a clear Gedanken experiment. When two particles in a spin 0 state move apart, measuring one particle's spin orientation implies an *immediate* collapse also of the other particle's spin, namely in the exactly opposite direction. This happens instantaneously over the whole separation distance; no speed limit is obeyed. In other words, entanglement seems to lead to faster-than-light communication.

Ref. 906, Ref. 907

However, in Bohm's experiment, no energy is transported faster than light. No non-locality is present, despite numerous claims of the contrary by certain authors. The two entangled electrons belong to one system: assuming that they are separate only because the wave function has two distant maxima is a conceptual mistake. In fact, no signal can be transmitted with this method; the decoherence is a case of prediction which looks like a signal without being one. Bohm's experiment, like any other EPR-like experiment, does not allow communication faster than light. We already discussed such cases in the section on electrodynamics.

Page 757

Bohm's experiment has actually been performed. The first and most famous realization was realized in 1982 by Alain Aspect; he used photons instead of electrons. Like all latter tests, it has fully confirmed quantum mechanics.

Ref. 908

In fact, experiments such as the one by Aspect confirm that it is impossible to treat either of the two particles as a system by itself; it is impossible to ascribe any physical property, such as a spin orientation, to either of them alone. (The Heisenberg picture would express this restriction even more clearly.)

The mentioned two examples of apparent non-locality can be dismissed with the remark that since obviously no energy flux faster than light is involved, no problems with causality appear. Therefore the following example is more interesting. Take two identical

* David Joseph Bohm (1917–1992) American–British physicist. He codiscovered the Aharonov–Bohm effect; he spent a large part of his later life investigating the connections between quantum physics and philosophy.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

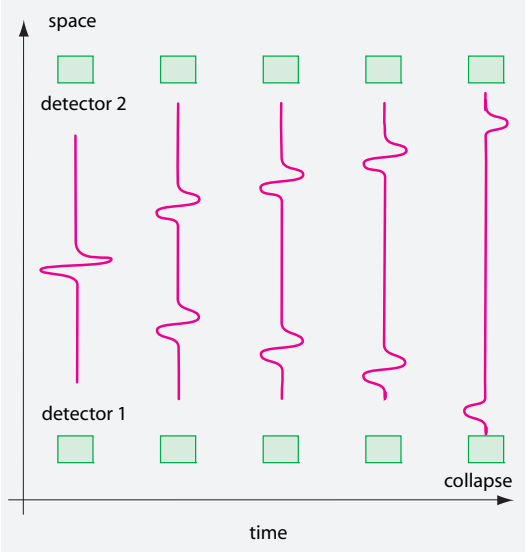

FIGURE 485 Bohm's Gedanken experiment

atoms, one in an excited state, one in the ground state, and call l the distance that separates them. Common sense tells that if the first atom returns to its ground state emitting a photon, the second atom can be excited only after a time $t = l/c$ has been elapsed, i.e., after the photon has travelled to the second atom.

Surprisingly, this conclusion is wrong. The atom in its ground state has a non-zero probability to be excited at the same moment in which the first is de-excited. This has been shown most simply by Gerhard Hegerfeldt. The result has even been confirmed experimentally.

Ref. 909

More careful studies show that the result depends on the type of superposition of the two atoms at the beginning: coherent or incoherent. For incoherent superpositions, the intuitive result is correct; the counter-intuitive result appears only for coherent superpositions. Again, a careful discussion shows that no real non-locality of energy is involved.

In summary, faster-than-light speeds in wave function collapse do not contradict the limit on energy speed of special relativity. Collapse speeds are phase velocities. In nature, phase velocities are unlimited; unlimited phase velocities never imply energy transport faster than light.

Curiosities and fun challenges about superpositions

Challenge 1449 s Can a photograph show an object at two different places at the same time?

* *

In a few cases, the superposition of different macroscopic states can actually be observed by lowering the temperature to sufficiently small values and by carefully choosing suitably small masses or distances. Two well-known examples of coherent superpositions are those observed in gravitational wave detectors and in Josephson junctions. In the first case, one observes a mass as heavy as 1000 kg in a superposition of states located

Ref. 899

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

at different points in space: the distance between them is of the order of 10^{-17} m. In the second case, in superconducting rings, superpositions of a state in which a macroscopic current of the order of 1 pA flows in clockwise direction with one where it flows in counter-clockwise direction have been produced.

Ref. 917

* *

Ref. 911 Superpositions of magnetization in up and down direction at the same time have also be observed for several materials.

* *

Some people wrongly state that an atom that is in a superposition of states centred at different positions has been photographed. (This lie is even used by some sects to attract believers.) Why is this not true?

Challenge 1450 s

* *

Since the 1990s, the sport of finding and playing with new systems in coherent macroscopic superpositions has taken off across the world. The challenges lie in the clean experiments necessary. Experiments with single atoms in superpositions of states are among the most popular ones.

Ref. 913

Ref. 914

* *

Ref. 915 In 1997, coherent atom waves were extracted from a cloud of sodium atoms.

* *

Macroscopic objects usually are in incoherent states. This is the same situation as for light. The world is full of 'macroscopic', i.e., incoherent light: daylight, and all light from lamps, from fire and from glow-worms is incoherent. Only very special and carefully constructed sources, such as lasers or small point sources, emit coherent light. Only these sources allow to study interference effects. In fact, the terms 'coherent' and 'incoherent' originated in optics, since for light the difference between the two, namely the capacity to interfere, had been observed centuries before the case of matter.

Coherence and incoherence of light and of matter manifest themselves differently, because matter can stay at rest but light cannot and because matter is made of fermions, but light is made of bosons. Coherence can be observed easily in systems composed of bosons, such as light, sound in solids, or electron pairs in superconductors. Coherence is less easily observed in systems of fermions, such as systems of atoms with their electron clouds. However, in both cases a decoherence time can be defined. In both cases coherence in many particle systems is best observed if all particles are in the same state (superconductivity, laser light) and in both cases the transition from coherent to incoherent is due to the interaction with a bath. A beam is thus incoherent if its particles arrive randomly in time and in frequency. In everyday life, the rarity of observation of coherent matter superpositions has the same origin as the rarity of observation of coherent light.

Page 1071

* *

We will discuss the relation between the environment and the *decay* of unstable systems later on. The phenomenon is completely described by the concepts given here.

Some people say that quantum theory could be used for quantum computing, by using coherent superpositions of wave functions. Can you give a general reason that makes this aim very difficult –even though not impossible – even without knowing how such a quantum computer might work, or what the so-called *qubits* might be?
Ref. 919
Challenge 1455 s

WHAT IS ALL THE FUSS ABOUT MEASUREMENTS IN QUANTUM THEORY?

Measurements in quantum mechanics are disturbing. They lead to statements in which *probabilities* appear. For example, we speak about the probability of finding an electron at a certain distance from the nucleus of an atom. Statements like this belong to the general type 'when the observable A is measured, the probability to find the outcome a is p.' In the following we will show that the probabilities in such statements are inevitable for any measurement, because, as we will show, any measurement and any observation is a special case of decoherence or disentanglement process. (Historically, the process of measurement was studied *before* the more general process of decoherence. That explains in part why the topic is so confused in many peoples' minds.)

Page 812 What is a measurement? As already mentioned earlier on, a measurement is any interaction which produces a record or a memory. (Any effect of everyday life is a record; but this is not true in general. Can you give some examples of effects that are records and some effects which are not?) Measurements can be performed by machines; when they are performed by people, they are called *observations*. In quantum theory, the process of measurement is not as straightforward as in classical physics. This is seen most strikingly when a quantum system, such as a single electron, is first made to pass a diffraction slit, or better – in order to make its wave aspect become apparent – a double slit and then is made to hit a photographic plate, in order to make also its particle aspect appear. Experiment shows that the blackened dot, the spot where the electron has hit the screen, cannot be determined in advance. (The same is true for photons or any other particle.) However, for large numbers of electrons, the spatial distribution of the black dots, the
Challenge 1456 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

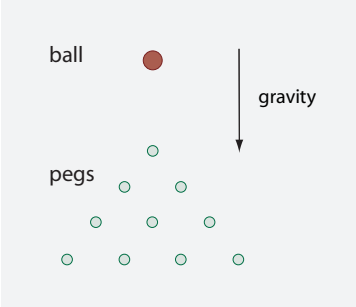

FIGURE 486 A system showing probabilistic behaviour

so-called *diffraction pattern*, can be calculated in advance with high precision.

The outcome of experiments on microscopic systems thus forces us to use probabilities for the description of microsystems. We find that the probability distribution $p(\boldsymbol{x})$ of the spots on the photographic plate can be calculated from the wave function ψ of the electron at the screen surface and is given by $p(\boldsymbol{x}) = |\psi^\dagger(\boldsymbol{x})\psi(\boldsymbol{x})|^2$. This is in fact a special case of the general *first property of quantum measurements*: the measurement of an observable A for a system in a state ψ gives as result one of the eigenvalues a_n, and the probability P_n to get the result a_n is given by

$$P_n = |\varphi_n^\dagger \psi|^2 \,, \tag{672}$$

Page 889 where φ_n is the eigenfunction of the operator A corresponding to the eigenvalue a_n. This experimental result requires an explanation.

Experiments also show a *second property of quantum measurements:* after the measurement, the observed quantum system is in the state φ_n corresponding to the measured eigenvalue a_n. One also says that during the measurement, the wave function has *collapsed* from ψ to φ_n. By the way, these experimental results can also be generalized to the more general cases with degenerate and continuous eigenvalues.

Ref. 916

At first sight, the sort of probabilities encountered in quantum theory are different from the probabilities we encounter in everyday life. Take roulette, dice, pachinko machines or the direction in which a pencil on its tip falls: all have been measured experimentally to be random (assuming no cheating by the designer or operators) to a high degree of accuracy. These everyday systems do not puzzle us. We unconsciously assume that the random outcome is due to the small, but uncontrollable variations of the starting conditions or the environment every time the experiment is repeated.*

But microscopic systems seem to be different. The two properties of quantum measurements just mentioned express what physicists observe in every experiment, even if the initial conditions are taken to be *exactly* the same every time. But why then is the position for a single electron, or most other observables of quantum systems, not predictable? In other words, what happens during the collapse of the wave function? How

* To get a feeling for the limitations of these unconscious assumptions, you may want to read the already mentioned story of those physicists who built a machine that could predict the outcome of a roulette ball from the initial velocity imparted by the croupier.

long does it take? In the beginning of quantum theory, there was the perception that the observed unpredictability is due to the lack of information about the state of the particle. This lead many to search for so-called 'hidden variables'. All these attempts were doomed to fail, however. It took some time for the scientific community to realize that the unpredictability is *not* due to the lack of information about the state of the particle, which is indeed described *completely* by the state vector ψ.

In order to uncover the origin of probabilities, let us recall the nature of a measurement, or better, of a general observation. *Any observation is the production of a record.* The record can be a visual or auditive memory in our brain, or a written record on paper, Page 811 or a tape recording, or any such type of object. As explained in a previous chapter, an object is a record if it cannot have arisen or disappeared by chance. To avoid the influence of chance, all records have to be protected as much as possible from the *external* world; e.g. one typically puts archives in earthquake safe buildings with fire protection, keeps documents in a safe, avoids brain injury as much as possible, etc.

On top of this, records have to be protected from their *internal* fluctuations. These internal fluctuations are due to the many components any recording device is made of. If the fluctuations were too large, they would make it impossible to distinguish between the possible contents of a memory. Now, fluctuations decrease with increasing size of a system, typically with the square root of the size. For example, if a hand writing is too small, it is difficult to read if the paper gets brittle; if the magnetic tracks on tapes are too small, they demagnetize and lose the stored information. In other words, a record is rendered stable against internal fluctuations by making it of sufficient size. Every record thus consists of many components and shows small fluctuations.

The importance of size can be expressed in another way: every system with memory, i.e., every system capable of producing a record, contains a *bath*. In summary, the statement that any observation is the production of a record can be expressed more precisely as: *Any observation of a system is the result of an interaction between that system and a bath in the recording apparatus.**

In addition, any observation measuring a physical quantity uses an interaction *depending* on that same quantity. With these seemingly trivial remarks, we can describe in more detail the process of observation, or, as it is usually called in the quantum theory, the measurement process.

Any measurement apparatus, or *detector*, is characterized by two main aspects, shown in Figure 487: the interaction it has with the microscopic system, and the bath it contains Ref. 912 to produce the record. Any description of the measurement process thus is the description of the evolution of the microscopic system *and* the detector; therefore one needs the Hamiltonian for the particle, the interaction Hamiltonian, and the bath properties (such as the relaxation time t_r). The interaction specifies what is measured and the bath realizes the memory.

We know that only classical thermodynamic systems can be irreversible; quantum systems are not. We therefore conclude: a measurement system *must* be described classically: otherwise it would have no memory and would not be a measurement system: it would not produce a record! Memory is a classical effect. (More precisely, memory is an effect that only appears in the classical limit.) Nevertheless, let us see what happens if we

* Since baths imply friction, we can also say: memory needs friction.

describes its possible states
is determined by the type of measurement
describes its friction, e.g. due to heat flow

FIGURE 487 The concepts used in the description of measurements

describe the measurement system quantum mechanically.

Let us call A the observable which is measured in the experiment and its eigenfunctions φ_n. We describe the quantum mechanical system under observation – often a particle – by a state ψ. The full state of the system can always be written as

$$\psi = \psi_p \, \psi_{\text{other}} = \sum_n c_n \varphi_n \, \psi_{\text{other}} \,. \tag{673}$$

Here, ψ_p is the aspect of the (particle or system) state that we want to measure, and ψ_{other} represents all other degrees of freedom, i.e., those not described – *spanned*, in mathematical language – by the operator A corresponding to the observable we want to measure. The numbers $c_n = |\varphi_n^\dagger \psi_p|$ give the expansion of the state ψ_p, which is taken to be normalized, in terms of the basis φ_n. For example, in a typical position measurement, the functions φ_n would be the position eigenfunctions and ψ_{other} would contain the information about the momentum, the spin and all other properties of the particle.

How does the system–detector interaction look like? Let us call the state of the apparatus before the measurement χ_{start}. The measurement apparatus itself, by definition, is a device which, when it is hit by a particle in the state $\varphi_n \psi_{\text{other}}$, changes from the state χ_{start} to the state χ_n. One then says that the apparatus has *measured* the eigenvalue a_n corresponding to the eigenfunction φ_n of the operator A. The index n is thus the record of the measurement; it is called the *pointer* index or variable. This index tells us in which state the microscopic system was before the interaction. The important point, taken from our previous discussion, is that the states χ_n, being records, are macroscopically distinct, precisely in the sense of the previous section. Otherwise they would not be records, and the interaction with the detector would not be a measurement.

Of course, during measurement, the apparatus sensitive to φ_n changes the part ψ_{other} of the particle state to some other situation $\psi_{\text{other},n}$, which depends on the measurement and on the apparatus; we do not need to specify it in the following discussion.* But let

* How does the interaction look like mathematically? From the description we just gave, we specified the final state for every initial state. Since the two density matrices are related by

$$\rho_{\text{f}} = T \rho_{\text{i}} T^\dagger \tag{674}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

us have an intermediate check of our reasoning. Do apparatuses as described here exist? Yes, they do. For example, any photographic plate is a detector for the position of ionizing particles. A plate, and in general any apparatus measuring position, does this by changing its momentum in a way depending on the measured position: the electron on a photographic plate is stopped. In this case, χ_{start} is a white plate, φ_n would be a particle localized at spot n, χ_n is the function describing a plate blackened at spot n and $\psi_{\text{other,n}}$ describes the momentum and spin of the particle after it has hit the photographic plate at the spot n.

Now we are ready to look at the measurement process itself. For the moment, let us disregard the bath in the detector, and let us just describe it with a state as well, which we call χ_{start}. In the time before the interaction between the particle and the detector, the combined system (including the detector) was in the initial state ψ_i given simply by

$$\psi_i = \psi_p \chi_{\text{start}} = \sum_n c_n \varphi_n \psi_{\text{other}} \chi_{\text{start}} \,, \tag{676}$$

where ψ_p is the (particle or system) state. After the interaction, using the just mentioned, experimentally known characteristics of the apparatus, the combined state ψ_a is

$$\psi_a = \sum_n c_n \varphi_n \psi_{\text{other},n} \chi_n \,. \tag{677}$$

This evolution from ψ_i to ψ_a follows from the evolution equation applied to the particle–detector combination. Now, the combined state ψ_a is a superposition of macroscopically distinct states: it is a superposition of distinct macroscopic states of the detector. In our example ψ_a could correspond to a superposition of one state where a spot on the left upper corner is blackened on an otherwise white plate with another state where a spot on the right lower corner of the otherwise white plate is blackened. Such a situation is never observed. Let us see why.

The density matrix ρ_a of the combined state ψ_a after the measurement, given by

$$\rho_a = \psi_a \otimes \psi_a^\dagger = \sum_{n,m} c_n c_m^* (\varphi_n \psi_{\text{other},n} \chi_n) \otimes (\varphi_m \psi_{\text{other},m} \chi_m)^\dagger \,, \tag{678}$$

contains large non-diagonal terms, i.e., terms for $n \neq m$, whose numerical coefficients are different from zero. Now let us take the bath back in. From the previous section we know the effect of a bath on such a macroscopic superposition. We found that a density matrix such as ρ_a decoheres extremely rapidly. We assume here that the decoherence time is negligibly small, in practice thus instantaneous,* so that the off-diagonal terms

Challenge 1457 ny

we can deduce the Hamiltonian from the matrix T. Are you able to see how?

By the way, one can say in general that an apparatus measuring an observable A has a system interaction Hamiltonian depending on the pointer variable A, and for which one has

$$[H + H_{\text{int}}, A] = 0 \,. \tag{675}$$

* Note however, that an *exactly* vanishing decoherence time, which would mean a *strictly* infinite number of degrees of freedom of the environment, is in contradiction with the evolution equation, and in particu-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

vanish, and only the final, diagonal density matrix ρ_f, given by

$$\rho_f = \sum_n |c_n|^2 (\varphi_n \psi_{\text{other},n} \chi_n) \otimes (\varphi_n \psi_{\text{other},n} \chi_n)^\dagger \tag{679}$$

has experimental relevance. As explained above, such a density matrix describes a mixed state and the numbers $P_n = |c_n|^2 = |\varphi_n^\dagger \psi_p|^2$ give the probability of measuring the value a_n and of finding the particle in the state $\varphi_n \psi_{\text{other,n}}$ as well as the detector in the state χ_n. But this is precisely what the two properties of quantum measurements state.

We therefore find that describing a measurement as an evolution of a quantum system interacting with a macroscopic detector, itself containing a bath, we can *deduce* the two properties of quantum measurements, and thus the collapse of the wave function, from the quantum mechanical evolution equation. The decoherence time t_d of the previous section becomes the time of collapse in the case of a measurement; in addition we find

$$t_{\text{collapse}} = t_d < t_r \,. \tag{680}$$

In other words, the collapse tie is always smaller than the relaxation time of the bath. We thus have a formula for the time the wave function takes to collapse. The first experimen-
Ref. 918 tal measurements of the time of collapse have appeared and confirmed this result.

Hidden variables

A large number of people are not satisfied with the arguments just presented. They long for more mystery in quantum theory. They do not like the idea that probabilities are due to baths. The most famous prejudice they cultivate is the idea that the probabilities are due to some hidden aspect of nature which is still unknown to humans. These imagined, unknown aspects are called *hidden variables*.

The beautiful thing about quantum mechanics is that it allows both conceptual and experimental tests on whether such hidden variables exist without the need of knowing them. Hidden variables controlling the evolution of microscopic system would contradict the result that action values below $\hbar/2$ cannot be detected. This minimum observable action is the reason for the random behaviour of microscopic systems. A minimal action thus excludes hidden variables.

Historically, the first argument against hidden variables was given by John von Neumann.*

– CS – to be written – CS –

lar with unitarity, locality and causality. It is essential in the whole argument not to confuse the logical consequences of a extremely small decoherence time with those of an exactly vanishing decoherence time.

* János von Neumann (b. 1903 Budapest, d. 1957 Washington DC) Hungarian mathematician. One of the greatest and clearest minds of the twentieth century, he settled already many questions, especially in applied mathematics and quantum theory, that others still struggle with today. He worked on the atomic and the hydrogen bomb, on ballistic missiles, and on general defence problems. In another famous project, he build the first US-American computer, building on his extension of the ideas of Konrad Zuse.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

An additional no-go theorem for hidden variables was published by Kochen and Specker in 1967, (and independently by Bell in 1969). It states that non-contextual hidden variables are impossible, if the Hilbert space has a dimension equal or larger than three. The theorem is about non-contextual variables, i.e., about hidden variables *inside* the quantum mechanical system. The Kochen–Specker theorem thus states that there is no non-contextual hidden variables model, because mathematics forbids it. This result essentially eliminates all possibilities, because usual quantum mechanical systems have Hilbert space dimensions much larger than three.

Ref. 920

Of course, one cannot avoid noting that about *contextual* hidden variables, i.e., variables in the environment, there are no restricting theorems; indeed, their necessity was shown earlier in this section.

But also common sense eliminates hidden variables, without any recourse to mathematics, with an argument often overlooked. If a quantum mechanical system had internal hidden variables, the measurement apparatus would have zillions of them.* And that would mean that it could not work as a measurement system.

Despite all these results, people have also looked for experimental tests on hidden variables. Most tests are based on the famed *Bell's equation*, a beautifully simple relation published by John Bell** in the 1960s.

The starting idea is to distinguish quantum theory and locally realistic theories using hidden variables by measuring the polarizations of two correlated photons. Quantum theory says that the polarization of the photons is fixed only at the time it is measured, whereas local realistic theories say that it is fixed already in advance. Experiment can be used to decide which approach is correct.

Imagine the polarization is measured at two distant points A and B, each observer can measure 1 or −1 in each of his favourite direction. Let each observer choose two directions, 1 and 2, and call their results a_1, a_2, b_1 and b_2. Since the measurement results all are either 1 or −1, the value of the specific expression $(a_1 + a_2)b_1 + (a_2 - a_1)b_2$ has always the value ±2.

Ref. 921

Imagine you repeat the experiment many times, assuming that the hidden variables appear statistically. You then can deduce (a special case of) Bell's inequality for two hidden variables; it predicts that

Challenge 1458 e

$$|(a_1 b_1) + (a_2 b_1) + (a_2 b_2) - (a_1 b_2)| \leqslant 2 \,. \tag{681}$$

Here, the expressions in brackets are the averages of the measurement products over a large number of samples. This result holds independently of the directions of the involved polarizers.

On the other hand, for the case that the polarizers 1 and 2 at position A and the corresponding ones at position B are chosen with angles of $\pi/4$, quantum theory predicts that

$$|(a_1 b_1) + (a_2 b_1) + (a_2 b_2) - (a_1 b_2)| = 2\sqrt{2} > 2 \,. \tag{682}$$

* Which leads to the definition: one zillion is 10^{23}.

** John Stewart Bell (1928–1990), theoretical physicist who worked mainly on the foundations of quantum theory.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This prediction is in complete contradiction with the hidden variable result.

All experimental checks of Bell's equation have confirmed standard quantum mechanics. No evidence for hidden variables has ever been found. This is not really surprising, since the search for such variables is based on a misunderstanding of quantum mechanics or on personal desires on how the world should be, instead of relying on experimental evidence.

Another measurable contradiction between quantum theory and locally realistic theories has been predicted by Greenberger, Horn and Zeilinger. Experiments trying to check the result are being planned. Again, no deviation from quantum theory is expected.

Summary on probabilities and determinism

> Geometric demonstramus quia facimus; si physics demonstrare possemus, faceremus.
> Giambattista Vico*

From the arguments presented here we draw a number of conclusions which we need for the rest of our mountain ascent. Note that these conclusions are not yet shared by all physicists! The whole topic is still touchy.

— Probabilities do not appear in measurements because the state of the quantum system is unknown or fuzzy, but because the detailed state of the bath in the environment is unknown. *Quantum mechanical probabilities are of statistical origin and are due to baths in the environment (or in the measurement apparatus).* The probabilities are due to the large number of degrees of freedom contained in any bath. These large numbers make the outcome of experiments unpredictable. If the state of the bath were known, the outcome of an experiment could be predicted. The probabilities of quantum theory are 'thermodynamic' in origin.

  In other words, there are *no* fundamental probabilities in nature. All probabilities in nature are due to decoherence; in particular, all probabilities are due to the statistics of the many particles – some of which may be virtual – that are part of the baths in the environment. Modifying well-known words by Albert Einstein, 'nature really does not play dice.' We therefore called ψ the *wave function* instead of 'probability amplitude', as is often done. An even better name would be *state function*.

— Any observation in everyday life is a special case of decoherence. What is usually called the 'collapse of the wave function' is a decoherence process due to the interaction with the baths present in the environment or in the measuring apparatus. Because humans are warm-blooded and have memory, humans themselves are thus measurement apparatuses. The fact that our body temperature is 37 °C is thus the reason that we see only a single world, and no superpositions. (Actually, there are many additional reasons; can you name a few?) Challenge 1459 s

— A measurement is complete when the microscopic system has interacted with the bath in the measuring apparatus. Quantum theory as a description of nature does not

* 'We are able to demonstrate geometrical matters because we make them; if we could prove physical matters we would be able to make them.' Giovanni Battista Vico (b. 1668 Napoli, d. 1744 Napoli) important Italian philosopher and thinker. In this famous statement he points out a fundamental distinction between mathematics and physics.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

require detectors; the evolution equation describes all examples of motion. However, *measurements* do require the existence of detectors. Detectors, being machines that record observations, have to include a bath, i.e., have to be classical, macroscopic objects. In this context one speaks also of a *classical apparatus*. This necessity of the measurement apparatus to be classical had been already stressed in the very early stages of quantum theory.

— All measurements, being decoherence processes that involve interactions with baths, are irreversible processes and increase entropy.

— A measurement is a special case of quantum mechanical evolution, namely the evolution for the combination of a quantum system, a macroscopic detector and the environment. Since the evolution equation is relativistically invariant, no causality problems appear in measurements; neither do locality problems and logical problems appear.

— Since both the evolution equation and the measurement process does not involve quantities other than space-time, Hamiltonians, baths and wave-functions, no other quantity plays a role in measurement. In particular, no human observer nor any consciousness are involved or necessary. Every measurement is complete when the microscopic system has interacted with the bath in the apparatus. The decoherence inherent in every measurement takes place even if nobody is looking. This trivial consequence is in agreement with the observations of everyday life, for example with the fact that the Moon is orbiting the Earth even if nobody looks at it.* Similarly, a tree falling in the middle of a forest makes noise even if nobody listens. Decoherence is independent of human observation, of the human mind and of human existence.

— In every measurement the quantum system interacts with the detector. Since there is a minimum value for the magnitude of action, every *observation influences the observed*. Therefore every measurement *disturbs* the quantum system. Any precise description of observations must also include the description of this disturbance. In the present section the disturbance was modelled by the change of the state of the system from ψ_{other} to $\psi_{\text{other,n}}$. Without such a change of state, without a disturbance of the quantum system, a measurement is impossible.

— Since the complete measurement is described by quantum mechanics, unitarity is and remains the basic property of evolution. There are no non-unitary processes in quantum mechanics.

— The description of the collapse of the wave function as a decoherence process is an explanation exactly in the sense in which the term 'explanation' was defined earlier on; it describes the relation between an observation and all the other aspects of reality, in this case the bath in the detector or the environment. The collapse of the wave function has been both calculated and *explained*. The collapse is not a question of 'interpretation', i.e., of opinion, as unfortunately often is suggested.**

Page 866

— It is not useful to speculate whether the evolution for a *single* quantum measurement could be determined if the state of the environment around the system were known.

* The opposite view is sometimes falsely attributed to Niels Bohr. The Moon is obviously in contact with many radiation baths. Can you list a few?

Challenge 1460 s

** This implies that the so-called 'many worlds' interpretation is wishful thinking. The conclusion is confirmed when studying the details of this religious approach. It is a belief system, not based on facts.

Ref. 922

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

> Measurements need baths. But a bath, being irreversible, cannot be described by a wave function, which behaves reversibly.* Quantum mechanics is deterministic. Baths are probabilistic.

In summary, there is *no* irrationality in quantum theory. Whoever uses quantum theory as argument for superstitions, irrational behaviour, new age beliefs or ideologies is guilty of disinformation. The statement by Gell-Mann at the beginning of this chapter is thus such an example. Another is the following well-known, but incorrect statement by Richard Feynman:

Ref. 923

> ... nobody understands quantum mechanics.

Nobel Prizes obviously do not prevent views distorted by ideology.

The process of decoherence allows understanding many other issues. We explore a few interesting ones.

What is the difference between space and time?

Space and time differ. Objects are localized in space but not in time. Why is this the case? In nature, most bath–system interactions are mediated by a potential. All potentials are by definition position dependent. Therefore, every potential, being a function of the position $\boldsymbol{x}$, commutes with the position observable (and thus with the interaction Hamiltonian). The decoherence induced by baths – except if special care is taken – thus first of all destroys the non-diagonal elements for every superposition of states centred at different locations. In short, *objects are localized because they interact with baths via potentials.*

For the same reason, objects also have only one spatial orientation at a time. If the system–bath interaction is spin-dependent, the bath leads to 'localization' in the spin variable. This occurs for all microscopic systems interacting with magnets. As a result, macroscopic superpositions of magnetization are almost never observed. Since electrons, protons and neutrons have a magnetic moment and a spin, this conclusion can even be extended: everyday objects are never seen in superpositions of different rotation states because their interactions with baths are spin-dependent.

As a counter-example, most systems are not localized in time, but on the contrary exist for very long times, because practically all system–bath interactions do *not* commute with time. In fact, this is the way a bath is defined to begin with. In short, *objects are permanent because they interact with baths.*

Challenge 1461 s

Are you able to find an interaction which is momentum-dependent instead of position-dependent? What is the consequence for macroscopic systems?

In other words, in contrast to general relativity, quantum theory produces a distinction between space and time. In fact, we can *define* position as the observable that commutes with interaction Hamiltonians. This distinction between space and time is due to the properties of matter and its interactions. We could not have deduced this distinction

* This very strong type of determinism will be very much challenged in the last part of this text, in which it will be shown that time is not a fundamental concept, and therefore that the debate around determinism looses most of its interest.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

in general relativity.

Are we good observers?

Are humans classical apparatuses? Yes, they are. Even though several prominent physicists claim that free will and probabilities are related, a detailed investigation shows that this in not the case. Our senses are classical machines in the sense described above: they record observations by interaction with a bath. Our brain is also a classical apparatus: the neurons are embedded in baths. Quantum probabilities do not play a determining role in the brain.

Ref. 924

Any observing entity needs a bath and a memory to record its observations. This means that observers have to be made of matter; an observer cannot be made of radiation. Our description of nature is thus severely biased: we describe it from the standpoint of matter. That is a bit like describing the stars by putting the Earth at the centre of the universe. Can we eliminate this basic anthropomorphism? We will find out as we continue.

Page 1416

What connects information theory, cryptology and quantum theory?

Physics means talking about observations of nature. Like any observation, also measurements produce information. It is thus possible to translate much (but not all) of quantum theory into the language of information theory. In particular, the existence of a minimal change in nature implies that the information about a physical system can never be complete, that information transport has its limits and that information can never be fully trusted. The details of these studies form a fascinating way to look at the microscopic world.

The analogy between quantum theory and information theory becomes even more interesting when the statements are translated into the language of cryptology. Cryptology is the science of transmitting hidden messages that only the intended receiver can decrypt. In our modern times of constant surveillance, cryptology is an important tool to protect personal freedom.*

Ref. 925

The quantum of action implies that messages can be sent in an (almost) safe way. Listening to a message is a measurement process. Since there is a smallest action, one can detect whether somebody has tried to listen to a sent message. A man in the middle attack – somebody who pretends to be the receiver and then sends a copy of the message to the real, intended receiver – can be avoided by using *entangled* systems as signals to transmit the information. Quantum cryptologists therefore usually use communication systems based on entangled photons.

The major issue of quantum cryptology is the key distribution problem. All secure communication is based on a secret key that is used to decrypt the message. Even if the communication channel is of the highest security – like entangled photons – one still has

* Cryptology consists of the field of *cryptography*, the art of coding messages, and the field of *cryptoanalysis*, the art of deciphering encrypted messages. For a good introduction to cryptology, see the text by Albrecht Beutelspacher, Jörg Schwenk & Klaus-Dieter Wolfenstätter, *Moderne Verfahren der Kryptographie*, Vieweg 1995.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to find a way to send the communication partner the secret key necessary for the decryption of the messages. Finding such methods is the main aspect of quantum cryptology, a large research field. However, close investigation shows that all key exchange methods are limited in their security.

In short, due to the quantum of action, nature provides limits on the possibility of sending encrypted messages. The statement of these limits is (almost) equivalent to the statement that change in nature is limited by the quantum of action.

Is the universe a computer?

The quantum of action provides a limit to secure information exchange. This connection also allows to brush aside several incorrect statements often found in the media. Stating that 'the universe is information' or that 'the universe is a computer' is as unreasonable as saying that the universe is an observation, a measurement apparatus, a clockwork or a chewing-gum dispenser. Any expert of motion should beware of these and similarly fishy statements; people who use them either deceive themselves or try to deceive others.

Page 1441

Does the universe have a wave function? And initial conditions?

The wave function of the universe is frequently invoked in discussions about quantum theory. Many deduce conclusions from this idea, for example on the irreversibility of time, on the importance of initial conditions, on changes required to quantum theory and much more. Are these arguments correct?

The first thing to clarify is the meaning of 'universe'. As explained above, the term can have two meanings: either the collection of all matter and radiation, or this collection *plus* all of space-time. Let us also recall the meaning of 'wave function': it describes the *state* of a system. The state distinguishes two otherwise identical systems; for example, position and velocity distinguish two otherwise identical ivory balls on a billiard table. Alternatively and equivalently, the state describes changes in time.

Page 571

Does the universe have a state? If we take the wider meaning of universe, it does not. Talking about the state of the universe is a contradiction: by definition, the concept of state, defined as the non-permanent aspects of an object, is applicable only to *parts* of the universe.

Page 34

We then can take the narrower sense of 'universe' – the sum of all matter and radiation only – and ask the question again. To determine the state of all matter and radiation, we need a possibility to measure it: we need an environment. But the environment of matter and radiation is space-time only; initial conditions cannot be determined since we need measurements to do this, and thus an apparatus. An apparatus is a material system with a bath attached to it; however, there is no such system outside the universe.

In short, quantum theory does not allow for measurements of the universe; therefore the universe has no state. Beware of anybody who claims to know something about the wave function of the universe. Just ask him: If you know the wave function of the universe, why aren't you rich?

Despite this conclusion, several famous physicists have proposed evolution equations for the wave function of the universe. (The best-known is the Wheeler–DeWitt equation.) It seems a silly point, but the predictions of these equations have not been compared to experiments; the arguments just given even make this impossible in principle. Exploring

Ref. 926

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

this direction, so interesting it may seem, must therefore be avoided if we want to reach the top of Motion Mountain.

There are many additional twists to this story. One twist is that space-time itself, even without matter, might be a bath. This speculation will be shown to be correct later on; this result seems to allow speaking of the wave function of all matter. But then again, it turns out that time is *undefined* at the scales where space-time is an effective bath; this implies that the concept of state is not applicable there.

A lack of 'state' for the universe is a strong statement. It also implies a lack of initial conditions! The arguments are precisely the same. This is a tough result. We are so used to think that the universe has initial conditions that we never question the term. (Even in this text the mistake might appear every now and then.) But there are no initial conditions of the universe.

We can retain as summary, valid even in the light of the latest research: the universe has *no* wave function and *no* initial conditions, independently of what is meant by 'universe'.

BIBLIOGRAPHY

805 Giuseppe Fumagalli, *Chi l'ha detto?*, Hoepli, Milano, 1983. Cited on page 976.

806 The quantum of action was introduced in Max Planck, Über irreversible Strahlungsvorgänge, *Sitzungsberichte der Preußischen Akademie der Wissenschaften, Berlin* pp. 440–480, 1899. In the paper, Planck used the letter *b* for what nowadays is called *h*. Cited on page 977.

807 Bohr explained the indivisibilty of the quantum of action in his famous Como lecture. N. Bohr, *Atomtheorie und Naturbeschreibung*, Springer, 1931. On page 16 he writes: 'No more is it likely that the fundamental concepts of the classical theories will ever become superfluous for the description of physical experience. The recognition of the indivisibility of the quantum of action, and the determination of its magnitude, not only depend on an analysis of measurements based on classical concepts, but it continues to be the application of these concepts alone that makes it possible to relate the symbolism of the quantum theory to the data of experience.' He also writes: '...the fundamental postulate of the indivisibility of the quantum of action is itself, from the classical point of view, an irrational element which inevitably requires us to forgo a causal mode of description and which, because of the coupling between phenomena and their observation, forces us to adopt a new mode of description designated as complementary in the sense that any given application of classical concepts precludes the simultaneous use of other classical concepts which in a different connection are equally necessary for the elucidation of the phenomena ...' and '...the finite magnitude of the quantum of action prevents altogether a sharp distinction being made between a phenomenon and the agency by which it is observed, a distinction which underlies the customary concept of observation and, therefore, forms the basis of the classical ideas of motion.' Other statements about the indivisibility of the quantum of action can be found in N. Bohr, *Atomic Physics and Human Knowledge*, Science Editions, 1961. See also Max Jammer, *The Philosophy of Quantum Mechanics*, Wiley, first edition, 1974, pp. 90–91. Cited on page 977.

808 For some of the rare modern publications emphasizing the quantum of action see M. B. Mensky, The action uncertainty principle and quantum gravity, *Physics Letters A* **162**, p. 219, 1992, and M. B. Mensky, The action uncertainty principle in continuous quantum measurements, *Physics Letters A* **155**, pp. 229–235, 1991.

Schwinger's quantum-action principle is also used in Richard F. W. Bader, *Atoms in Molecules – A Quantum Theory*, Oxford University Press, 1994.

There are a large number of general textbooks on quantum theory. There is one for every taste.

A well-known *conceptual* introduction is Jean-Marc Lévy-Leblond & FranÁoise Balibar, *Quantique – Rudiments*, Masson, 1997, translated into English as *Quantics*, North-Holland, 1990.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

One of the most beautiful books is Julian Schwinger, *Quantum Mechanics – Symbolism of Atomic Measurements*, edited by Berthold-Georg Englert, Springer Verlag, 2001.

A modern approach with a beautiful introduction is Max Schubert & Gerhard Weber, *Quantentheorie – Grundlagen und Anwendungen*, Spektrum Akademischer Verlag, 1993.

A standard beginner's text is C. Cohen-Tannoudji, B. Diu & F. Laloë, *Mécanique quantique I et II*, Hermann, Paris, 1977. It is also available in several translations.

A good text is Asher Peres, *Quantum Theory – Concepts and Methods*, Kluwer, 1995.

For a lively approach, see Vincent Icke, *The Force of Symmetry*, Cambridge University Press, 1994.

New textbooks are published regularly around the world. Cited on page 1030.

809 Max Born, Zur Quantenmechanik der Stoßvorgänge (vorläufige Mitteilung), *Zeitschrift für Physik* **37**, pp. 863–867, 1926, Max Born, Quantenmechanik der Stoßvorgänge, *Zeitschrift für Physik* **38**, pp. 803–827, 1926. Cited on page 981.

810 See for example the papers by Jan Hilgevoord, The uncertainty principle for energy and time, *American Journal of Physics* **64**, pp. 1451–1456, 1996, and by Paul Busch, On the time–energy uncertainty reaction, parts 1 & 2, *Foundations of Physics* **20**, pp. 1–43, 1990. A classic is the paper by Eugene P. Wigner, On the time–energy uncertainty relation, in Abdus Salam & Eugene P. Wigner, editors, *Aspects of Quantum Theory*, Cambridge University Press, 1972. Cited on page 984.

811 See also the booklet by Claus Mattheck, *Warum alles kaputt geht – Form und Versagen in Natur und Technik*, Forschungszentrum Karlsruhe, 2003. Cited on page 987.

CHALLENGE HINTS AND SOLUTIONS

Challenge 1330, page 976: Classical physics fails in explaining any material property, such as colour or softness. Material properties result from nature's interactions; they are inevitably quantum. Explanations always require particles and their quantum properties.

Challenge 1331, page 977: Classical physics allows any observable to change *smoothly* with time. There is no minimum value for any observable physical quantity.

Challenge 1332, page 979: The higher the mass, the smaller the motion fuzziness induced by the quantum of action, because action is mass times speed times distance: For a large mass, the speed and distance variations are small.

Challenge 1333, page 979: The simplest time is $\sqrt{2G\hbar/c^5}$. The factor 2 is obviously not fixed; it is explained later on. Including it, this time is the shortest time measurable in nature.

Challenge 1334, page 980: The electron charge is special to the electromagnetic interactions; it does not take into account the nuclear interactions or gravity. It is unclear why the length defined with the elementary charge e should be of importance for neutral systems or for the vacuum. On the other hand, the quantum of action $\hbar$ is valid for all interactions and observations. However, one can also argue that the two options to define a fundamental length are not too different, as the electron charge is related to the quantum of action by $e = \sqrt{4\pi\varepsilon_0 \alpha c\hbar}$.

Challenge 1336, page 980: On purely dimensional grounds, the radius of an atom must be

$$r \approx \frac{\hbar^2 4\pi\varepsilon_0}{me^2} \tag{683}$$

This is about 160 nm; indeed, this guessed equation is simply π times the Bohr radius.

Challenge 1337, page 980: Due to the quantum of action, atoms in all people, be they giants or dwarfs, have the same size. That giants do not exist was shown already by Galilei. The argument is based on the given strength of materials, which thus implies that atoms are the same everywhere. That dwarfs cannot exist is due to the same reason; nature is not able to make people smaller than usual (except in the womb) as this would require smaller atoms.

Page 254

Challenge 1340, page 985: A disappearance of a mass m in a time Δt is an action change $mc^2\Delta t$. That is much larger than $\hbar$ for all objects of everyday life.

Challenge 1342, page 987: Tunnelling of a lion would imply action values S of the order of $S = 100\,\mathrm{kg}1\,\mathrm{m}1\,\mathrm{m/s} \ll \hbar$. This cannot happen spontaneously.

Challenge 1345, page 987: Yes! Many beliefs and myths are due to the neglect of quantum effects.

Challenge 1346, page 987: Continuous flow is in contrast to the fuzziness of motion induced by the quantum of action.

Challenge 1347, page 988: The impossibility of following particles appears when their distance d is smaller than their position indeterminacy due to their relative momentum p, thus when $d < \hbar/p$. Check the numbers with electrons, atoms, molecules, bacteria, people and galaxies.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1348, page 988: Also photons are indistinguishable. See page 1011.

Challenge 1350, page 992: The big bang cannot have been an event, for example.

Challenge 1351, page 992: The total angular momentum counts, including the orbital angular momentum. The orbital angular momentum $\boldsymbol{L}$ is given, using the radius and the linear momentum, $\boldsymbol{L} = \boldsymbol{r} \times \boldsymbol{p}$.

Challenge 1352, page 992: Yes, we could have!

Challenge 1353, page 992: That is just the indeterminacy relation. Bohr expanded this to idea to all sort of other pairs of concepts, more in the philosophical domain, such as clarity and precision of explanations: both cannot be high at the same time.

Challenge 1354, page 993: Growth is not proportional to light intensity or to light frequency, but shows both intensity and frequency thresholds. That is a quantum effects.

Challenge 1355, page 993: All effects mentioned above, such as tunnelling, interference, decay, transformation, non-emptiness of the vacuum, indeterminacy and randomness, are also observed in the nuclear domain.

Challenge 1356, page 993: This is not evident from what was said so far, but it turns out to be correct. In fact, there is no other option, as you will see when you try to find one.

Challenge 1368, page 1006: To be observable to the eye, the interference fringes need to be visible for around 0.1 s. That implies a maximum frquency difference between the two beams of around 10 Hz. This is achievable only if either a single beam is split into two or if the two beams come from high-precision, stabilized lasers.

Challenge 1382, page 1017: Use the temperature to calculate the average kinetic energy, and thus the average speed of atoms.

Challenge 1383, page 1017: The atoms cannot be fully distinguished; they form a state of matter with peculiar properties, called a *condensate*. The condensate is not at rest either; but due to its large mass, its fluctuations are greatly reduced, compared to those of a single atom.

Challenge 1386, page 1021: Use $\Delta E < E$ and $a\ \Delta t < c$.

Challenge 1394, page 1033: Terabyte chips would need to have small memory cells. Small cells imply thin barriers. Thin barriers imply high probabilities for tunneling. Tunneling implies lack of memory.

Challenge 1400, page 1039: The difficulties to see hydrogen atoms are due to their small size and their small number of electrons. As a result, hydrogen atoms produce only weak contrasts in X-ray images. For the same reasons it is difficult to image them using electrons; the Bohr radius of hydrogen is only slightly larger than the electron Compton wavelength.

Challenge 1404, page 1040: $r = 86\,\mathrm{pm}$, thus $T = 12\,\mathrm{eV}$. That compares to the actual value of 13.6 eV. The trick for the derivation of the formula is to use $< \psi | r_x^2 | \psi >= \frac{1}{3} < \psi | \boldsymbol{r}\boldsymbol{r} | \psi >$, a relation valid for states with no orbital angular momentum. It is valid for all coordinates and also for the three momentum observables, as long as the system is non-relativistic.

Challenge 1415, page 1051: A change of physical units such that $\hbar = c = e = 1$ would change the value of ε_0 in such a way that $4\pi\varepsilon_\mathrm{o} = 1/\alpha = 137.036\ldots$

Challenge 1416, page 1052: Point particles cannot be marked; nearby point particles cannot be distinguished, due to the quantum of action.

Challenge 1417, page 1052: The solution is *two* gloves. In other words, if two men and two women want to make love without danger and , they need only *two* condoms. You can deduce the procedure by yourself.

Challenge 1421, page 1053: The Sackur–Tetrode formula is best deduced in the following way. We start with an ideal monoatomic gas of volume V, with N particles, and total energy U. In

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

phase space, *state sum* Z is given by

$$Z = \frac{V^N}{N!}\frac{1}{\Lambda^{3N}} \,. \tag{684}$$

We use Stirling's approximation $N! \approx N^N/e^N$, and the definition of the entropy as $S = \partial(kT \ln Z)/\partial T$. Inserting the definition of Λ, this gives the Sackur–Tetrode equation.

Challenge 1422, page 1055: For a large number of particles, the interaction energy will introduce errors. For very large numbers, the gravitational binding energy will do so as well.

Challenge 1424, page 1056: Two write two particles on paper, one has to distinguish them, even if the distinction is arbitrary.

Challenge 1425, page 1057: Trees, like all macroscopic objects, have a spin value that depends on their angular momentum. Being classical objects whose phase can be observed, the spin value is uncertain. (But even large multiples of $\hbar$ are too small to be measurable in everyday life.) Generally speaking, trees, mountains and people are spin 1 objects. The spin 1 value implies that these objects are unchanged after a full rotation. (How does a block of silver, made of an odd number of silver atoms, each with spin 1/2, relate to this answer?)

Challenge 1429, page 1062: Twins differ in the way their intestines are folded, in the lines of their hands and other skin folds. Sometimes, but not always, features like black points on the skin are mirror inverted on the two twins.

Challenge 1435, page 1068: Three.

Challenge 1436, page 1069: Angels can be distinguished by name, can talk and can sing; thus they are made of a large number of fermions. In fact, many angels are human sized, so that they do not even fit on the tip of a pin.

Challenge 1443, page 1073: Ghosts, like angels, can be distinguished by name, can talk and can be seen; thus they contain fermions. However, they can pass through walls and they are transparent; thus they cannot be made of fermions, but must be images, made of bosons. That is a contradiction.

Challenge 1445, page 1077: The loss of non-diagonal elements leads to an increase in the diagonal elements, and thus of entropy.

Challenge 1448, page 1082: The energy speed is given by the advancement of the outer two tails; that speed is never larger than the speed of light.

Challenge 1449, page 1084: No, as taking a photo implies an interaction with a bath, which would destroy the superposition.

Challenge 1450, page 1085: A photograph requires illumination; illumination is a macroscopic electromagnetic field; a macroscopic field is a bath; a bath implies decoherence; decoherence destroys superpositions.

Challenge 1453, page 1086: It depends. They can be due to interference or to intensity sums. In the case of radio the effect is clearer. If at a particular frequency the signals changes periodically from one station to another, one has a genuine interference effect.

Challenge 1455, page 1086: Such a computer requires clear phase relations between components; such phase relations are extremely sensitive to outside disturbances. At present, they do not hold longer than a microsecond, whereas long computer programs require minutes and hours to run.

Challenge 1459, page 1093: Any other bath also does the trick, such as the atmosphere, sound vibrations, electromagnetic fields, etc.

Challenge 1460, page 1094: The Moon is in contact with baths like the solar wind, falling meteorites, the electromagnetic background radiation of the deep universe, the neutrino flux from the Sun, cosmic radiation, etc.

Fifth Part

Pleasure, Technology and Stars

In our quest to understand how things move
as a result of a minimal change in nature, we discover
that interactions are exchanges of radiation particles,
why the floor does not fall but keeps on carrying us,
why a smallest change is necessary to make pleasure possible,
why empty space pulls mirrors together,
why the stars shine,
and why swimming and flying is not so easy.

Chapter 40

MOTION FOR ENJOYING LIFE

> Homo sum, humani nil a me alienum puto.*
>
> Terence

Since we now can look at quantum effects without ideological baggage, let us have some serious fun in the world of quantum theory. The quantum of action has significant consequences for medicine, biology, chemistry, material science, and engineering. We will only explore a cross-section of these topics, but it will be worth it. But also art, the colours and materials it uses, the creative process in the artist, are based on quantum physics.** From a physics standpoint, all these domains study small motions of electric charges; thus understanding the details requires quantum theory – though usually not much.

Three special forms of electromagnetic motion are of special importance to humans: life, reproduction and death. We mentioned at the start of quantum theory that none of them can be described by classical physics. Life, sexuality and death are quantum effects. Let us see why.

BIOLOGICAL MACHINES

Living beings can be described as objects showing metabolism, information processing, information exchange, reproduction and motion. Obviously, all these properties follow from a single one, to which the others are enabling means:

▷ *Living beings are objects able to (self-)reproduce.****

From your biology lessons in secondary school you might remember the main properties of heredity. Reproduction is characterized by random changes from one generation to the next. The statistics of mutations, for example Mendel's 'laws' of heredity, and the lack of intermediate states, are direct consequences of quantum theory. In other words, reproduction and growth are quantum effects.

---

* 'I am a man and nothing human is alien to me.' Terence is Publius Terentius Afer (*c.* 190–159 BCE), the important roman poet. He writes this in his play *Heauton Timorumenos*, verse 77.

** The photograph on page 1115 shows a soap bubble, the motion of the fluid in it, and the interference colours; it was taken and is copyright by Jason Tozer for Creative Review/Sony.

*** However, there are examples of objects which reproduce and which nobody would call living. Can you find some examples, together with a sharper definition? Challenge 1462 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In order to reproduce, living beings must be able to move in self-directed ways. An object able to perform self-directed motion is called a *machine*. All self-reproducing beings are machines.

Since reproduction and growth is simpler the smaller the system is, most living beings are extremely small machines for the tasks they perform, especially when compared to human made machines. This is the case even though the design of human machines has considerably fewer requirements: human-built machines do not need to be able to reproduce; as a result, they do not need to be made of a single piece of matter, as all living beings have to. Indeed, despite all the restrictions nature has to live with, living beings hold many miniaturization world records:

— The brain has the highest processing power per volume of any calculating device so far. Just look at the size of chess champion Gary Kasparov and the size of the computer against which he played. Or look at the size of any computer that attempts to speak.
— The brain has the densest and fastest memory of any device so far. The set of compact discs (CDs) or digital versatile discs (DVDs) that compare with the brain is many thousand times larger. Page 813
— Motors in living beings are many orders of magnitude smaller than human-built ones. Just think about the muscles in the legs of an ant.
— The motion of living beings beats the acceleration of any human-built machine by orders of magnitude. No machine moves like a grasshopper.
— Living being's sensor performance, such as that of the eye or the ear, has been surpassed by human machines only recently. For the nose this feat is still far away. Nevertheless, the sensor sizes developed by evolution – think also about the ears or eyes of a common fly – are still unbeaten.
— Living beings that fly, swim or crawl – such as fruit flies, plankton or amoebas – are still thousands of times smaller than anything built by humans. In particular, the navigation systems built by nature are far smaller than anything built by human technology.
— Can you spot more examples? Challenge 1463 s

The superior miniaturization of living beings – compared to human-built machines – is due to their continuous strife for efficient construction. In the structure of living beings, everything is connected to everything: each part influences many others. Indeed, the four basic processes in life, namely metabolic, mechanical, hormonal and electrical, are intertwined in space and time. For example, breathing helps digestion; head movements pump liquid through the spine; a single hormone influences many chemical processes. In addition, all parts in living systems have more than one function. For example, bones provide structure and produce blood; fingernails are tools and shed chemical waste.

The miniaturization, the reproduction, the growth and the functioning of living beings all rely on the quantum of action. Let us see how.

Reproduction

> Life is a sexually transmitted disease.
>
> Anonymous

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 488 A quantum machine (© Elmar Bartel)

All the astonishing complexity of life is geared towards reproduction. *Reproduction* is the ability of an object to build other objects similar to itself. Quantum theory told us that only a *similar* object is possible, as an exact copy would contradict the quantum of action, as we found out above.

Page 1061

Since reproduction requires mass increase, reproducing objects show both metabolism and growth. In order that growth can lead to an object similar to the original, a construction plan is necessary. This plan must be similar to the plan used by the previous generation. Organizing growth with a construction plan is only possible if nature is made of smallest entities which can be assembled following that plan.

We can thus deduce that reproduction implies that matter is made of smallest entities. If matter were not made of smallest entities, there would be no way to realize reproduction. The observation of reproduction thus implies the existence of atoms and the necessity of quantum theory. Indeed, without the quantum of action there would be no DNA molecules and there would be no way to inherit our own properties – our own construction plan – to children.

Passing on a plan requires that living beings have ways to store information. Living beings must have some built-in memory. We know already that a system with memory must be made of many particles. There is no other way to store information. The large number of particles is mainly necessary to protect the information from the influences of the outside world.

Our own construction plan, made of what biologists call genes, is stored in DNA molecules. Reproduction is thus first of all a transfer of parent's genes to the next generation. We will come back to the details below. We first have a look on how our body moves itself and its genes around.

Page 1149

Quantum machines

Living beings are machines. How do these machines work? From a physical point of view, we need only a few sections of our walk so far to describe them: universal gravity and QED. Simply stated, life is an electromagnetic process taking place in weak gravity.*

* In fact, also the nuclear interactions play some role for life: cosmic radiation is one source for random mutations, which are so important in evolution. Plant growers often use radioactive sources to increase

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

But the details of this statement are tricky and interesting. Table 95 gives an overview of motion processes in living beings. Interestingly, all motion in living beings can be summarized in a few classes by asking for the motor driving it.

Nature only needs few small but powerful devices to realize all motion types used by humans and all other living beings: *pumps* and *motors*. Given the long time that living systems have been around, these devices are extremely efficient. In fact, ion pumps, chemical pumps, rotational and linear molecular motors are all specialized molecular machines. Ion and chemical pumps are found in membranes and transport matter. Rotational and linear motor move structures against membranes. In short, all motion in living beings is due to molecular motors. Even though there is still a lot to be learned about them, what is known already is spectacular enough.

How do we move? – Molecular motors

How do our muscles work? What is the underlying motor? One of the beautiful results of modern biology is the elucidation of this issue. It turns out that muscles work because they contain molecules which change shape when supplied with energy. This shape change is repeatable. A clever combination and repetition of these molecular shape changes is then used to generate macroscopic motion. There are three basic classes of molecular motors: linear motors, rotational motors and pumps.

1. *Linear motors* are at the basis of muscle motion; other linear motors separate genes during cell division. They also move organelles inside cells and displace cells through the body during embryo growth, when wounds heal, or in other examples of cell motility. A typical molecular motor consumes around 100 to 1000 ATP molecules per second, thus about 10 to 100 aW. The numbers are small; however, we have to take into account that the power due to the white noise of the surrounding water is 10 nW. In other words, in every molecular motor, the power of the environmental noise is eight to nine orders of magnitude higher than the power consumed by the motor. The ratio shows what a fantastic piece of machinery such a motor is.

Challenge 1464 s

2. We encountered *rotational motors* already above; nature uses them to rotate the cilia of many bacteria as well as sperm tails. Researchers have also discovered that evolution produced molecular motors which turn around DNA helices like a motorized bolt would turn around a screw. Such motors are attached at the end of some viruses and insert the DNA into virus bodies when they are being built by infected cells, or extract the DNA from the virus after it has infected a cell. Another rotational motor, the smallest known so far – 10 nm across and 8 nm high – is ATP synthase, a protein that synthesizes most ATP in cells.

Page 86
Ref. 931
Ref. 932

3. *Molecular pumps* are essential to life. They pump chemicals, such as ions or specific molecules, into every cell or out of it, using energy, even if the concentration gradient

Ref. 930 mutation rates. But obviously, radioactivity can also terminate life.

The nuclear interactions are also implicitly involved in several other ways. They were necessary to form the materials – carbon, oxygen, etc. – required for life. Nuclear interactions are behind the main mechanism for the burning of the Sun, which provides the energy for plants, for humans and for all other living beings (except a few bacteria in inaccessible places).

Summing up, the nuclear interactions play a role in the appearance and in the in destruction of life; but they play no (known) role for the actions of particular living beings.

TABLE 95 Motion and motors found in living beings

Motion type	Examples	Involved motors
Growth	collective molecular processes in cell growth	ion pumps
	gene turn-on and turn-off	linear molecular motors
	ageing	linear molecular motors
Construction	material types and properties (polysaccharides, lipids, proteins, nucleic acids, others)	material transport through muscles
	forces and interactions between biomolecules	cell membrane pumps
Functioning	muscle working	linear molecular motors
	metabolism (respiration, digestion)	muscles, ion pumps
	thermodynamics of whole living system and of its parts	muscles
	nerve signalling	ion motion, ion pumps
	brain working, thinking	ion motion, ion pumps
	memory: long-term potentiation	chemical pumps
	hormone production	chemical pumps
	illnesses	cell motility, chemical pumps
	viral infection of a cell	rotational molecular motors for RNA transport
Defence	the immune system	cell motility, linear molecular motors
	blood clotting	chemical pumps
Sensing	eye	chemical pumps, ion pumps
	ear	hair motion sensors, ion pumps
	smell	ion pumps
	touch	ion pumps
Reproduction	information storage and retrieval	linear molecular motors inside cells, sometimes rotational motors, as in viruses
	cell division	linear molecular motors inside cells
	sperm motion	rotational molecular motors
	courting	muscles, brain, linear molecular motors
	evolution	muscles, linear molecular motors

tries to do the opposite. Molecular pumps are thus essential in ensuring that life is a process *far* from equilibrium. Malfunctioning molecular pumps are responsible for many problems, for example the water loss in cholera.

In the following, we concentrate on linear motors. The ways molecules produce move-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 933 ment in linear motors was uncovered during the 1990s. The results started a wave of research on all other molecular motors found in nature. All molecular motors share several characteristic properties: molecular motors do not involve temperature gradients involved, as car engines do, they do not involve electrical currents, as electrical motors do, and they do not rely on concentration gradients, as chemically induced motion, such as the rising of a cake, does.

Linear molecular motors

The central element of the most important linear molecular motor is a combination of two protein molecules, namely myosin and actin. Myosin changes between two shapes and literally *walks* along actin. It moves in regular small steps, as shown in Figure 489. The motion step size has been measured with beautiful experiments to always be an inte-
Ref. 933 ger multiple of 5.5 nm. A step, usually forward, but sometimes backwards, results whenever an ATP (adenosine triphosphate) molecule, the standard biological fuel, hydrolyses to ADP (adenosine diphosphate), thus releasing its energy. The force generated is about 3 to 4 pN; the steps can be repeated several times a second. Muscle motion is the result of thousand of millions of such elementary steps taking place in concert.

How do molecular motors work? Molecular motors are are so small that the noise due to the molecules of the liquid around them is not negligible. But nature is smart: with two tricks it takes advantage of Brownian motion and transforms it into macroscopic molecular motion. Molecular motors are therefore also called *Brownian motors*. The transformation of disordered molecular motion into ordered macroscopic motion is one of the great wonders of nature. The first trick of nature is the use of an asymmetric, but periodic potential, a so-called *ratchet*.* The second trick of nature is a temporal variation of the potential, together with an energy input to make it happen. The most
Ref. 934 important realizations are shown in Figure 491.

The periodic potential variation in a molecular motor ensures that for a short, recurring time interval the free Brownian motion of the moving molecule – typically 1 µm/s – affects its position. Subsequently, the molecule is fixed again. In most of the short time intervals of free Brownian motion, the position will not change. But if the position does change, the intrinsic asymmetry of the ratchet shape ensures that with high probability the molecule advances in the preferred direction. (The animation of Figure 489 lacks this irregularity.) Then the molecule is fixed again, waiting for the next potential change. On average, the myosin molecule will thus move in one direction. Nowadays the motion of single molecules can be followed in special experimental set-ups. These experiments confirm that muscles use such a ratchet mechanism. The ATP molecule adds energy to the system and triggers the potential variation through the shape change it induces in the myosin molecule. That is how our muscles work.

Another well-studied linear molecular motor is the kinesin–microtubule system that carries organelles from one place to the other within a cell. As in the previous example, also in this case chemical energy is converted into unidirectional motion. Researchers were able to attach small silica beads to single molecules and to follow their motion. Using laser beams, they could even apply forces to these single molecules. Kinesin was

* It was named by Walt Disney after by Ratchet Gearloose, the famous inventor from Duckburg.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

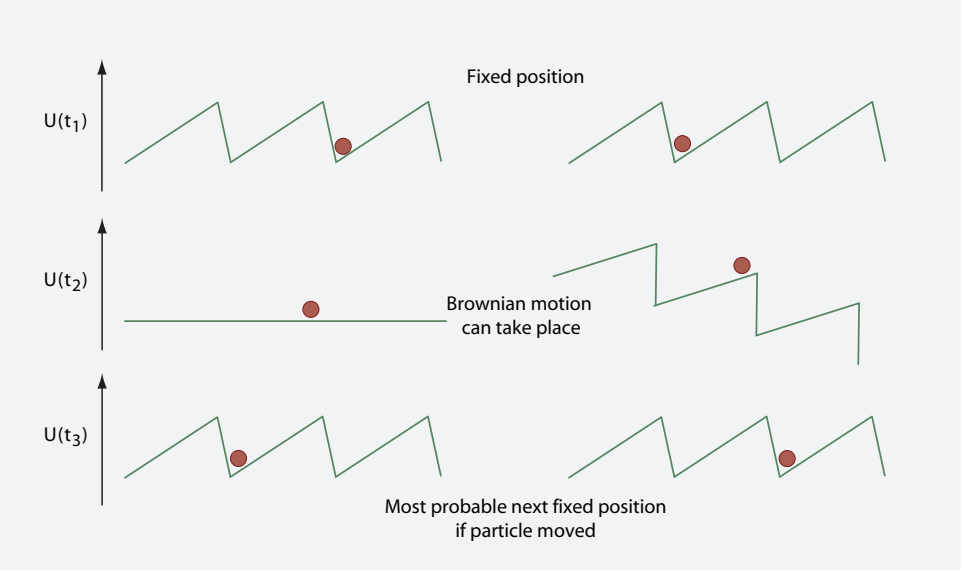

FIGURE 491 Two types of Brownian motors: switching potential (left) and tilting potential (right)

found to move with around 800 nm/s, in steps lengths which are multiples of 8 nm, using one ATP molecule at a time, and exerting a force of about 6 pN.

Quantum ratchet motors do not exits only in living systems; they also exist as human-built systems. Examples are electrical ratchets that move single electrons and optical ratchets that drive small particles. Extensive experimental research is going on in these fields.

Classical ratchets exist in many forms. For example, many piezoelectric actuators work as ratchets. All atomic force microscopes and scanning electron microscopes use such actuators.

Curiosities and fun challenges about biology

> Una pelliccia è una pelle che ha cambiato bestia.*
>
> Girolamo Borgogelli Avveduti

Discuss the following argument: If nature were classical instead of quantum, there would not be just *two* sexes – or any other discrete number of them – but there would be a *continuous range* of them. In a sense, there would be an infinite number of sexes. True? Challenge 1465 s

* *

Biological evolution can be summarized in three statements:

1. All living beings are different – also in a species.
2. All living beings have a tough life – due to competition.
3. Living beings with an advantage will survive and reproduce.

* 'A *fur* is a skin that has changed beast.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

As a result of these three points, with each generation, *species and living beings can change*. The result of accumulated generational change is called biological evolution. The last point is often called the 'survival of the fittest'.

These three points explain, among others, the change from unicellular to multicellular life, from fish to land animals, and from animals to people.

We note that quantum physics enters in every point that makes up evolution. For example, the differences mentioned in the first point are due to quantum physics: perfect copies of macroscopic systems are impossible. And of course, life and metabolism are quantum effects. The second point mentions competition; that is a type of measurement, which, as we saw, is only possible due to the existence of a quantum of action. The third point mentions reproduction: that is again a quantum effect, based on the copying of genes, which are quantum structures. In short, both life and its evolution are quantum effects.

* *

Challenge 1466 s How would you determine which of two identical twins is the father of a baby?

* *

Can you give at least five arguments to show that a human clone, if there will ever be one, Challenge 1467 s is a completely different person than the original?

It is well known that the first cloned cat, *copycat*, born in 2002, looked completely different from the 'original' (in fact, its mother). The fur colour and its patch pattern were completely different from that of the mother. Analogously, identical human twins have different finger prints, iris scans, blood vessel networks and intrauterine experiences, among others.

* *

A famous unanswered question: how did the first *kefir grains* form? Kefir grains produce the kefir drink when covered with milk for about 8 to 12 hours. The grains consist of a balanced mixture of about 40 types of bacteria and yeasts. All kefir grains in the world Challenge 1468 r are related. But how did the first ones form, about 1000 years ago?

* *

Many molecules found in living beings, such as sugar, have mirror molecules. However, in all living beings only one of the two sorts is found. Life is intrinsically asymmetric. Challenge 1469 s How can this be?

* *

How is it possible that the genetic difference between man and chimpanzee is regularly given as about 1 %, whereas the difference between man and woman is one chromosome Challenge 1470 s in 46, in other words, about 2.2 %?

* *

What is the longest time a single bacterium has survived? Not 5000 years as the bacteria Ref. 935 found in Egyptian mummies, not even 25 million years as the bacteria spores resurrected from the intestines in insects enclosed in amber. It is much longer, namely an astonishing

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 96 Approximate number of living species

Life group	Described species	Estimated species min.	Estimated species max.
Viruses	4 000	$50 \cdot 10^3$	$1 \cdot 10^6$
Prokaryotes ('bacteria')	4 000	$50 \cdot 10^3$	$3 \cdot 10^6$
Fungi	72 000	$200 \cdot 10^3$	$2.7 \cdot 10^6$
Protozoa	40 000	$60 \cdot 10^3$	$200 \cdot 10^3$
Algae	40 000	$150 \cdot 10^3$	$1 \cdot 10^6$
Plants	270 000	$300 \cdot 10^3$	$500 \cdot 10^3$
Nematodes	25 000	$100 \cdot 10^3$	$1 \cdot 10^6$
Crustaceans	40 000	$75 \cdot 10^3$	$200 \cdot 10^3$
Arachnids	75 000	$300 \cdot 10^3$	$1 \cdot 10^6$
Insects	950 000	$2 \cdot 10^6$	$100 \cdot 10^6$
Molluscs	70 000	$100 \cdot 10^3$	$200 \cdot 10^3$
Vertebrates	45 000	$50 \cdot 10^3$	$55 \cdot 10^3$
Others	115 000	$200 \cdot 10^3$	$800 \cdot 10^3$
Total	$1.75 \cdot 10^6$	$3.6 \cdot 10^6$	$112 \cdot 10^6$

250 million years. This is the time that bacteria discovered in the 1960s by Hans Pflug in (low-radioactivity) salt deposits in Fulda (Germany) have hibernated there before being Ref. 936 brought back to life in the laboratory. The result has been recently confirmed by the discovery of another bacterium in a North-American salt deposit in the Salado formation.

* *

Molecular motors are quite capable. The molecular motors in the sooty shearwater (*Puffinus griseus*), a 20 cm long bird, allow it to fly 74 000 km in a year, with a measured record of 1094 km a day.

* *

In 1967, a TV camera was deposited on the Moon. Unknown to everybody, it contained a small patch of *Streptococcus mitis*. Three years later, the camera was brought back to Ref. 937 Earth. The bacteria were still alive. They had survived for three years without food, water or air. Life can be resilient indeed.

* *

In biology, classifications are extremely useful. (This is similar to the situation in astrophysics, but in full contrast to the situation in physics.) Table 96 gives an overview of the Ref. 938 magnitude of the task. This wealth of material can be summarized in one graph, shown in Figure 492. Newer research seems to suggest some slight changes to the picture. So far however, there still is only a single root to the tree.

* *

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

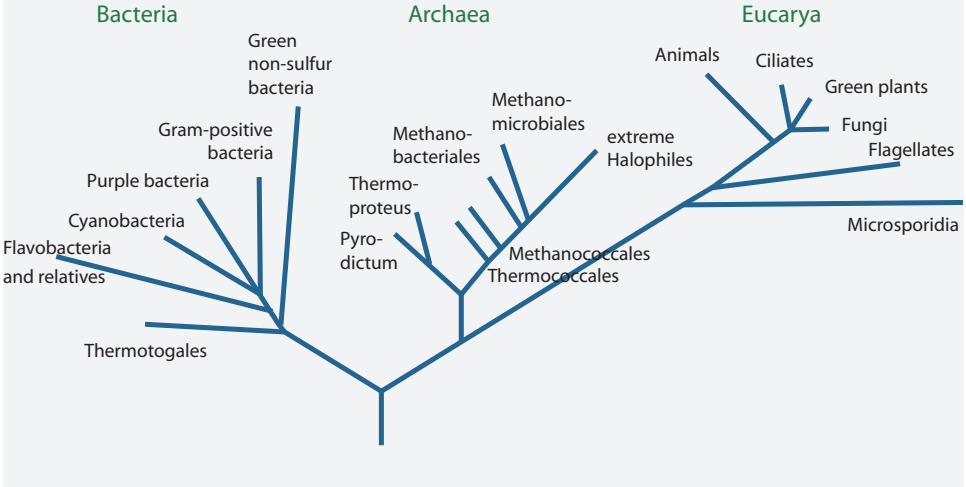

FIGURE 492 A modern version of the evolutionary tree

Muscles produce motion through electrical stimulation. Can technical systems do the same? There is a candidate. So-called electroactive polymers change shape when they are activated with electrical current or with chemicals. They are lightweight, quiet and simple to manufacture. However, the first arm wrestling contest between human and artificial muscles held in 2005 was won by a teenage girl. The race to do better is ongoing.

* *

Life is not a clearly defined concept. The definition used above, the ability to reproduce, has its limits when applied to old animals, to a hand cut off by mistake, to sperm or to ovules. It also gives problems when trying to apply it to single cells. Is the definition of life as 'self-determined motion in the service of reproduction' more appropriate? Or is the definition of living beings as 'what is made of cells' more precise?

Challenge 1471 ny

* *

Also growth is a type of motion. Some is extremely complex. Take the growth of acne. It requires a lack of zinc, a weak immune system, several bacteria, as well as the help of *Demodex brevis*, a mite (a small insect) that lives in skin pores. With a size of 0.3 mm, somewhat smaller than the full stop at the end of this sentence, this and other animals living on the human face can be observed with the help of a strong magnifying glass.

Humans have many living beings on board. For example, humans need bacteria to live. It is estimated that 90% of the bacteria in the human mouth alone are not known yet; only 500 species have been isolated so far. These useful bacteria help us as a defence against the more dangerous species.

* *

How do trees grow? When a tree – a *monopodal phanerophyte* – grows and produces leaves, between 40% and 60% of the mass it consists of, namely the water and the min-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

erals, has to be lifted upwards from the ground. (The rest of the mass comes from the CO_2 in the air.) How does this happen? The materials are pulled upwards by the water columns inside the tree; the pull is due to the negative pressure that is created when the top of the column evaporates. This is called the *transpiration-cohesion-tension model*. (This summary is the result of many experiments.) In other words, no energy is needed for the tree to pump its materials upwards.

Due to the energyless water transport system, a tree grows purely by adding material to its surface. This implies that when a tree grows, a branch that is formed at a given height is also found at that *same* height during the rest of the life of that tree. Just check this observation with the trees in your garden.

Challenge 1472 e

* *

Mammals have a narrow operating temperature. In contrast to machines, humans function only if the internal temperature is within a narrow range. Why? And does this requirement also apply to extraterrestrials – provided they exist?

Challenge 1473 d

* *

How did the first cell arise? This question is still open. However, researchers have found several substances that spontaneously form closed membranes in water. Such substances also form foams. It might well be that life formed in foam. Other options discussed are that life formed underwater, at the places where magma rises into the ocean. Elucidating the question is one of the great open riddles of biology.

Challenge 1474 r

* *

Challenge 1475 s Could life have arrived to Earth from outer space?

* *

What could *holistic medicine* mean to a scientist, i.e., avoiding bullshit and beliefs? Holistic medicine means treating illness with view on the whole person. That translates to four domains:

— *physical* support, to aid mechanical or thermal healing processes in the body;
— *chemical* support, with nutrients or vitamines;
— *signalling* support, with electrical or chemical means, to support the signalling system of the body;
— *psychicological* support, to help all above processes.

When all theses aspects are taken care of, healing is as rapid and complete as possible. However, one main rule remains: *medicus curat, natura sanat*.*

* *

What are the effects of environmental pollution on life? Answering this question is an intense topic of modern research. Here are some famous stories.

— Herbicides and many genetically altered organisms kill bees. For this reason, bees are dying (in 2007) in the United States; as a result, many crops – such as almonds and or-

* The physician helps, but nature heals

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

anges – are endangered there. In countries where the worst herbicides and genetically modified crops have been banned, bees have no problems.
— Chemical pollution leads to malformed babies. In mainland China, one out of 16 children is malformed for this reason (in 2007). In Japan, malformations have been much reduced – though not completely – since strict anti-pollution laws have been passed.
— Radioactive pollution kills. In Russia, the famous Karachay lake had to be covered by concrete because its high radioactivity killed anybody that walked along it for half an hour.
— Smoking kills – though slowly. Countries that have lower smoking rates or that have curbed smoking have reduced rates for cancer and several other illnesses.
— Eating tuna is dangerous for your health, because of the heavy metals it contains.
— Cork trees are disappearing. The wine industry has started large research programs to cope with this problem.
— Even arctic animals have livers full of human-produced chemical poisons.
— Burning fuels rises the CO_2 level of the atmosphere. This leads to many effects for the Earth's climate, including a rise in average temperature and sea level.

Ecological research is uncovering many additional connections. Let us hope that the awareness for these issues increases across the world.

* *

In the twentieth century, biological research has uncovered several mechanisms responsible for aging and death. One of the most well-known mechanisms limits the number of division that a cell can undergo. The number of cell divisions, typically between 50 and 200, is finite for most cell types. (An exception are reproductory cells – we would not exist if they would not be able to divide endlessly.) The cell division counter has been identified; it is embodied in the *telomeres*, special structures of DNA and proteins found at both ends of each chromosome. These structures are reduced by a small amount during each cell division. When the structures are too short, cell division stops.

THE PHYSICS OF PLEASURE

> What is mind but motion in the intellectual sphere?
> Oscar Wilde (1854–1900) *The Critic as Artist*.

Pleasure is a quantum effect. The reason is simple. Pleasure comes from the senses. All senses measure. And all measurements rely on quantum theory. The human body, like an expensive car, is full of sensors. Evolution has build these sensors in such a way that they trigger pleasure sensations whenever we do with our body what we are made for.

Of course, no scientist will admit that he studies pleasure. Therefore he will say that he studies the senses. (Pleasure, or indeed, all human sensors, exist to let life continue. Pleasure is highest when life is made to continue. In the distant past, the appearance of new sensors has always had important effects of evolution, for example during the Cambrian explosion.) Researching pleasure and sensors is a fascinating field that is still evolving; here we can only have a quick tour of the present knowledge.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

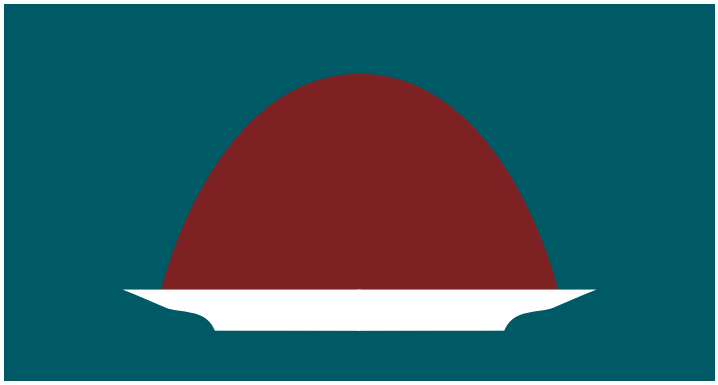

FIGURE 493 The different speed of the eye's colour sensors, the cones, lead to a strange effect when this picture (in colour version) is shaken right to left in *weak* light

Among the most astonishing aspects of our body sensors is their sensitivity. The *ear* is so sensitive and at the same time so robust against large signals that the experts are still studying how it works. No known sound sensor can cover an energy range of 10^{13}; indeed, the detected sound intensities range from 1 pW/m^2 (some say 50 pW/m^2) to 10 W/m^2, the corresponding air pressure variations from 20 μPa to 60 Pa. The lowest intensity is that of a 20 W sound source heard at a distance of 10 000 km, if no sound is lost in between.

Audible sound wavelengths span from 17 m (20 Hz) to 17 mm (20 kHz). In this range, the ear is able to distinguish at least 1500 pitches with its 16 000 to 20 000 hair cells. But the ear is also able to distinguish 400 from 401 Hz using a special pitch sharpening mechanism.

The *eye* is a position dependent photon detector. Each eye contains around 126 million separate detectors on the retina. Their spatial density is the highest possible that makes sense, given the diameter of the lens of the eye. They give the eye a resolving power of 1′ and the capacity to detect down to 60 incident photons in 0.15 s, or 4 absorbed photons in the same time. There are about 6 million not so sensitive colour detectors, the *cones*, whose distribution we have seen earlier on. The different chemicals in the three cone types (red, green, blue) lead to different sensor speeds; this can be checked with the simple test shown in Figure 493. The images of the eye are only sharp if the eye constantly moves in small random motions. If this motion is stopped, for example with chemicals, the images produced by the eye become unsharp.

Page 764

Ref. 939

The eye also contains 120 million highly sensitive general light intensity detectors, the *rods*. Rods cannot distinguish colours. The sensitivity difference between rods and cones is the reason that at night all cats are grey. Until recently, human built light sensors with the same sensitivity as rods had to be helium cooled, because technology was not able to build sensors at room temperature that were as sensitive as the human eye.

The *touch sensors* are distributed over the skin, with a surface density which varies from one region to the other. It is lowest on the back and highest in the face and on the tongue. There are separate sensors for pressure, for deformation, for vibration, for tickling, for heat, for coldness, and for pain. Some react proportionally to the stimulus intensity, some differentially, giving signals only when the stimulus changes. Many of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

these sensors are also found inside the body.

The taste mechanisms of *tongue* are only partially known. Since 2005, the tongue is known to produces six taste signals* – sweet, salty, bitter, sour, proteic and fat – and the mechanisms are just being unravelled. (The sense for proteic, also called umami, has been discovered in 1907, by Ikeda Kikunae; the sense for 'fat' has been discovered only in 2005.) Democritus imagined that taste depends on the shape of atoms. Today it is known that sweet taste is connected with certain shape of molecules. Despite all this, no sensor with a distinguishing ability of the same degree as the tongue has yet been built by humans.

Ref. 940

The *nose* has about 350 different smell receptors; through combinations it is estimated that it can smell about 10 000 different smells.** Together with the five signals that the sense of taste can produce, the nose also produces a vast range of taste sensations. It protects against chemical poisons, such as smoke, and against biological poisons, such as faecal matter. In contrast, artificial gas sensors exist only for a small range of gases. Good artificial taste and smell sensors would allow to check wine or cheese during their production, thus making its inventor extremely rich.

Challenge 1477 ny

The human body also contains *orientation sensors* in the ear, *extension sensors* in each muscle, and *pain sensors* almost all over the skin and inside the body.

Page 682

Other animals feature additional types of sensors. Sharks can feel electrical fields, snakes have sensors for infrared light; both are used to locate prey. Pigeons, trout and sharks can feel magnetic fields, and use this sense for navigation. Many birds and certain insects can see UV light. Bats and dolphins are able to hear ultrasound up to 100 kHz and more. Whales and elephants can detect and localize infrasound signals.

In summary, the sensors with which nature provides us are state of the art; their sensitivity and ease of use is the highest possible. Since all sensors trigger pleasure or help to avoid pain, nature obviously wants us to enjoy life with the most intense pleasure possible. Studying physics is one way to do this.

Ref. 941

> There are two things that make life worth living:
> Mozart and quantum mechanics.
> Victor Weisskopf***

* Taste sensitivity is *not* separated on the tongue into distinct regions; this is an incorrect idea that has been copied from book to book for over a hundred years. You can perform a falsification by yourself, using sugar or salt grains.

Challenge 1476 s

** Linda Buck and Richard Axel received the 2004 Nobel Prize for medicine and physiology for their unravelling of the working of the sense of smell.

*** Victor Friedrich Weisskopf (b. 1908 Vienna, d. 2002 Cambridge), acclaimed theoretical physicist who worked with Einstein, Born, Bohr, Schrödinger and Pauli. He catalysed the development of quantum electrodynamics and nuclear physics. He worked on the Manhattan project but later in life intensely campaigned against the use of nuclear weapons. During the cold war he accepted the membership in the Soviet Academy of Sciences. He was professor at MIT and for many years director of CERN, in Geneva. He wrote several successful physics textbooks. The author heard him making the above statement at CERN, in 1981, during one of his lectures.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The nerves and the brain

> There is no such thing as perpetual tranquillity of mind while we live here; because life itself is but motion, and can never be without desire, nor without fear, no more than without sense.
> Thomas Hobbes (1588–1679) *Leviathan*.

The main unit processing all the signals arriving from the sensors, the brain, is essential for all feelings of pleasure. The human brain has the highest complexity of all brains known.* In addition, the processing power and speed of the human brain is still larger than any device build by man.

We saw already earlier on how electrical signals from the sensors are transported into the brain. In the brain itself, the arriving signals are classified and stored, sometimes for a short time, sometimes for a long time. The various storage mechanisms, essentially taking place in the structure and the connection strength between brain cells, were elucidated by modern neuroscience. The remaining issue is the process of classification. For certain low level classifications, such as geometrical shapes for the eye or sound harmonies for the ear, the mechanisms are known. But for high-level classifications, such as the ones used in conceptual thinking, the aim is not yet achieved. It is not yet known how to describe the processes of reading, understanding and talking in terms of signal motions. Research is still in full swing and will probably remain so for the largest part of the twenty-first century.

Page 240

In the following we look at a few abilities of our brain, of our body and of other bodies that are important for the pleasures in the study of motion.

Living clocks

> L'horologe fait de la réclame pour le temps.**
> Georges Perros

We have given an overview of living clocks already before. They are common in bacteria, plants and animals.

Page 48

When we sing a musical note that we just heard we are able to reproduce the original frequency with high accuracy. We also know from everyday experience that humans are able to keep the beat to within a few per cent for a long time. When doing sport or when dancing, we are able to keep the timing to high accuracy. (For shorter or longer times, the internal clocks are not so precise.) All these clocks are located in the brain.

Ref. 942

Brains process information. Also computers do this, and like computers, all brains need a clock to work well. Every clock is made up of the same components. It needs an *oscillator* determining the rhythm and a mechanism to feed the oscillator with energy. In addition, every clock needs an oscillation *counter*, i.e., a mechanism that reads out the clock signal, and a means of *signal distribution* throughout the system is required,

* This is not in contrast with the fact that one or two whale species have brains with a slightly larger mass. The larger mass is due to the protection these brains require against the high pressures which appear when whales dive (some dive to depths of 1 km). The number of neurons in whale brains is considerably smaller than in human brains.

** Clocks are ads for time.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

synchronizing the processes attached to it. Finally, a clock needs a *reset mechanism*. If the clock has to cover many time scales, it needs several oscillators with different oscillation frequencies and a way to reset their relative phases.

Even though physicists know fairly well how to build good clocks, we still do not know many aspects of biological clocks. Most biological oscillators are chemical systems; some, like the heart muscle or the timers in the brain, are electrical systems. The general elucidation of chemical oscillators is due to Ilya Prigogine; it has earned him a Nobel Prize for chemistry in 1977. But not all the chemical oscillators in the human body are known yet, not to speak of the counter mechanisms. For example, a 24-minute cycle inside each human cell has been discovered only in 2003, and the oscillation mechanism is not yet fully clear. (It is known that a cell fed with heavy water ticks with 27–minute instead of 24–minute rhythm.) It might be that the daily rhythm, the circadian clock, is made up of or reset by 60 of these 24–minute cycles, triggered by some master cells in the human body. The clock reset mechanism for the circadian clock is also known to be triggered by daylight; the cells in the eye who perform this resetting action have been pinpointed only in 2002. The light signal from these cells is processed by the superchiasmatic nuclei, two dedicated structures in the brain's hypothalamus. The various cells in the human body act differently depending on the phase of this clock.

Ref. 947

Ref. 946

The clock with the longest cycle in the human body controls ageing. A central mechanism for this clock seems to be the number of certain molecules attached to the DNA of the human chromosomes. At every division, one molecule is lost. When the molecules are all lost, the cell dies. Research into the mechanisms and the exceptions to this process, such as cancer and sexual cells, is ongoing.

The basis of the monthly period in women is equally interesting and complex.

Other fascinating clocks are those at the basis of conscious time. Of these, the brain's stopwatch or *interval timer*, has been most intensely studied. Only recently was its mechanism uncovered by combining data on human illnesses, human lesions, magnetic resonance studies, and effects of specific drugs. The basic interval timing mechanism takes place in the striatum in the basal ganglia of the brain. The striatum contains thousands of timer cells with different periods. They can be triggered by a 'start' signal. Due to their large number, for small times of the order of one second, every time interval has a different pattern across these cells. The brain can read these patterns and learn them. In this way we can time music or specific tasks to be performed, for example, one second after a signal.

Ref. 948

Even though not all the clock mechanisms in humans are known, natural clocks share a property with human-built clocks: they are limited by quantum mechanics. Even the simple pendulum is limited by quantum theory. Let us explore the topic.

When do clocks exist?

> Die Zukunft war früher auch besser.*
>
> Karl Valentin.

* 'Also the future used to be better in the past.' Karl Valentin (b. 1882 Munich, d. 1948 Planegg), German author and comedian.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In general relativity, we found out that purely gravitational clocks do not exist, because there is no unit of time that can be formed using the constants c and G. Clocks, like any measurement standard, need matter and non-gravitational interactions to work. This is the domain of quantum theory. Let us see what the situation is in this case.

Page 620

First of all, in quantum theory, the time operator is not an observable. Indeed, the time operator is not Hermitean. In other words, quantum theory states that there is no physical observable whose value is proportional to time. On the other hand, clocks are quite common; for example, the Sun or Big Ben work to most people's satisfaction. Observations thus encourages us to look for an operator describing the position of the hands of a clock. However, if we look for such an operator we find a strange result. Any quantum system having a Hamiltonian bounded from below – having a lowest energy – lacks a Hermitean operator whose expectation value increases monotonically with time. This result can be proven rigorously. In other words, quantum theory states that time cannot be measured.

Challenge 1478 ny

That time cannot be measured is not really a surprise. The meaning of this statement is that every clock needs to be wound up after a while. Take a mechanical pendulum clock. Only if the weight driving it can fall forever, without reaching a bottom position, can the clock go on working. However, in all clocks the weight has to stop when the chain end is reached or when the battery is empty. In other words, in all real clocks the Hamiltonian is bounded from below.

In short, quantum theory shows that exact *clocks do not exist in nature*. Quantum theory states that any clock can only be *approximate*. Obviously, this result is of importance for high precision clocks. What happens if we try to increase the precision of a clock as much as possible?

High precision implies high sensitivity to fluctuations. Now, all clocks have a motor inside that makes them work. A high precision clock thus needs a high precision motor. In all clocks, the position of the motor is read out and shown on the dial. The quantum of action implies that a precise clock motor has a position indeterminacy. The clock precision is thus limited. Worse, like any quantum system, the motor has a small, but finite probability to stop or to run backwards for a while.

You can check this prediction yourself. Just have a look at a clock when its battery is almost empty, or when the weight driving the pendulum has almost reached the bottom position. It will start doing funny things, like going backwards a bit or jumping back and forward. When the clock works normally, this behaviour is strongly suppressed; however, it is still possible, though with low probability. This is true even for a sundial.

Challenge 1479 ny

In other words, clocks necessarily have to be macroscopic in order to work properly. A clock must be as large as possible, in order to average out its fluctuations. Astronomical systems are good examples. A good clock must also be well-isolated from the environment, such as a freely flying object whose coordinate is used as time variable, as is done in certain optical clocks.

The precision of clocks

Given the limitations due to quantum theory, what is the ultimate precision of a clock? To start with, the indeterminacy relation provides the limit on the mass of a clock. The

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1480 ny mass M must be larger than

$$M > \frac{\hbar}{c^2\tau} \tag{685}$$

Challenge 1481 e which is obviously always fulfilled in everyday life. But we can do better. Like for a pendulum, we can relate the accuracy τ of the clock to its maximum reading time T. The Ref. 943 idea was first published by Salecker and Wigner. They argued that

$$M > \frac{\hbar}{c^2\tau}\frac{T}{\tau} \tag{686}$$

where T is the time to be measured. You might check that this condition directly requires Challenge 1482 e that any clock must be *macroscopic*.

Let us play with the formula by Salecker and Wigner. It can be rephrased in the following way. For a clock that can measure a time t, the size l is connected to the mass m by

$$l > \sqrt{\frac{\hbar t}{m}} \,. \tag{687}$$

Ref. 945 How close can this limit be achieved? It turns out that the smallest clocks known, as well as the clocks with most closely approach this limit, are bacteria. The smallest bacteria, the *mycoplasmas*, have a mass of about $8 \cdot 10^{-17}$ kg, and reproduce every 100 min, with a precision of about 1 min. The size predicted from expression (687) is between 0.09 μm and 0.009 μm. The observed size of the smallest mycoplasmas is 0.3 μm. The fact that bacteria can come so close to the clock limit shows us again what a good engineer evolution has been.

Note that the requirement by Salecker and Wigner is not in contrast with the possibility to make the *oscillator* of the clock very small; researchers have built oscillators made Ref. 944 of a single atom. In fact, such oscillations promise to be the most precise human built Page 1134 clocks. But the oscillator is only one part of any clock, as explained above.

In the real world, the clock limit can be tightened even more. The whole mass M cannot be used in the above limit. For clocks made of atoms, only the binding energy between atoms can be used. This leads to the so-called *standard quantum limit for clocks*; it limits the accuracy of their frequency ν by

$$\frac{\delta\nu}{\nu} = \sqrt{\frac{\Delta E}{E_{\text{tot}}}} \tag{688}$$

where $\Delta E = \hbar/T$ is the energy indeterminacy stemming from the finite measuring time T and $E_{\text{tot}} = NE_{\text{bind}}$ is the total binding energy of the atoms in the metre bar. So far, the quantum limit has not yet been achieved for any clock, even though experiments are getting close to it.

In summary, clocks exist only in the limit of $\hbar$ being negligible. In practice, the errors made by using clocks and metre bars can be made as small as required; it suffices to make the clocks large enough. Clock built into human brains comply with this requirement. We can thus continue our investigation into the details of matter without much worry, at

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

least for a while. Only in the last part of our mountain ascent, where the requirements for precision will be higher and general relativity will limit the size of physical systems, trouble will appear again: the impossibility to build precise clocks will then become a central issue.

Page 1401

Why are predictions so difficult, especially of the future?

> Future: that period of time in which our affairs prosper, our friends are true, and our happiness is assured.
>
> Ambrose Bierce

We have seen that predictions of the future are made difficult by nonlinearities and the divergence from similar conditions; we have seen that many particles make it difficult to predict the future due to the statistical nature of their initial conditions; we have seen that quantum theory makes it often hard to fully determine initial states; we have seen that a non-trivial space-time topology can limit predictability; finally, we will discover that black hole and similar horizons can limit predictability due to their one-way transmission of energy, mass and signals.

If due to the quantum of action perfect clocks do not exist, is determinism still the correct description of nature? Yes and no. We learned that all the mentioned limitations of clocks can be overcome for limited time intervals; in practice, these time intervals can be made so large that the limitations do not play a role in everyday life. As a result, in quantum systems both determinism and time remain applicable, as long as we do not extend it to infinite space and time. However, when extremely large dimensions and intervals need to be taken into account, quantum theory cannot be applied alone; in those cases, general relativity needs to be taken into account.

Page 1396

Decay and the golden rule

> I prefer most of all to remember the future.
>
> Salvador Dal ì

The decoherence of superposition of macroscopically distinct states plays an important role in another common process: the decay of unstable systems or particles. Decay is any spontaneous change. Like the wave aspect of matter, decay is a process with no classical counterpart. It is true that decay, including the ageing of humans, can be observed classically; however, its *origin* is a pure quantum effect.

Experiments show that the prediction of decay, like that of scattering of particles, is only possible on average, for a large number of particles or systems, never for a single one. These results confirm the quantum origin of the process. In every decay process, the superposition of macroscopically distinct states – in this case those of a decayed and an undecayed particle – is made to decohere rapidly by the interaction with the environment. Usually the 'environment' vacuum, with its fluctuations of the electromagnetic, weak and strong fields, is sufficient to induce decoherence. As usual, the details of the involved environment states are unknown for a single system and make any prediction for a specific system impossible.

Decay, including that of radioactive nuclei, is influenced by the environment, even

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

in the case that it is 'only' the vacuum. The statement can be confirmed by experiment. By enclosing a part of space between two conducting plates, one can change the degrees of freedom of the vacuum electromagnetic field contained between them. Putting an electromagnetically unstable particle, such as an excited atom, between the plates, indeed changes the lifetime of the particle. Can you explain why this method is not useful to lengthen the lifespan of humans?

Ref. 949

Challenge 1483 ny

What is the *origin* of decay? Decay is always due to tunnelling. With the language of quantum electrodynamics, we can say that decay is motion induced by the vacuum fluctuations. Vacuum fluctuations are random. The experiment between the plates confirms the importance of the environment fluctuations for the decay process.

For a system consisting of a large number N of identical particles, the decay is described by

$$\dot{N} = -\frac{N}{\tau} \quad \text{where} \quad \frac{1}{\tau} = \frac{2\pi}{\hbar} \left|\langle \psi_{\text{initial}} | H_{\text{int}} | \psi_{\text{final}} \rangle\right|^2 \,. \tag{689}$$

The decay is thus essentially an exponential one, independently of the details of the physical process. In addition, the decay time τ depends on the interaction and on the square modulus of the transition matrix element. This result was named the *golden rule* by Fermi,* because it works so well despite being an approximation whose domain of applicability is not easy to specify.

The golden rule leads to

$$N(t) = N_0 \, \mathrm{e}^{-t/\tau} \,. \tag{690}$$

Decay is thus predicted to follow an exponential law. For over half a century, all experiments confirmed this result.

On the other hand, when quantum theory is used to derive the golden rule, it is found that decay is exponential only in certain special systems. A calculation that takes into account higher order terms predicts two deviations from exponential decay for completely isolated systems: for short times, the decay rate should *vanish*; for long times, the decay rate should follow an *algebraic* – not an exponential – dependence on time, in some cases even with superimposed oscillations. After an intense experimental search, deviations for short times have been observed. The observation of deviations at long times are rendered impossible by the ubiquity of thermal noise. It turns out that decay is exponential only when the environment is noisy, the system made of many weakly interacting particles, or both. Since this is usually the case, the exceptional exponential decay becomes the (golden) rule in observation.

* Originally, the golden rule is a statement from the christian bible, namely the sentence 'Do to others what you want them to do to you'.

** 'Use your time.' *Tristia* 4, 3, 83

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Many thinkers advise to enjoy the present. As shown by perception research, what humans call 'present' has a duration of a few tenths of a second. This leads us to ask whether the *physical* present might have a duration as well.

Ref. 952

In everyday life, we are used to imagine that shortening the time taken to measure the position of a point object as much as possible will approach the ideal of a particle fixed at a given point in space. When Zeno discussed flight of an arrow, he assumed that this is possible. However, quantum theory changes the situation.

We know that the quantum of action makes rest an impossibility. However, the issue here is different: we are asking whether we can say that a moving system is at a given spot at a given time. In order to determine this, we could use a photographic camera whose shutter time can be reduced at will. What would we find? When the shutter time approaches the oscillation period of light, the sharpness of the image would decrease; in addition, the colour of the light would be influenced by the shutter motion. We can increase the energy of the light used, but the smaller wavelengths only shift the problem, they do not solve it. Worse, at extremely small wavelengths, matter becomes transparent, and shutters cannot be realized any more. Whenever we reduce shutter times as much as possible, observations become unsharp. Quantum theory thus does not confirm the naive expectation that shorter shutter times lead to sharper images. In contrast, the quantum aspects of nature show us that there is no way in principle to approach the limit that Zeno was discussing.

This counter-intuitive result is due to the quantum of action: through the indeterminacy relation, the smallest action prevents that moving objects are at a fixed position at a given time. Zeno's discussion was based on an extrapolation of classical physics into domains where it is not valid any more. Every observation, like every photograph, implies a *time average*: observations average interactions over a given time.* For a photograph, the duration is given by the shutter time; for a measurement, the average is defined by the details of the set-up. Whatever this set-up might be, the averaging time is never zero. There is no 'point-like' instant of time that describes the present. The observed *present* is always an average over a non-vanishing interval of time. The present has a duration in nature.

Why can we observe motion?

Zeno was thus wrong in assuming that motion is a sequence of specific positions in space. Quantum theory implies that motion is *not* the change of position with time. The investigation of the issue showed that this statement is only an approximation for low energies or for long observation times.

Why then can we describe motion in quantum theory? Quantum theory shows that motion is the low energy approximation of quantum evolution. Quantum evolution assumes that space and time measurements of sufficient precision can be performed. We know that for any given observation energy, we can build clocks and metre bars with much higher accuracy than required, so that quantum evolution is applicable in all cases. This is the case in everyday life.

Obviously, this pragmatic description of motion rests on the assumption that for any observation energy we can find a still higher energy used by the measurement instru-

Page 1141

* The discussion of the quantum Zeno effect does not change the conclusions of this section.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ments to define space and time. We deduce that if a highest energy would exist in nature, we would get into big trouble, as quantum theory would then break down. As long as energy has no limits, all problems are avoided, and motion remains a sequence of quantum observables or quantum states, whichever you prefer.

The assumption of energy without limit works extremely well; it lies at the basis of quantum theory, even though it is rather hidden. In the final part of our ascent, we will discover that there indeed is a maximum energy in nature, so that we will need to change our approach. However, this energy value is so huge that it does not bother us at all at this point of our exploration. But it will do so later on.

Page 1475

Rest and the quantum Zeno effect

The quantum of action implies that there is no rest in nature. Rest is always approximate, or a time average. For example, if an electron is bound, not freely moving, one can have the situation that the probability cloud, or density distribution, is stationary in time.

There is another apparent case of rest in quantum theory, the quantum Zeno effect. Usually, observation changes the system. However, for certain systems, observation can have the opposite effect.

– CS – more to be told – CS –

The quantum Zeno effect was partially observed by Wayno Itano and his group in 1990, and definitively observed by Mark Raizen and his group in 2001.

Ref. 953

In a fascinating prediction, Saverio Pascazio and his team have predicted that the quantum Zeno effect can be used to realize X-ray tomography of objects with the lowest radiation levels imaginable.

Ref. 954

Consciousness – a result of the quantum of action

In the pleasures of life, consciousness plays an essential role. Consciousness is our ability to observe what is going on in our mind. This activity, like any type of change, can itself be observed and studied. Obviously, consciousness takes place in the brain. If it were not, there would be no way to keep it connected with a given person. We know that each brain moves with over one million kilometres per hour through the cosmic background radiation; we also observe that consciousness moves along with it.

Page 870

The brain is a quantum system; it is based on molecules and electrical currents. The changes in consciousness that appear when matter is taken away from the brain – in operations or accidents – or when currents are injected into the brain – in accidents, experiments or misguided treatments – have been described in great detail by the medical profession. Also the observed influence of chemicals on the brain – from alcohol to hard drugs – makes the same point. The brain is a quantum system.

Magnetic resonance imaging can detect which parts of the brain work when sensing, remembering or thinking. Not only is sight, noise and thought processed in the brain; we can follow the processing on computer screens. The other, more questionable experimental method, positron tomography, works by letting people swallow radioactive sugar. It confirms the findings on the location of thought and on its dependence on chemical fuel. In addition, we already know that memory depends on the particle nature of matter.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

All these observations depend on the quantum of action.

Not only the consciousness of others, also your own consciousness is a quantum process. Can you give some arguments? Challenge 1484 ny

In short, we know that thought and consciousness are examples of motion. We are thus in the same situation as material scientists were before quantum theory: they knew that electromagnetic fields influence matter, but they could not say *how* electromagnetism was involved in the build-up of matter. We know that consciousness is made from the signal propagation and signal processing in the brain; we know that consciousness is an electrochemical process. But we do not know yet the details of *how* the signals make up consciousness. Unravelling the workings of this fascinating quantum system is the aim of neurological science. This is one of the great challenges of twenty-first century science.

It is sometimes claimed that consciousness is not a physical process. Every expert of motion should be able to convincingly show the opposite, even though the details of consciousness are not clear yet. Can you add a few arguments to the ones given here? Challenge 1485 ny

Why can we observe motion? – Again

Studying nature can be one of the most intense pleasures of life. All pleasures are based on the ability to observe motion. Our human condition is central to this ability. In our adventure so far we found that we experience motion only because we are of finite size, only because we are made of a large but finite number of atoms, only because we have a finite but moderate temperature, only because we are a mixture of liquids and solids, only because we are electrically neutral, only because we are large compared to a black hole of our same mass, only because we are large compared to our quantum mechanical wavelength, only because we have a limited memory, only because our brain forces us to approximate space and time by continuous entities, and only because our brain cannot avoid describing nature as made of different parts. If any of these conditions were not fulfilled we would not observe motion; we would have no fun studying physics.

In addition, we saw that we have these abilities only because our forefathers lived on Earth, only because life evolved here, only because we live in a relatively quiet region of our galaxy, and only because the human species evolved long after than the big bang.

If any of these conditions were not fulfilled, or if we were not animals, motion would not exist. In many ways motion is thus an illusion, as Zeno of Elea had claimed. To say the least, the observation of motion is a result of the limitations of the human condition. A complete description of motion and nature must take this connection into account. Before we do that, we explore a few details of this connection.

Curiosities and fun challenges about quantum experience

Most clocks used in everyday life, those built inside the human body and those made by humans, are electromagnetic. Any clock on the wall, be it mechanical, quartz controlled, radio or solar controlled, is based on electromagnetic effects. Do you know an exception? Challenge 1486 s

* *

The sense of smell is quite complex. For example, the substance that smells most badly to humans is *skatole*, also called *3-methylindole*. This is the molecule to which the human

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

nose is most sensitive. Skatole makes faeces smell bad; it is a result of haemoglobin entering the digestive tract through the bile. (In contrast to humans, skatole attracts flies; it is also used by some plants for the same reason.)

On the other hand, *small* levels of skatole do not smell bad to humans. It is also used by the food industry in small quantities to give smell and taste to vanilla ice cream.

* *

It is worth noting that human senses detect energies of quite different magnitudes. The eyes can detect light energies of about 1 aJ, whereas the sense of touch can detect only energies as large as about 10 μJ. Is one of the two systems relativistic? Challenge 1487 s

* *

Compared to all primates, the human eye is special: it is white, thus allowing others to see the direction in which one looks. Comparison with primates shows that the white colour has evolved to allow more communication between individuals. Ref. 955

* *

Even at perfect darkness, the eye does not yield a black impression, but a slightly brighter one, called *eigengrau*. This is a result of noise created inside the eye, probably triggered by spontaneous decay of rhodopsin, or alternatively, by spontaneous release of neurotransmitters.

* *

The high sensitivity of the ear can be used to hear light. To do this, take an empty 750 ml jam glass. Keeping its axis horizontal, blacken the upper half of the inside with a candle. The lower half should remain transparent. After doing this, close the jam glass with its lid, and drill a 2 to 3 mm hole into it. If you now hold the closed jam glass with the hole to your ear, keeping the black side up, and shining into it from below with a 50 W light bulb, something strange happens: you hear a 100 Hz sound. Why? Challenge 1488 s

* *

Most senses work already before birth. It is well-known that playing the violin to a pregnant mother every day during the pregnancy has an interesting effect. Even if nothing is told about it to the child, it will become a violin player later on.

* *

There is ample evidence that not using the senses is damaging. People have studied what happens when in the first years of life the vestibular sense – the one used for motion detection and balance restoration – is not used enough. Lack of rocking is extremely hard to compensate later in life. Equally dangerous is the lack of use of the sense of touch. Babies, like all small mammals, that are generally and systematically deprived of these experiences tend to violent behaviour during the rest of their life. Ref. 956

* *

Nature has invented the senses to increase pleasure and avoid pain. But neurologists have found out that nature has gone even further; there is a dedicated *pleasure system* in the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

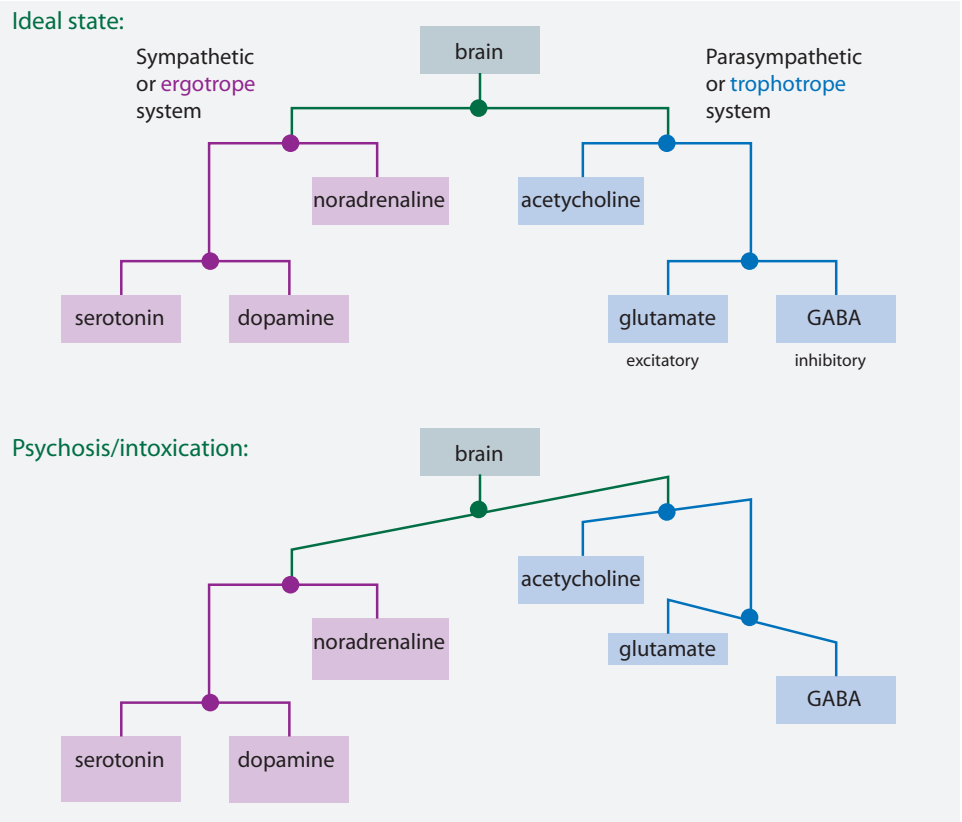

FIGURE 494 The 'neurochemical mobile' model of well-being, with one of the way it can get out of balance

brain, whose central parts are the ventral tegmental area in the midbrain and the nucleus accumbens in the forebrain. The two parts regulate each other mainly through *dopamine* and *GABA*, two important neurotransmitters. Research has shown that dopamine is produced whenever pleasure exceeds expectations. Nature has thus developed a special signal for this situation.

But well-being and pleasure are controlled by a larger number of neurotransmitters and by many additional regulation circuits. Researchers are trying to model the pleasure system with hundreds of coupled differential equations, with the distant aim being to understand addiction and depression, for example. On the other side, also simple models are possible. One, shown in Figure 494, is the 'neurochemical mobile' model of the brain. In this model, well-being is achieved whenever the six most important neurotransmitters are in relative equilibrium. The different possible departures from equilibrium, at each joint of the mobile, can be used to describe depression, schizophrenia, psychosis, the effect of nicotine or alcohol intake, alcohol dependency, delirium, drug addiction, detoxication, epilepsy and more.

Ref. 957

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Summary on pleasure

To increase pleasure and avoid pain, evolution has supplied the human body with numerous sensors and sensor mechanisms. In addition, it has also built a pleasure system deep into the brain.

In short, nature has invented pleasure as a guide for human behaviour. Now, all biological pleasure sensors and systems are based on chemistry and materials science. We therefore explore both fields.

Chapter 41

CHANGING THE WORLD WITH QUANTUM THEORY

Quantum theory has changed the world dramatically. The distribution of music, the possibilities of telecommunications and of the internet, and the progress in chemistry, material science, medicine and electronics would not have been possible without quantum theory. In the following, we give a short overview of these connections.

CHEMISTRY – FROM ATOMS TO DNA

It is an old truth that Schrödinger's equation contains all of chemistry.* With quantum theory, for the first time people were able to calculate the strengths of chemical bonds, and what is more important, the angle between them. Quantum theory thus explains the *shape* of molecules and thus indirectly, the shape of all matter.

To understand molecules, the first step is to understand atoms. The early quantum theorists, lead by Niels Bohr, spent a lot of energy in understanding their structure. The main result is that in atoms with more than one electron, the various electron clouds form spherical layers around the nucleus. The layers can be grouped into groups of related clouds, called *shells*. For electrons outside a given shell, the nucleus and the inner shells, the atomic *core*, can often be approximated as a single charged entity.

Shells are numbered from the inside out. This *principal quantum number*, usually written n, is deduced and related to the quantum number that identifies the states in the hydrogen atom.

Quantum theory shows that the first shell has room for two electrons, the second for 8, the third for 18, and the general n-th shell for $2n^2$ electrons. A way to picture this connection is shown in Figure 497. It is called the *periodic table of the elements*. The standard way to show the table is shown in Appendix E.

Ref. 972
Page 1351

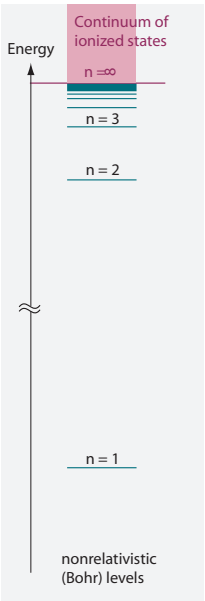

FIGURE 495 The principal quantum numbers in hydrogen

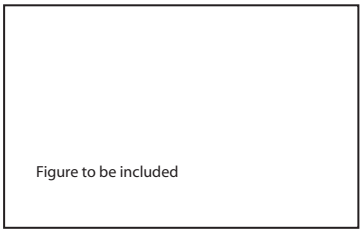

FIGURE 496 Atoms and dangling bonds

Bonds

When atoms approach each other, their electron clouds are deformed and mixed. The reason for these changes is the combined influence of the two nuclei. The effect for these changes is highest for the outermost electrons: they form chemical bonds.

The cloud overlap lead to a gain in energy. That is the reason that fire is hot. After the energy has been released, a certain distance between the atoms appears, as shown in Figure 498. A lower distance would lead to electrostatic repulsion between the atomic cores.

Many atoms can bind to several neighbours. In this case, energy minimization leads to specific bond angles, as shown in Figure 499. Do you remember those funny pictures of school chemistry about orbitals and dangling bonds? Well, dangling bonds can now

Ref. 973

* The correct statement is: the *Dirac* equation contains all of chemistry. The relativistic effects that distinguish the two equations are necessary, for example, to understand why gold is yellow and does not like to react or why mercury is liquid.

Ref. 958

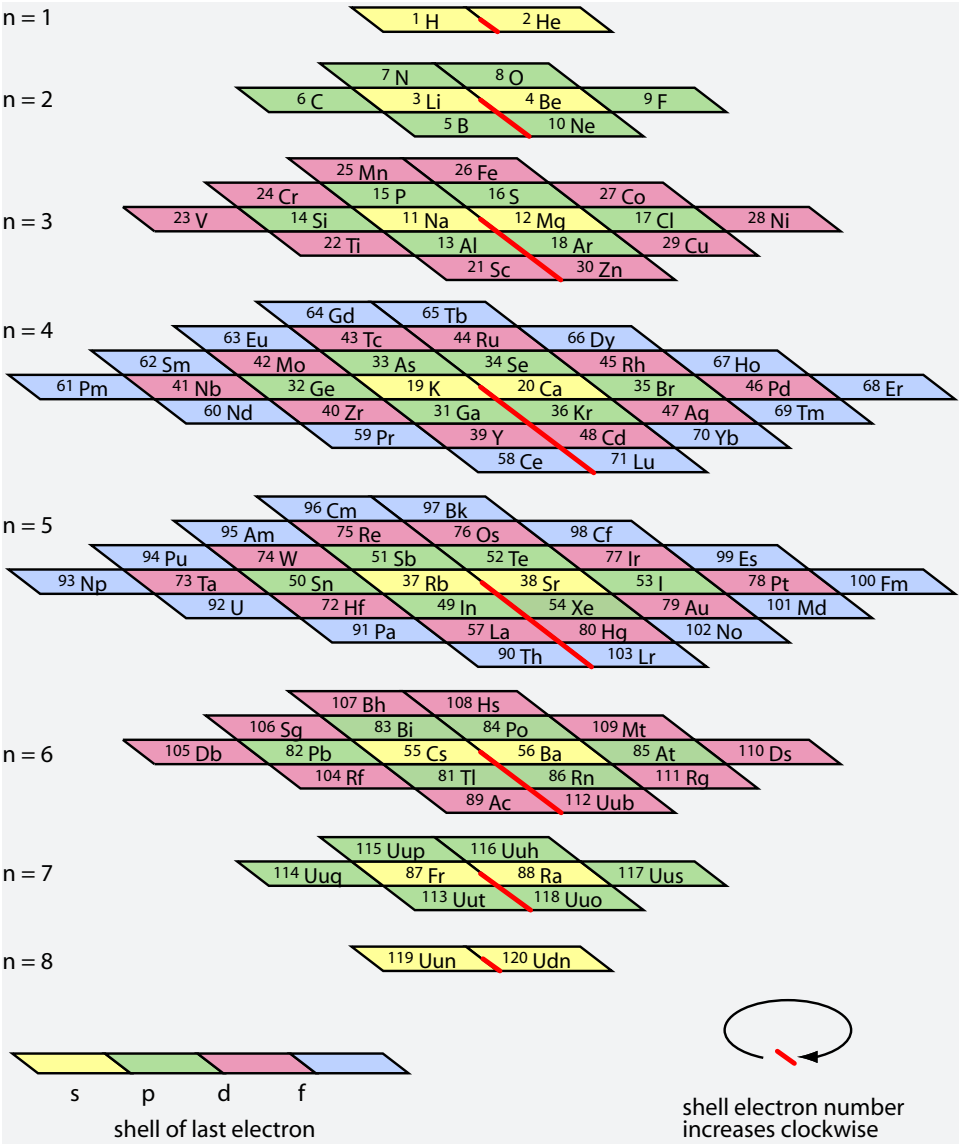

FIGURE 497 An unusual form of the periodic table of the elements

be seen. Several groups were able to image them using scanning force or scanning tunnelling microscopes. Ref. 974

The repulsion between the clouds of each bond explains why angle values near that of tetrahedral skeletons ($2 \arctan\sqrt{2} = 109.47°$) are so common in molecules. For example, the H-O-H angle in water molecules is 107°. Challenge 1489 e

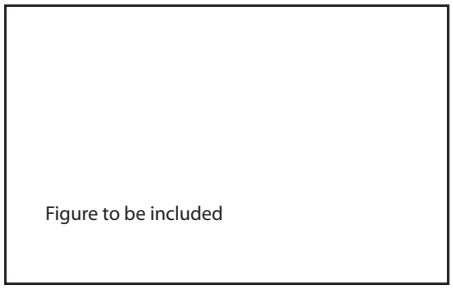

FIGURE 498 The forming of a chemical bond between two atoms

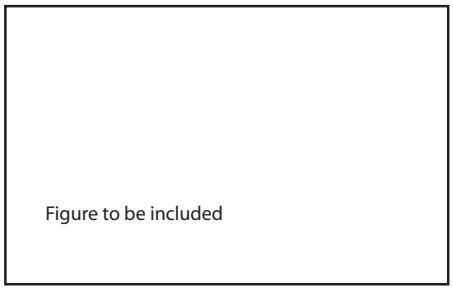

FIGURE 499 Chemical bonds between several atoms

Ribonucleic acid and deoxyribonucleic acid

Probably the most fascinating molecule of all is human deoxyribonucleic acid. The nucleic acids where discovered in 1869 by the Swiss physician Friedrich Miescher (1844–1895) in white blood cells. In 1874 he published an important study showing that the molecule is contained in spermatozoa, and discussed the question if this substance could be related to heredity. With his work, Miescher paved the way to a research field that earned many colleagues Nobel Prizes (though not for himself).

DNA is a polymer, as shown in Figure 500, and is among the longest molecules known. Human DNA molecules, for example, can be up to 10 cm in length. It consists of a double helix of sugar derivates, to which four nuclei acids are attached in irregular order. Nowadays, it is possible to image single DNA molecules, as shown in Figure 501.

Ref. 960

At the start of the twentieth century it became clear that Desoxyribonukleinsäure (DNS) – translated as deoxyribonucleic acid (DNA) into English – was precisely what Erwin Schrödinger had predicted to exist in his book *What Is Life?* As central part of the chromosomes contained the cell nuclei, DNA is responsible for the storage and reproduction of the information on the construction and functioning of Eukaryotes. The information is coded in the ordering of the four nucleic acids. DNA is the carrier of hereditary information. DNA determines in great part how the single cell we all once have been grows into the complex human machine we are as adults. For example, DNA determines the hair colour, predisposes for certain illnesses, determines the maximum size one can grow to, and much more. Of all known molecules, human DNA is thus most intimately related to human existence. The large size of the molecules is the reason that understanding its full structure and its full contents is a task that will occupy scientists for several

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

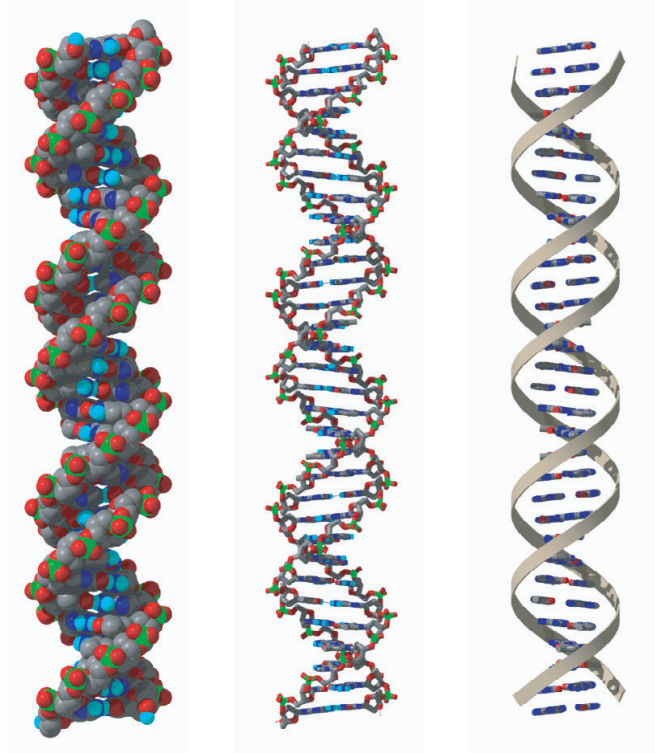

FIGURE 500 Several ways to picture B-DNA, all in false colours (© David Deerfield)

generations to come.

Curiosities and fun challenges about chemistry

One of the most fascinating topics of chemistry is that of poisons. Over 50 000 poisons are known, starting with water (usually kills when drunk in amounts larger than about 10 l) and table salt (can kill when 100 g are ingested) up to polonium 210 (kills in doses as low as 5 ng, much less than a spec of dust). Most countries have publicly accessible poison databases; see for example www.gsbl.de.

Challenge 1490 e

Can you imagine why 'toxicology', the science of poisons, actually means 'bow science' in Greek?

However, not all poisons are chemical. Paraffin and oil for lamps, for example, regularly kill children because the oil enters the lung and forms a thin film over the alveoles, preventing oxygen intake. This so-called *lipoid pneumonia* can be deadly even when only a single drop of oil is in the mouth and then inhaled by a child.

* *

Challenge 1491 ny

MATERIALS SCIENCE

> Did you know that one cannot use a boiled egg as a toothpick?
>
> Karl Valentin

It was mentioned several times that the quantum of action explains all properties of matter. Many researchers in physics, chemistry, metallurgy, engineering, mathematics and biology have cooperated in the proof of this statement. In our mountain ascent we have only a little time to explore this vast topic. Let us walk through a selection.

Why does the floor not fall?

We do not fall through the mountain we are walking on. Some interaction keeps us from falling through. In turn, the continents keep the mountains from falling through them. Also the liquid magma in the Earth's interior keeps the continents from sinking. All these statements can be summarized in two ideas: Atoms do not penetrate each other: despite being mostly empty clouds, atoms keep a distance. And atoms cannot be compressed in size. Both properties are due to Pauli's exclusion principle between electrons. The fermion character of electrons avoids that atoms shrink or interpenetrate – on Earth.

Page 1068

Not all floors keep up due to the fermion character of electrons. Atoms are not impenetrable at all pressures. At sufficiently large pressures, atoms can collapse, and form new types of floors. Some floors are so exciting to study that people have spent their whole life to understand why they do not fall, or when they do, how it happens: the surfaces of stars.

In most stars, the radiation pressure of the light plays only a minor role. Light pressure does play a role in determining the size of red giants, such as Betelgeuse; but for average stars, light pressure is negligible.

In most stars, such as in the Sun, the gas pressure takes the role which the incompressibility of solids and liquids has for planets. The pressure is due to the heat produced by the nuclear reactions.

The next star type appears whenever light pressure, gas pressure and the electronic Pauli pressure cannot keep atoms from interpenetrating. In that case, atoms are com-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

pressed until all electrons are pushed into the protons. Protons then become neutrons, and the whole star has the same mass density of atomic nuclei, namely about $2.3 \cdot 10^{17}\,\mathrm{kg/m^3}$. A drop weighs about 200 000 tons. In these so-called *neutron stars*, the floor – or better, the size – is also determined by Pauli pressure; however, it is the Pauli pressure between neutrons, triggered by the nuclear interactions. These neutron stars are all around 10 km in radius.

Page 1237

If the pressure increases still further, the star becomes a black hole, and never stops collapsing. Black holes have no floor at all; they still have a constant size though, determined by the horizon curvature.

Page 604

The question whether other star types exist in nature, with other floor forming mechanisms – such as quark stars – is still a topic of research.

Rocks and stones

If a geologist takes a stone in his hands, he is usually able to give, within an error of a few per cent, the age of the stone. The full story forms a large part of geology, but the general lines should be known to every physicist.

Every stone arrives in your hand through the *rock cycle*. The rock cycle is a process that transforms magma from the interior of the Earth into *igneous (or magmatic) rocks* through cooling and crystallization. Igneous rocks, such as basalt, can transform through erosion, transport and deposition into *sedimentary rocks*. Either of these two rock types can be transformed through high pressures or temperatures into *metamorphic rocks*, such as marble. Finally, most rocks are generally – but not always – transformed back into magma.

The full rock cycle takes around 110 to 170 million years. For this reason, rocks that are older than this age are much less common on Earth. Any stone is the product of erosion of one of the rock types. A geologist can usually tell, simply by looking at it, the type of rock it belongs to; if he sees the original environment, he can also give the age, without any laboratory.

Some interesting crystals

Every crystal, like every structure in nature, is the result of growth. Every crystal is thus the result of motion. To form a *regular* crystal, the required motion is a *slow* growth of facets from the liquid (or gaseous) basic ingredients. The growth requires a certain pressure, temperature and temperature gradient for a certain time. In the case of gemstones, the conditions are usually quite extreme; this is the reason for their durability. The conditions are realized in specific rocks deep inside the Earth, where the growth process can take thousands of years. Mineral crystals can form in all three types of rocks: igneous (magmatic), metamorphic, and sedimentary. Other crystals can be made in the laboratory in minutes, hours or days and have led to a dedicated industry. Only a few crystals grow from liquids at standard conditions; examples are gypsum and several other sulfates, which can be crystallized at home, potassium bitartrate, which appears in the making of wine, and the crystals grown inside plants or animals, such as teeth, bones or magnetosensitive crystallites.

Page 1153

Growing, cutting, treating and polishing crystals is an important industry. Especially the growth of crystals is a science in itself. Can you show with pencil and paper that

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 97 The types of rocks and stones

Type	Properties	Subtype	Example
Igneous rocks (magmatites)	formed from magma, 95% of all rocks	volcanic or extrusive	basalt (ocean floors, Giant's Causeway), andesite, obsidian
		plutonic or intrusive	granite, gabbro
Sedimentary rocks (sedimentites)	often with fossils	clastic	shale, siltstone, sandstone
		biogenic	limestone, chalk, dolostone
		precipitate	halite, gypsum
Metamorphic rocks (metamorphites)	transformed by heat and pressure	foliated	slate, schist, gneiss (Himalayas)
		non-foliated (grandoblastic or hornfelsic)	marble, skarn, quartzite
Meteorites	from the solar system	rock meteorites	
		iron meteorites	

Challenge 1496 e only the slowest growing facets are found in crystals? In the following, a few important crystals are presented.

* *

Quartz, amethyst (whose colour is due to radiation and iron Fe^{4+} impurities), citrine (whose colour is due to Fe^{3+} impurities), smoky quartz (with colour centres induced by radioactivity), agate and onyx are all forms of crystalline silicon dioxyde or SiO_2. Quartz forms in igneous and in magmatic rocks; crystals are also found in many sedimentary rocks. Quartz crystals can be larger than human. By the way, most amethysts lose their colour with time, so do not waste money buying them.

Quartz is the most common crystal on Earth's crust and is also grown synthetically for many high-purity applications. The structure is rombohedral, and the ideal shape is a six-sided prism with six-sided pyramids at its ends. Quartz melts at 1986 K and is piezo- and pyroelectric. Its piezoelectricity makes it useful as electric oscillator and filter. A film of an oscillating clock quartz is shown on page page 228. Quartz is also used for glass production, in communication fibres, for coating of polymers, in gas lighters, as source of silicon and for many other applications.

* *

Corundum, ruby and sapphire are crystalline variations of alumina. Corundum is pure and colourless Al_2O_3, ruby is Cr doped and blue sapphire is Ti or Fe doped. They have trigonal crystal structure and melt at 2320 K. Natural gems are formed in metamorphic

rocks. Yellow, green, purple, pink, brown, grey and salmon-coloured sapphires also exist, when doped with other impurities. The colours of natural sapphires, like that of many other gemstones, are often changed by baking and other treatments.

Corundum, ruby and sapphire are used in jewelry, as heat sink and growth substrate, and for lasers. Corundum is also used as scratch-resistant 'glass' in watches. Ruby was the first gemstone that was grown synthetically in gem quality, in 1892 by Auguste Verneuil (1856-1913), who made his fortune in this way.

Tourmaline is a frequently found mineral and can be red, blue, green, orange, yellow, pink or black, depending on its composition. The chemical formula is astonishingly complex and varies from type to type. Tourmaline has trigonal structure and usually forms columnar crystals that have triangular cross-section. It is only used in jewelry. Paraiba tourmalines, a very rare type of green or blue tourmaline, are among the most beautiful gemstones and are, if untreated, more expensive than diamonds.

FIGURE 508 Natural bicoloured tourmaline found in Paprok, Afghanistan, picture size 9 cm (© Rob Lavinsky)

Garnets are a family of compounds of the type $X_2Y_3(SiO_4)_3$. They have cubic crystal structure. They can have any colour, depending on composition. They show no cleavage and their common shape is a rhombic dodecahedron. Some rare garnets differ in colour when looked at in daylight or in incandescent light. Natural garnets form in metamorphic rocks and are used in jewelry, as abrasive and for water filtration. Synthetic garnets are used in many important laser types.

* *

Alexandrite, a chromium-doped doped variety of chrysoberyl, is used in jewelry and in lasers. Its composition is $BeAl_2O_4$; the crystal structure is orthorhombic. Chrysoberyl melts at 2140 K. Alexandrite is famous for its colour-changing property: it is green in daylight or fluorescent light but amethystine in incandescent light, as shown in Figure 510. The effect is due to its chromium content: the ligand field is just between that of chromium in red ruby and that in green emerald. A few other gems also show this effect, in particular the rare blue garnet and some Paraiba tourmalines.

Diamond is a metastable variety of graphite, thus pure carbon. Theory says that graphite is the stable form; practice says that diamond is still more expensive. In contrast to graphite, diamond has face-centred cubic structure, is a large band gap semiconductor and typically has octahedral shape. Diamond burns at 1070 K; in the absence of oxygen it converts to graphite at around 1950 K. Diamond can be formed in magmatic and in metamorphic rocks. Diamonds can be synthesized in reasonable quality, though gemstones of large size and highest quality are not yet possible. Diamond can be coloured and be doped to achieve electrical conductivity in a variety of ways. Diamond is mainly used in jewelry, for hardness measurements and as abrasive.

Silicon, Si, is not found in nature in pure form; all crystals are synthetic. The structure is face-centred cubic, thus diamond-like. It is moderately brittle, and can be cut in thin wafers which can be further thinned by grinding or chemical etching, even down to a thickness of 10 µm. Being a semiconductor, the band structure determines its black colour, its metallic shine and its brittleness. Silicon is widely used for silicon chips and electronic semiconductors. Today, human-sized silicon crystals can be grown free of dislocations and other line defects.

Teeth are the structures that allowed animals to be so successful in populating the Earth. They are composed of several materials; the outer layer, the *enamel*, is 97% hydroxylapatite, mixed with a small percentage of two proteins groups, the amelogenins and the enamelins. The growth of teeth is still not fully understood; neither the molecular level nor the shape-forming mechanisms are completely clarified. Hydroxylapatite is soluble in acids; addition of fluorine ions changes the hydroxylapatite to fluorapatite and greatly reduces the solubility. This is the reason for the use of fluorine in tooth paste.

Hydroxylapatite (or hydroxyapatite) has the chemical formula $Ca_{10}(PO_4)_6(OH)_2$, possesses hexagonal crystal structure, is hard (more than steel) but relatively brittle. It occurs as mineral in sedimentary rocks (see Figure 522), in bones, renal stones, bladders tones, bile stones, atheromatic plaque, cartilage arthritis and teeth. Hydroxylapatite is mined as a phosphorus ore for the chemical industry, is used in genetics to separate single and double-stranded DNA, and is used to coat implants in bones.

FIGURE 522 Hydroxylapatite found in Snarum, Norway, picture size 5 cm (© Rob Lavinsky)

FIGURE 523 The main and the reserve teeth on the jaw bone of a shark, all covered in hydroxylapatite, picture size 15 cm (© Peter Doe)

* *

Pure metals, such as gold, silver and even copper, are found in nature, usually in magmatic rocks. But only a few metallic compounds form crystals, such as pyrite. Monocrystalline pure metal crystals are all synthetic. Monocrystalline metals, for example iron, aluminium, gold or copper, are extremely soft and ductile. Either bending them repeatedly – a process called cold working – adding impurities, or forming alloys makes them hard and strong. Stainless steel, a carbon-rich iron alloy, is an example that uses all three processes.

* *

There are about 4000 known mineral types. On the other hand, there are ten times as many obsolete mineral names, namely around 40 000. An official list can be found in various places on the internet, including www.mindat.org or www.minieralienatlas.de. To explore the world of crystal shapes, see the www.smorf.nl website. Around new 40 minerals are discovered each year. Searching for minerals and collecting them is a fascinating pastime.

How can one look through matter?

Quantum theory showed us that all obstacles have only finite potential heights. That leads to a question: Is it possible to look through matter? For example, can we see what is hidden inside a mountain? To be able to do this, we need a signal which fulfils two conditions: it must be able to *penetrate* the mountain, and it must be scattered in a *material-dependent* way. Table 98 gives an overview of the possibilities.

We see that many signals are able to penetrate a mountain. However, only sound or radio waves provide the possibility to distinguish different materials, or to distinguish solids from liquids and from air. In addition, any useful method requires a large number of signal sources and of signal receptors, and thus a large amount of cash. Will there ever be a simple method allowing to look into mountains as precisely as X-rays allow to study human bodies? For example, will it ever be possible to map the interior of the pyramids?

Challenge 1497 s A motion expert like the reader should be able to give a definite answer.

One of the high points of twentieth century physics was the development of the best method so far to look into matter with dimensions of about a metre or less: magnetic

Page 1222 resonance imaging. We will discuss it later on.

The other modern imaging technique, ultrasound imaging, is getting more and more criticized. It is much used for prenatal diagnostics of embryos. However, studies have found that ultrasound produces extremely high levels of audible sound to the baby, especially when the ultrasound is switched on or off, and that babies react negatively to this loud noise.

What is necessary to make matter invisible?

You might have already imagined what adventures would be possible if you could be invisible for a while. Some years ago, a team of Dutch scientists found a material that

Ref. 959 can be switched from mirror mode to transparent mode using an electrical signal. This seems a first step to realize the dream to become invisible at will.

In 2006, researchers made the headlines in the popular press by claiming that they could build a cloak of invisibility. A blatant lie.

Nature shows us how to be invisible. An object is invisible if it has no surface, no absorption and small size. In short, invisible objects are either small clouds or composed of them. Most atoms and molecules are examples. Homogeneous non-absorbing gases

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 98 Signals penetrating mountains and other matter

Signal	Penetration depth in stone	Achieved resolution	Material dependence	Use
Matter				
Diffusion of water or liquid chemicals	*c.* 5 km	*c.* 100 m	medium	mapping hydrosystems
Diffusion of gases	*c.* 5 km	*c.* 100 m	medium	studying vacuum systems
Electromagnetism				
Infrasound and earthquakes	100 000 km	100 km	high	mapping of Earth crust and mantle
Sound, explosions, seismic waves	0.1 – 10 m	*c.* $\lambda/100$	high	oil and ore search, structure mapping in rocks, searching for underwater treasures in sunken ship with sub-bottom-profilers
Ultrasound		1 mm	high	medical imaging, acoustic microscopy
Static magnetic field variation			medium	cable search, cable fault localization, search for structures and metal inside soil, rocks and seabed
Electrical currents				soil and rock investigations, search for tooth decay
Electromagnetic sounding, 0.2 – 5 Hz				soil and rock investigations in deep water and on land
Radio waves	10 m	30 m to 1 mm	small	soil radar (up to 10 MW), magnetic imaging, research into solar interior
Ultra-wide band radio	10 cm	1 mm	sufficient	searching for wires and tubes in walls, breast cancer detection
Mm and THz waves	below 1 mm	1 mm		see through clothes, envelopes and teeth Ref. 961
Infrared	*c.* 1 m	0.1 m	medium	mapping of soil over 100 m
Visible light	*c.* 1 cm	0.1 µm	medium	imaging of many sorts
X-rays	a few metre	5 µm	high	medicine, material analysis, airports
Muons created by cosmic radiation	up to *c.* 300 m	0.1 m	small	finding caves in pyramids, imaging interior of trucks
Weak interactions				
Neutrino beams	light years	zero	very weak	studies of Sun
Strong interactions				
Cosmic radiation	1 m to 1 km			
Radioactivity	1 mm to 1 m			airport security checks
Gravitation				
Variation of g		50 m	low	oil and ore search

also realize these conditions. That is the reason that air is (usually) invisible. When air is not homogeneous, it can be visible, e.g. above hot surfaces.

In contrast to gases, solids or liquids do have surfaces. Surfaces are usually visible, even if the body is transparent, because the refractive index changes there. For example, quartz can be made so transparent that one can look through 1 000 km of it; pure quartz is thus more transparent than usual air. Still, objects made of pure quartz are visible to the eye due to their refractive index. Quartz can be invisible only when submerged in liquids with the same refractive index.

A frequent lie – used to get funding – is that objects can be made invisible by covering them with metamaterials. The impossibility has been already shown earlier on.

Page 756

In other words, to become invisible, we must transform ourselves into a diffuse cloud of non-absorbing atoms. On the way to become invisible, we would lose all memory and all genes, in short, we would lose all our individuality. But an individual cannot be made of gas. An individual is defined through its boundary. There is no way that we can be invisible; a reversible way to perform the feat is also impossible. In summary, quantum theory shows that only the dead can be invisible.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The causes of colour

Quantum theory explains all colours in nature. Here is a summary of the various mechanisms one observes.*

TABLE 99 Causes of colour

Colour type	Example	Details
Class I: Colours due to simple excitations		
	**1. Incandescence**	
	Carbon arc lamp, hot steel, lightbulb wire, most stars, magma, lava, hot melts	colours are due to continuous spectrum emitted by all hot matter; colour sequence, given by Wien's rule, is black, red, orange, yellow, white, blue-white (molten lead and silver © Graela)
	Wood fire, candle	wood and wax flames are yellow due to incandescence if carbon-rich and oxygen-poor
	White fireworks, flashlamp, sparklers	due to metals burning to oxide at high temperature, such as magnesium, zinc, iron, aluminium or zirconium (sparkler © Sarah Domingos)
	2. Atomic gas excitations	
	Red neon lamp, blue argon lamp, UV mercury lamp, yellow sodium street lamps, most gas lasers, metal vapour lasers, some fluorescence	colours are due to transitions between atomic energy levels (gas discharges © Pslawinski)
	Aurora, triboluminescence in scotch tape, crystalloluminescence in strontium bromate	in air, blue and red colours are due to atomic and molecular energy levels of nitrogen, whereas green, yellow, orange colours are due to oxygen (aurora © Jan Curtis)
	Lightning, arcs, sparks, coloured fireworks, most coloured flames, some electroluminescence	colour lines are due to energy levels of highly excited atoms (flames of K, Cu, Cs, B, Ca © Philip Evans)

* See also the fascinating book by Kurt Nassau, *The Physics and Chemistry of Color – the fifteen causes of color*, J. Wiley & Sons, 1983, and the excellent webexhibits.org/causesofcolour website.

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
	3. Vibrations and rotations of molecules	
	Bluish water, blue ice when clear, violet iodine, red-brown bromine, yellow-green chlorine, red flames from CN or blue-green flames from CH, some gas lasers	colours are due to quantized levels of rotation and vibrations in molecules (blue iceberg © Marc Shandro)
Class II: Colours due to ligand field effects		
	**4. Transition metal compounds**	
	Green malachite $Cu_2CO_3(OH)_2$, blue cobalt oxide, blue azurite $Cu_3(CO_3)_2(OH)_2$, red to brown hematite Fe_2O_3, green MnO, white $Mn(OH)_2$, brown manganite, chrome green Cr_2O_3, green praesodymium, pink europium and yellow samarium compounds, piezochromic and thermochromic $Cr_2O_3 - Al_2O_3$ UV and electron phosphors, scintillation, some fluorescence, some lasers	colours are due to electronic states of the ions; phosphors are used in cathodes tubes for TV/computer displays and on fluorescent lamp tubes (green malachite on yellow kasolite, a uranium mineral, picture width 5 mm, found in Kolwezi, Zaire/Congo, © Stephan Wolfsried, television shadow mask photo © Planemad)
	5. Transition metal impurities	
	Ruby, emerald, alexandrite, perovskites, corresponding lasers	electronic states of transition metal ions are excited by light and thus absorb specific wavelengths (ruby on calcite from Mogok, Myanmar, picture width 3 cm, © Rob Lavinsky)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
Class III: Colours due to molecular orbitals		
	6. Organic compounds	
	Red haemoglobin in blood, green chlorophyll in plants, yellow or orange carotenes in carrots, flowers and yellow autumn leaves, red or purple anthocyanins in berries, flowers and red autumn leaves, blue indigo, red lycopene in tomatoes, red meat from iron-containing myoglobin, brown glucosamine in crust of baked food, brown tannins, black eumelanin in human skin, hair and eye, iron-rich variation pheomelanin in redheads, black melanin also in cut apples and bananas as well as in movable sacks in chameleons, brown-black asphalt, some fluorescence, chemiluminescence, phosphorescence, halochromism, electrochromism and thermochromism, dye lasers	colours are due to conjugated π-bonds, i.e. to alternating single and double bonds in molecules; floral pigments are almost all anthocyanins, betalains or carotenes; used in colourants for foods and cosmetics, in textile dyes, in electrochromic displays, in inks for colour printers, in photosensitizers (narcissus © Thomas Lüthi)
	Glow-worms, deap-sea fish, bacteria, funghi	bioluminescence is due to excited molecules, generally called *luciferines* (angler fish, length 4.5 cm, © Steve Haddock)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
	**7. Inorganic charge transfer**	
	Blue sapphire, blue lapis lazuli, green amazonite, brown-black magnetite Fe_3O_4 and most other iron minerals (colouring basalt black, beer bottles brown, quartz sand yellow, and many other rocks with brown or red tones), black graphite, purple permanganate, orange potassium dichromate, yellow molybdates, red hematite Fe_2O_3, black graphite, some fluorescence	light induces change of position of an electron from one atom to another; for example, in blue sapphire the transition is between Ti and Fe impurities; many paint pigments use charge transfer colours; fluorescent analytical reagents are used in molecular medicine and biology (magnetite found in Laach, Germany, picture width 10 mm, © Stephan Wolfsried)
Class IV: Colours due to energy band effects		
	8. Metallic bands	
	Gold (green in transmission), pyrite, iron, brass, alloys, silver, copper, ruby glass	colours in reflection and in transmission are due to transitions of electrons between overlapping bands (saxophone © Selmer)
	9. Pure semiconductor bands	
	Silicon, GaAs, black galena PbS, red cinnabar HgS, cadmium yellow CdS, black CdSe, red CdS_xSe_{1-x}, white ZnO, orange vermillion HgS, colourless diamond, black to gold piezochromic SmS	colour due to electron transitions between separate bands; colour series is black, red, orange, yellow, white/colourless; some used as pigments
	10. Doped semiconductor bands	
	Blue, yellow, green and black diamond; LEDs; semiconductor lasers; solar cells; ZnS and $Zn_xCd_{1-x}S$ based and other phosphors	colours are due to transitions between dopants and semiconductor bands (e.g. blue diamond: boron accepters, black diamond: nitrogen donors) (quantum dots © Andrey Rogach)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
	11. Colour centres	
	Amethyst, smoky quartz, fluorite, green diamonds, blue, yellow and brown topaz, brown salt, purple colour of irradiated glass containing Mn^{2+}, lyoluminescence, some fluorescence, F-centre lasers	colours due to colour centres, i.e. to electrons or to holes bound at crystal vacancies; colour centres are usually are created by radiation (amethyst © Rob Lavinsky)
	Some light-dependent sunglasses	the photochrmoic colouring is due to colour centres formed by the UV light of the Sun
Class V: Colours due to physical and geometrical optics		
	12. Dispersive refraction and polarization	
	Cut diamond, cut zirconia, halos and sun dogs formed by ice crystals in the air	spectral decomposition (sparkle or 'fire' of gemstones) is due to dispersion in crystals (zirconia photo © Gregory Phillips)
	Rainbow	colours of primary and secondary bow are due to dispersion in water droplets
	Green flash	dispersion in the atmosphere shifts the sun colours
	13. Scattering	
	Blue sky, blue colouring of distant mountains, red sunset; colour intensification by pollution; blue quartz	blue light is scattered more than red light by Rayleigh scattering, when scatterers (molecules, dust) are smaller than the wavelength of light (Tokyo sunset © Altus Plunkett, blue quartz © David Lynch)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
	White colour of hair, milk, beer foam, clouds, fog, cigarette smoke coming out of lungs, snow, whipped cream, shampoo, stars in gemstones	the white colour is due to wavelength-independent Mie scattering, i.e. scattering at particles larger than the wavelength of light (snow man © Andreas Kostner)
	Blue human skin colour in cold weather, blue and green eyes in humans, blue monkey skin, blue turkey necks, most blue fish, blue reptiles, blue cigarette smoke	Tyndall blue colours are due to scattering on small particles in front of a dark background (blue poison frog *Dendrobates azureus* © Lee Hancock)
	Ruby glass	the red colour of Murano glass is due to scattering by tiny colloidal gold particles included in the glass in combination with the metallic band structure of gold (ruby glass © murano-glass-shop.it)
	Nonlinearities, Raman effect, potassium dihydrogen phosphate (KDP)	frequency-shifting scattering, second harmonic generation and other nonlinearities of certain materials change the colour of light impinging with high intensities (800 nm to 400 nm frequency doubling ring laser © Jeff Sherman)
	14. Interference (without diffraction)	
	Nacre, oil films, soap bubbles, coatings on camera lenses, eyes of cats in the dark, wings of flies and dragonflies, fish scales, some snakes, pearls	thin film interference produces a standard colour sequence that allows precise thickness determination (abalone shell © Anne Elliot)
	Polarization colours of thin layers of birefringent crystals or thicker layers of stressed polymers	due to interference, as shown by the dependence on layer thickness

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
	Supernumerary rainbows (see page 726)	due to interference, as shown by the dependence on drop size
	Iridescent beetles, butterflies and bird feathers, iridescent colours on banknotes and on cars	due to scattering at small structures or at nanoparticles, as shown by the angular dependence of the colour (mallard duck © Simon Griffith)
15. Diffraction (with interference)		
	Opal	colours are due to the tiny spheres included in the water inside the opal; colours can change if the opal dries out (polished Brazilian opal © Opalsnopals)
	Aureole, glory, corona	colours are due to diffraction at the tiny mist droplets (aeroplane condensation cloud iridescence © Franz Kerschbaum)
	Diffraction gratings, CDs, vinyl records, some beetles and snakes	colours are due to diffraction and interference at tiny, regular pits (CD illuminated by flashlamp © Alfons Reichert)
	Cholesteric liquid crystals, certain beetles	colours are due to diffraction and interference in internal material layers
	photonic crystals	a modern research topic
Class VI: Colours due to eye limitations		
Fechner colours, as on lite.bu.edu/vision/applets/Color/Benham/Benham.html	Benham's top	colours are due to different speed response of different photoreceptors
Internal colour production when eyes are stimulated	Phosphenes	occur through pressure (rubbing, sneeze), or with electric or magnetic fields
Polarization colours	Haidinger's brush	see page 730
Colour illusions, as on www.psy.ritsumei.ac.jp/~akitaoka/color9e.html	Appearing and disappearing colours	effects are due to combinations of brain processing and eye limitations

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 99 Causes of colour (continued)

Colour type	Example	Details
False colour output, as described on page 764	Red light can be seen as green	observable with adaptive optics, if red light is focused on a green-sensitive cone
Colour-blind or 'daltonic' person, see page 771, with reduced colour spectrum	Protan, deutan or tritan	each type limits colour perception in a different way

The above table tries to include all colours that appear in everyday life. (Can you find one that is missing?) Some issues are still topic of research. For example, until recently it was unclear why exactly asphalt is black. The exact structure of the chemical compounds, the *asphaltenes*, that produce the very dark brown colour was unknown. Recent research has settled this question.

Challenge 1498 s

Ref. 977

Colours fascinate. Fascination also means business; indeed, a large part of the chemical industry is dedicated to synthesizing colourants for paints, clothes, food and cosmetics. Also evolution uses the fascination of colours for its own business: propagating life. The specialists in this domain are the flowering plants. The chemistry of colour production in plants is extremely involved and at least as interesting as the production of colours in factories. Practically all flower colourants, from white, yellow, orange, red to blue, are from three chemical classes: the carotenoids, the anthocyanins (flavonoids) and the betalains. These colourants are stored in petals inside dedicated containers, the *vacuoles*. There are many good review articles giving more details.

Ref. 975

Even though colours are common in plants and animals, most higher animals do not produce many colourants themselves. For example, humans produce only one colourant: *melanin*. (*Hemoglobin*, which colours blood red, is not a dedicated colourant, but transports the oxygen from the lungs through the body. Also the pink *myoglobin* in the muscles is not a dedicated colourant.) Many higher animals, such as birds, need to *eat* the colourants that are so characteristic for their appearance. The yellow colour of legs of pigeons is an example. It has been shown that the connection between colour and nutrition is regularly used by potential mates to judge from the body colours whether a proposing partner is sufficiently healthy, and thus sufficiently sexy.

Ref. 976

How does matter behave at the lowest temperatures?

The low-temperature behaviour of matter has numerous experimental and theoretical aspects. The first issue is whether matter is always solid at low temperatures. The answer is no. All phases exist at low temperatures, as shown in Table 100.

Concerning the electric properties of matter at lowest temperatures, the present status is that matter is either insulating or superconducting. Finally, one can ask about the magnetic properties of matter at low temperatures. We know already that matter can not be paramagnetic at lowest temperatures. It seems that matter is either ferromagnetic, diamagnetic or antiferromagnetic at lowest temperatures.

More about superfluidity and superconductivity will be told below.

Page 1176

TABLE 100 Matter at lowest temperatures

PHASE	TYPE	LOW TEMPERATURE BEHAVIOUR	EXAMPLE
Solid	conductor	superconductivity	lead, MgB_2 (40 K)
		antiferromagnet	chromium, MnO
		ferromagnet	iron
	insulator	diamagnet	
Liquid	bosonic	Bose–Einstein condensation, i.e., superfluidity	^{4}He
	fermionic	pairing, then BEC, i.e., superfluidity	^{3}He
Gas	bosonic	Bose–Einstein condensation	^{87}Rb, ^{7}Li, ^{23}Na, H, ^{4}He, ^{41}K
	fermionic	pairing, then Bose–Einstein condensation	^{40}K, ^{6}Li

CURIOSITIES AND FUN CHALLENGES ABOUT MATERIALS SCIENCE

What is the maximum height of a mountain? This question is of course of interest to all climbers. Many effects limit the height. The most important is the fact that under heavy pressure, solids become liquid. For example, on Earth this happens at about 27 km. This is quite a bit more than the highest mountain known, which is the volcano Mauna Kea in Hawaii, whose top is about 9.45 km above the base. On Mars gravity is weaker, so that mountains can be higher. Indeed the highest mountain on Mars, Olympus mons, is 80 km high. Can you find a few other effects limiting mountain height?

Robert Full has shown that van der Waals forces are responsible for the way that geckos walk on walls and ceilings. The gecko, a small reptile with a mass of about 100 g, uses an elaborate structure on its feet to perform the trick. Each foot has 500 000 hairs each split in up to 1000 small spatulae, and each spatula uses the van der Waals force (or alternatively, capillary forces) to stick to the surface. As a result, the gecko can walk on vertical glass walls or even on glass ceilings; the sticking force can be as high as 100 N per foot.

Ref. 963

The same mechanism is used by jumping spiders (*Salticidae*). For example, *Evarcha arcuata* have hairs at their feet which are covered by hundred of thousands of setules. Again, the van der Waals force in each setule helps the spider to stick on surfaces.

Ref. 964

Researchers have copied these mechanisms for the first time in 2003, using microlithography on polyimide, and hope to make durable sticky materials in the future.

* *

Millimetre waves or terahertz waves are emitted by all bodies at room temperature. Modern camera systems allow to image them. In this way, it is possible to see through clothes. This ability could be used in future to detect hidden weapons in airports. But the development of a practical and affordable detector which can be handled as easily as a binocular is still under way. The waves can also be used to see through paper, thus making it unnecessary to open letters in order to read them. Secret services are exploiting this technique. A third application of terahertz waves might be in medical diagnostic, for example for the search of tooth decay. Terahertz waves are almost without side effects, and thus superior to X-rays. The lack of low-priced quality sources is still an obstacle to their application.

* *

Does the melting point of water depend on the magnetic field? This surprising claim was made in 2004 by Inaba Hideaki and colleagues. They found a change of 0.9 mK/T. It is known that the refractive index and the near infrared spectrum of water is affected by magnetic fields. Indeed, not everything about water might be known yet.

Ref. 965

* *

Plasmas, or ionized gases, are useful for many applications. Not only can they be used for heating or cooking and generated by chemical means (such plasmas are variously called fire or flames) but they can also be generated electrically and used for lighting or deposition of materials. Electrically generated plasmas are even being studied for the disinfection of dental cavities.

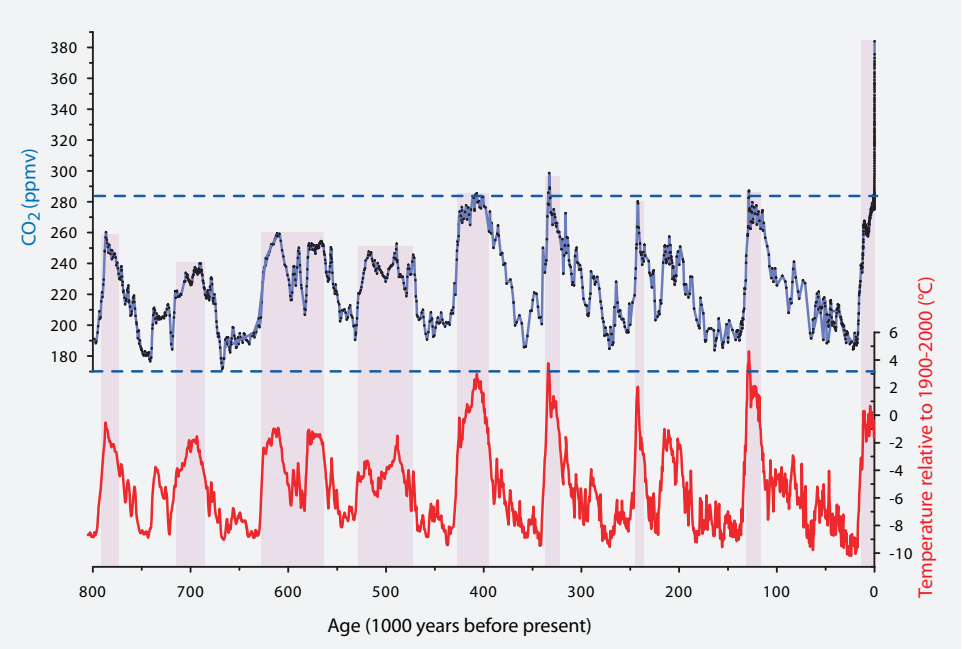

FIGURE 527 The concentration of CO_2 and the change of average atmospheric temperature in the past 0.8 million years (© Dieter Lüthi)

* *

It is known that the concentration of CO_2 in the atmosphere between 1800 and 2005 has increased from 280 to 380 parts per million, as shown in Figure 527. (How would you measure this?) It is known without doubt that this increase is due to human burning of fossil fuels, and not to natural sources such as the oceans or volcanoes. There are three arguments. First of all, there was a parallel decline of the $^{14}C/^{12}C$ ratio. Second, there was a parallel decline of the $^{13}C/^{12}C$ ratio. Finally, there was a parallel decline of the oxygen concentration. All three measurements independently imply that the CO_2 increase is due to the burning of fuels, which are low in ^{14}C and in ^{13}C, and at the same time decrease the oxygen ratio. Natural sources do not have these three effects. Since CO_2 is a major greenhouse gas, the data implies that humans are also responsible for a large part of the temperature increase during the same period. Global warming exists and is mainly due to humans.

Making crystals can make one rich. The first man who did so, the Frenchman Auguste Verneuil (1856–1913), sold rubies grown in his laboratory for many years without telling anybody. Many companies now produce synthetic gems.

Synthetic diamonds have now displaced natural diamonds in almost all applications. In the last years, methods to produce large, white, jewel-quality diamonds of ten carats and more are being developed. These advances will lead to a big change in all the domains that depend on these stones, such as the production of the special surgical knives used

in eye lens operation.

* *

The technologies to produce *perfect* crystals, without grain boundaries or dislocations, are an important part of modern industry. Perfectly regular crystals are at the basis of the integrated circuits used in electronic appliances, are central to many laser and telecommunication systems and are used to produce synthetic jewels.

* *

Challenge 1508 ny How can a small plant pierce through tarmac?

* *

The Lorentz force leads to an interesting effect inside materials. If a current flows along a conducting strip that is in a (non-parallel) magnetic field, a voltage builds up between two edges of the conductor, because the charge carriers are deflected in their flow. This effect is called the (classical) *Hall effect* after the US-American physicist Edwin Hall (1855–1938), who discovered it in 1879, during his PhD. The effect, shown in Figure 528, is regularly used, in so-called *Hall probes*, to measure magnetic fields; the effect is also used to read data from magnetic storage media or to measure electric currents (of the order of 1 A or more) in a wire without cutting it. Typical Hall probes have sizes of around 1 cm down to 1 µm and less. The Hall voltage V turns out to be given by

$$V = \frac{IB}{ned} \,, \tag{691}$$

where n is the electron number density, e the electron charge, and d is the thickness of the probe, as shown in Figure 528. Deducing the equation is a secondary school exercise. The Hall effect is a material effect, and the material parameter n determines the Hall voltage. The sign of the voltage also tells whether the material has positive or negative charge carriers; indeed, for metal strips the voltage polarity is opposite to the one shown in the figure.

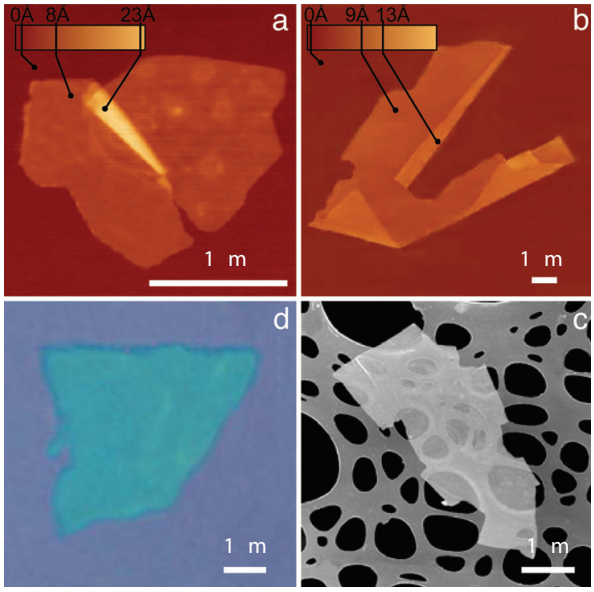

FIGURE 529 Single atom sheets, mapped by atomic force microscopy, of $NbSe_2$ (a) and of graphite or graphene (b), a single atom sheet of MoS_2 imaged by optical microscopy (d), and a single atom sheet of $Bi_2Sr_2CaCu_2O_x$ on a holey carbon film imaged by scanning electron microscopy (c) (from Ref. 971, © 2005 National Academy of Sciences)

Many variations of the Hall effect have been studied. For example, the *quantum* Hall
Page 1178 effect will be explored below.

In 1998, Geert Rikken and his coworkers found that in certain materials photons can
Ref. 968 also be deflected by a magnetic field; this is the *photonic Hall effect*.

In 2005, again Geert Rikken and his coworkers found a material, a terbium gallium garnet, in which a flow of phonons in a magnetic field leads to temperature difference on
Ref. 969 the two sides. They called this the *phonon Hall effect*.

* *

Do magnetic fields influence the crystallization of calcium carbonate in water? This issue
Ref. 970 is topic of intense debates. It might be, or it might not be, that magnetic fields change the crystallization seeds from calcite to aragonite, thus influencing whether water tubes are covered on the inside with carbonates or not. The industrial consequences of reduction in *scaling*, as this process is called, would be enormous. But the issue is still open, as are convincing data sets.

* *

Ref. 971 It has recently become possible to make the thinnest possible sheets of graphite and other materials (such as BN, MoS_2, $NbSe_2$, $Bi_2Sr_2CaCu_2O_x$): these crystal sheets are precisely one atom thick! The production of *graphene* – that is the name of a monoatomic graphite layer – is extremely complicated: you need graphite from a pencil and a roll of adhesive tape. That is probably why it was necessary to wait until 2004 for the development of the technique. (In fact, the stability of monoatomic sheets was questioned for many years before that. Some issues in physics cannot be decided with paper and pencil; sometimes you need adhesive tape as well.) Graphene and the other so-called *two-dimensional crys-*

Like trees, crystals can have growth rings. Smoke quartz is known for these so-called *phantoms*, but also fluorite and calcite.

QUANTUM TECHNOLOGY

> I were better to be eaten to death with a rust than to be scoured to nothing with perpetual motion.
>
> William Shakespeare (1564–1616) *King Henry IV*.

Quantum effects do not appear only in microscopic systems. Several quantum effects are important in modern life; transistors, lasers, superconductivity and a few other effects and systems have shaped modern life in many ways.

Motion without friction – superconductivity and superfluidity

We are used to thinking that friction is inevitable. We even learned that friction was an inevitable result of the particle structure of matter. It should come to the surprise of every physicist that motion without friction is possible.

In 1911 Gilles Holst and Heike Kamerlingh Onnes discovered that at low temperatures, electric currents can flow with no resistance, i.e., with no friction, through lead. The observation is called *superconductivity*. In the century after that, many metals, alloys and ceramics have been found to show the same behaviour.

The condition for the observation of motion without friction is that quantum effects play an essential role. That is the reason for the requirement of low temperature in such experiments. Nevertheless, it took over 50 years to reach a full understanding of the effect. This happened in 1957, when Bardeen, Cooper and Schrieffer published their results. Ref. 984 At low temperatures, electron behaviour is dominated by an attractive interaction that makes them form pairs – today called *Cooper pairs* – that are effective bosons. And bosons can all be in the same state, thus effectively moving without friction.

For superconductivity, the attractive interaction between electrons is due to the deformation of the lattice. Two electrons attract each other in the same way as two masses attract each other due to deformation of the space-time mattress. However, in the case of solids, the deformations are quantized. With this approach, Bardeen, Cooper and Schrieffer explained the lack of electric resistance of superconducting materials, their complete

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

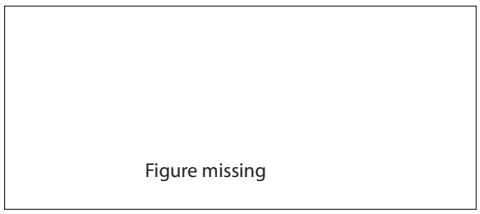

FIGURE 530 Nuclear magnetic resonance shows that vortices in superfluid ^{3}He-B are quantized.

diamagnetism ($\mu_r = 0$), the existence of an energy gap, the second-order transition to normal conductivity at a specific temperature, and the dependence of this temperature on the mass of the isotopes. Last but not least, they received the Nobel Prize in 1972.*

Another type of motion without friction is *superfluidity*. Already in 1937, Pyotr Kapitsa had predicted that normal helium (^{4}He), below a transition observed at the temperature of 2.17 K, would be a superfluid. In this domain, the fluid moves without friction through tubes. (In fact, the fluid remains a mixture of a superfluid component and a normal component.) Helium is even able, after an initial kick, to flow over obstacles, such as glass walls, or to flow out of bottles. ^{4}He is a boson, so no pairing is necessary for it to flow without friction. This research earned Kapitsa a Nobel Prize in 1978.

The explanation of superconductivity also helped for fermionic superfluidity. In 1972, Richardson, Lee, and Osheroff found that even ^{3}He is superfluid, if temperatures are lowered below 2.7 mK. ^{3}He is a fermion, and requires pairing to become superfluid. In fact, below 2.2 mK, ^{3}He is even superfluid in two different ways; one speaks of phase A and phase B.**

In the case of ^{3}He, the theoreticians had been faster than the experimentalists. The theory for superconductivity through pairing had been adapted to superfluids already in 1958 – before any data were available – by Bohr, Mottelson and Pines. This theory was then adapted and expanded by Anthony Leggett.*** The attractive interaction between ^{3}He atoms, the basic mechanism that leads to superfluidity, turns out to be the spin-spin interaction.

In superfluids, like in ordinary fluids, one can distinguish between laminar and turbulent flow. The transition between the two regimes is mediated by the behaviour of vortices. But in superfluids, vortices have properties that do not appear in normal fluids. In the superfluid ^{3}He-B phase, vortices are *quantized*: vortices only exist in integer multiples of the elementary circulation $h/2m_{^3\mathrm{He}}$. Present research is studying how these vortices behave and how they induce the transition form laminar to turbulent flows.

Ref. 978

* For John Bardeen (1908–1991), this was his second, after he had got the first Nobel Prize in 1956, shared with William Shockley and Walter Brattain, for the discovery of the transistor. The first Nobel Prize was a problem for Bardeen, as he needed time to work on superconductivity. In an example to many, he reduced the tam-tam around himself to a minimum, so that he could work as much as possible on the problem of superconductivity. By the way, Bardeen is topped by Frederick Sanger and by Marie Curie. Sanger first won a Nobel Prize in Chemistry in 1958 by himself and then won a second one shared with Walter Gilbert in 1980; Marie Curie first won one with her husband and a second one by herself, though in two different fields.

** They received the Nobel Prize in 1996 for this discovery.

*** Aage Bohr, son of Niels Bohr, and Ben Mottelson received the Nobel Prize in 1975, Anthony Leggett in 2003.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In recent years, studying the behaviour of *gases* at lowest temperatures has become very popular. When the temperature is so low that the de Broglie wavelength is comparable to the atom-atom distance, bosonic gases form a Bose–Einstein condensate. The first one were realized in 1995 by several groups; the group around Eric Cornell and Carl Wieman used ^{87}Rb, Rand Hulet and his group used ^{7}Li and Wolfgang Ketterle and his group used ^{23}Na. For fermionic gases, the first degenerate gas, ^{40}K, was observed in 1999 by the group around Deborah Jin. In 2004, the same group observed the first gaseous Fermi condensate, after the potassium atoms paired up.

The fractional quantum Hall effect

The fractional quantum Hall effect is one of the most intriguing discoveries of materials science. The effect concerns the flow of electrons in a two-dimensional surface. In 1982, Ref. 980 Robert Laughlin predicted that in this system one should be able to observe objects with Ref. 979 electrical charge $e/3$. This strange and fascinating prediction was indeed verified in 1997.

The story begins with the discovery by Klaus von Klitzing of the quantum Hall effect. Ref. 983 In 1980, Klitzing and his collaborators found that in two-dimensional systems at low temperatures – about 1 K – the electrical conductance S is quantized in multiples of the quantum of conductance

$$S = n \frac{e^2}{\hbar} \,. \tag{692}$$

The explanation is straightforward: it is the quantum analogue of the classical Hall effect, which describes how conductance varies with applied magnetic field. The corresponding resistance values are

$$R = \frac{1}{n} \frac{\hbar}{e^2} = 25\,812,807557(18)\,\Omega/n \,. \tag{693}$$

The values are independent of material, temperature, or magnetic field. They are constants of nature. Von Klitzing received the Nobel Prize for physics for the discovery, because the effect was unexpected, allows a highly precise measurement of the fine structure constant, and also allows one to build detectors for the smallest voltage variations measurable so far. Their discovery started a large wave of subsequent research.

Two years later, it was found that in extremely strong magnetic fields and at extremely Ref. 981 low temperatures, the conductance could vary in steps *one third* that size. Shortly afterwards, even stranger numerical fractions were also found. In fact, all fractions of the form $m/(2m+1)$ or of the form $(m+1)/(2m+1)$, m being an integer, are possible. This is the *fractional quantum Hall effect*. In a landmark paper, Robert Laughlin explained all these Ref. 980 results by assuming that the electron gas could form collective states showing quasiparticle excitations with a charge $e/3$. This was confirmed 15 years later and earned him a Nobel price as well. We have seen in several occasions that quantization is best discovered through noise measurements; also in this case, the clearest confirmation came from electrical current noise measurements.

Subsequent experiments confirmed Laughlin's deduction. He had predicted the appearance of a new form of a *composite* quasi-particle, built of electrons and of one or several magnetic flux quanta. If an electron bonds with an *even* number of quanta, the composite is a fermion, and leads to Klitzing's *integral* quantum Hall effect. If the electron

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

bonds with an *odd* number of quanta, the composite is a boson, and the *fractional* quantum Hall effect appears. The experimental and theoretical details of these quasi-particles might well be the most complex and fascinating aspects of solid state physics, but exploring them would lead us too far from the aim of our adventure.

In 2007, a new chapter in the story was opened by Andre Geim and his own and a second team, when they discovered a new type of quantum Hall effect at room temperature. They used graphene, i.e., single-atom layers of graphite, and found a relativistic analogue of the quantum Hall effect. This effect was even more unexpected than the previous ones, is equally interesting, and can be performed on a table top. The groups are good candidates for a trip to Stockholm.

Ref. 982
Page 1175

What do we learn from these results? Systems in two dimensions have states which follow different rules than systems in three dimensions. The fractional charges in superconductors have no relation to quarks. Quarks, the constituents of protons and neutrons, have charges $e/3$ and $2e/3$. Might the quarks have something to do with superconductivity? At this point we need to stand the suspense, as no answer is possible; we come back to this issue in the last part of this adventure.

TABLE 101 A selection of lamps and lasers

Lamp type, application	Wavelength	Brightness or power	Cost	Lifetime
Incandescent lamps				
Tungsten wire light bulbs, halogen lamps, for illumination	300 to 800 nm	5 to 25 lm/W	0.1 cent/lm	700 h
Gas discharge lamps				
Oil lamps, candles, for illumination	white	up to 500 lm	1 cent/lm	5 h
Neon lamps, for advertizing	red			up to 30 kh
Mercury lamps, for illumination	UV plus spectrum	45 to 110 lm/W	0.05 cent/lm	3000 to 24 000 h
Metal halogenide lamps (ScI_3 or 'xenon light', NaI, DyI_3, HoI_3, TmI_5) for car headlights and illumination	white	110 lm/W	1 cent/lm	up to 20 kh
Sodium low pressure lamps for street illumination	589 nm yellow	200 lm/W	0.2 cent/lm	up to 18 kh
Sodium high pressure lamps for street illumination	broad yellow	120 lm/W	0.2 cent/lm	up to 24 kh
Xenon arc lamps, for cinemas	white	30 to 150 lm/W, up to 15 kW		100 to 2500 h
Recombination lamps

Lasers and other spin-one vector boson launchers

Photons are vector bosons; a lamp is thus a vector boson launcher. All lamps fall into one of three classes. Incandescent lamps use emission from a hot solid, gas discharge lamps use excitation of atoms, ions or molecules through collision, and solid state lamps generate (cold) light through recombination of charges in semiconductors.

Ref. 1001

Most solid state lamps are light emitting diodes. The large progress in brightness of light emitting diodes could lead to a drastic reduction in future energy consumption, if their cost is lowered sufficiently. Many engineers are working on this task. Since the cost is a good estimate for the energy needed for production, can you estimate which lamp is

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1511 s the most friendly to the environment?

Nobody thought much about lamps, until Albert Einstein and a few other great physicists came along, such as Theodore Maiman and Hermann Haken. Many other researchers later received Nobel Prizes by building on their work. In 1916, Einstein showed that there are two types of sources of light – or of electromagnetic radiation in general – both of which actually 'create' light. He showed that every lamp whose brightness is turned up high enough will change behaviour when a certain intensity threshold is passed. The main mechanism of light emission then changes from spontaneous emission to *stimulated emission*. Nowadays such a special lamp is called a *laser*. (The letters 'se' in laser are an abbreviation of 'stimulated emission'.) After a passionate worldwide research race, in 1960 Maiman was the first to build a laser emitting visible light. (So-called *masers* emitting microwaves were already known for several decades.) In summary, Einstein and the other physicists showed that lasers are lamps which are sufficiently turned up. Lasers consist of some light producing and amplifying material together with a mechanism to pump energy into it. The material can be a gas, a liquid or a solid; the pumping process can use electrical current or light. Usually, the material is put between two mirrors, in order to improve the efficiency of the light production. Common lasers are semiconductor lasers (essentially strongly pumped LEDs or light emitting diodes), He–Ne lasers (strongly pumped neon lamps), liquid lasers (essentially strongly pumped fire flies) and ruby lasers (strongly pumped luminescent crystals).

Lasers produce radiation in the range from microwaves and extreme ultraviolet. They have the special property of emitting *coherent* light, usually in a collimated beam. Therefore lasers achieve much higher light intensities than lamps, allowing their use as tools. In modern lasers, the coherence length, i.e., the length over which interference can be observed, can be thousands of kilometres. Such high quality light is used e.g. in gravitational wave detectors.

People have become pretty good at building lasers. Lasers are used to cut metal sheets up to 10 cm thickness, others are used instead of knives in surgery, others increase surface hardness of metals or clean stones from car exhaust pollution. Other lasers drill holes in teeth, measure distances, image biological tissue or grab living cells. Most materials can be used to make lasers, including water, beer and vodka.

Some materials amplify light so much that end mirrors are not necessary. This is the case for nitrogen lasers, in which nitrogen, or simply air, is used to produce a UV beam. Even a laser made of a single atom (and two mirrors) has been built; in this example, Ref. 1010 only eleven photons on average were moving between the two mirrors. Quite a small lamp. Also lasers emitting light in two dimensions have been built. They produce a light plane instead of a light beam.

Lasers have endless applications. Lasers read out data from compact discs (CDs), are used in the production of silicon integrated circuits, and transport telephone signals; we Page 297 already encountered lasers that work as loudspeakers. The biggest advances in recent years came from the applications of femtosecond laser pulses. Femtosecond pulses generate high-temperature plasmas in the materials they propagate, even in air. Such short pulses can be used to cut material without heating it, for example to cut bones in heart operations. Femtosecond lasers have been used to make high resolution hologram of human heads within a single flash. Recently such lasers have been used to guide lightning Ref. 1002 along a predetermined path and seem promising candidates for laser ligtning rods. A

curious application is to store information in fingernails (up to 5 Mbit for a few months) using such lasers, in a way not unlike that used in recordable compact discs (CD-R). Ref. 1011

Can two photons interfere?

In 1930, Dirac made the famous statement already mentioned above: Page 1008 Ref. 1003

> Each photon interferes only with itself. Interference between two different photons never occurs.

Often this statement is misinterpreted as implying that two separate photon *sources* cannot interfere. It is almost unbelievable how this false interpretation has spread through the literature. Everybody can check that this statement is incorrect with a radio: two distant radio stations transmitting on the same frequency lead to beats in amplitude, i.e., to *wave interference*. (This should not to be confused with the more common *radio interference*, with usually is simply a superposition of intensities.) Radio transmitters are coherent sources of photons, and any radio receiver shows that two such sources can indeed interfere. Ref. 1004

In 1949, interference of two different sources has been demonstrated with microwave beams. Numerous experiments with two lasers and even with two thermal light sources have shown light interference from the fifties onwards. In 1963, Magyar and Mandel used two ruby lasers emitting light pulses and a rapid shutter camera to produce spatial interference fringes. Ref. 1004

However, all these experimental results do not contradict the statement by Dirac. Indeed, two photons cannot interfere for several reasons.

— Interference is a result of space-time propagation of waves; photons appear only when the energy–momentum picture is used, mainly when interaction with matter takes place. The description of space-time propagation and the particle picture are mutually exclusive – this is one aspect of the complementary principle. Why does Dirac seem to mix the two in his statement? Dirac employs the term 'photon' in a very general sense, as quantized state of the electromagnetic field. When two coherent beams are superposed, the quantized entities, the photons, cannot be ascribed to either of the sources. Interference results from superposition of two coherent states, not of two particles.
— Interference is only possible if one cannot know where the detected photon comes from. The quantum mechanical description of the field in a situation of interference never allows to ascribe photons of the superposed field to one of the sources. In other words, if you can say from which source a detected photon comes from, you *cannot* observe interference.
— Interference between two beams requires a fixed phase between them, i.e., an uncertain particle number; in other words, interference is only possible if the photon number for each of the two beams is unknown.

A better choice of words is to say that interference is always between two (indistinguishable) states, or if one prefers, between two possible (indistinguishable) histories, but never between two particles. In summary, two different electromagnetic beams can

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

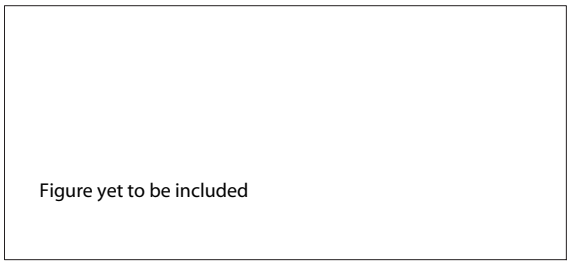

FIGURE 532 An electron hologram

interfere, but not two different photons.

Can two electron beams interfere?

Do coherent electron sources exist? Yes, as it is possible to make holograms with electron beams.* However, electron coherence is only transversal, not longitudinal. Transversal coherence is given by the possible size of wavefronts with fixed phase. The limit of this size is given by the interactions such a state has with its environment; if the interactions are weak, matter wave packets of several metres of size can be produced, e.g. in particle colliders, where energies are high and interaction with matter is low.

Actually, the term transversal coherence is a fake. The ability to interfere with oneself is not the definition of coherence. Transversal coherence only expresses that the source size is small. Both small lamps (and lasers) can show interference when the beam is split and recombined; this is not a proof of coherence. Similarly, monochromaticity is not a proof for coherence either.

A state is called *coherent* if it possesses a well-defined phase throughout a given domain of space or time. The size of that region or of that time interval defines the degree of coherence. This definition yields coherence lengths of the order of the source size for small 'incoherent' sources. Nevertheless, the size of an interference pattern, or the distance d between its maxima, can be much larger than the coherence length l or the source size s.

In summary, even though an electron can interfere with itself, it cannot interfere with a second one. Uncertain electron numbers are needed to see a macroscopic interference pattern. That is impossible, as electrons (at usual energies) carry a conserved charge.

Challenges, dreams and fun curiosities about quantum technology

Nowadays, we carry many electronic devices in our jacket or trousers. Almost all use batteries. In the future, there is a high chance that some of these devices will extract energy from the human body. There are several options. One can extract thermal energy with thermoelements, or one can extract vibrational energy with piezoelectric, electrostatic or

Ref. 1006 * In 2002, the first holograms have been produced that made use of neutron beams.

electromagnetic transducers. The challenge is to make these elements small and cheap. It will be interesting to find out which technology will arrive to the market first.

* *

In 2007, Humphrey Maris and his student Wei Guo performed an astonishing experiment: they filmed single electrons with a video camera. Well, the truth is a bit more complicated, but it is not a lie to summarize it in this way.

Ref. 985

Maris is an expert on superfluid helium. Since many years he knew that free electrons in superfluid helium repel helium atoms, and can move, surrounded by a small vacuum bubble, about 2 nm across, through the fluid. He also discovered that under negative pressure, these bubbles can grow and finally explode. When they explode, they are able to scatter light. With his student Wei Guo, he then injected electrons into superfluid helium through a tungsten needle under negative voltage, produced negative pressure by focussing waves from two piezoelectric transducers in the bulk of the helium, and shone light through the helium. When the pressure became negative enough they saw the explosions of the bubbles. Figure 533 shows the video. If the experiment is confirmed, it is one of the highlights of experimental physics in the last decade.

Chapter 42

QUANTUM ELECTRODYNAMICS – THE ORIGIN OF VIRTUAL REALITY

The central concept that quantum theory introduces in the description of nature is the idea of *virtual particles*. Virtual particles are short-lived particles; they owe their existence exclusively to the quantum of action. Because of the quantum of action, they do not need to follow the energy-mass relation that special relativity requires of normal, real particles. Virtual particles can move faster than light and can move backward in time. Despite these strange properties, they have many observable effects.

Ships, mirrors and the Casimir effect

When two parallel ships roll in a big swell, *without* even the slightest wind blowing, they will attract each other. This effect was well known up to the nineteenth century, when many places still lacked harbours. As Sipko Boersma tells, shipping manuals advised captains to let the ships be pulled apart using a well-manned rowing boat.

Ref. 989

Waves induce oscillations of ships because a ship absorbs energy from the waves. When oscillating, the ship also emits waves. This happens mainly towards the two sides of the ship. As a result, for a single ship, the wave emission has no net effect on its position. Now imagine that two parallel ships oscillate in a long swell, with a wavelength much larger than the distance between the ships. Due to the long wavelength, the two ships will oscillate in phase. The ships will thus not be able to absorb energy from each other. As a result, the energy they radiate towards the outside will push them towards each other.

The effect is not difficult to calculate. The energy of a rolling ship is

$$E = mgh\,\alpha^2/2 \tag{694}$$

where α is the roll angle amplitude, m the mass of the ship and $g = 9,8\,\mathrm{m/s^2}$ the acceleration due to gravity. The *metacentric height* h is the main parameter characterizing a ship, especially a sailing ship; it tells with what torque the ship returns to the vertical when inclined by an angle α. Typically, one has h =1.5 m.

When a ship is inclined, it will return to the vertical by a damped oscillation. A damped oscillation is characterized by a period T and a quality factor Q. The *quality factor* is the number of oscillations the system takes to reduce its amplitude by a factor $e = 2.718$. If the quality factor Q of an oscillating ship and its oscillation period T are

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

given, the radiated power W is

$$W = 2\pi \frac{E}{QT} \,. \tag{695}$$

We saw above that radiation force (radiation pressure times area) is W/c, where c is the wave propagation velocity. For water waves, we have the famous relation

$$c = \frac{gT}{2\pi} \,. \tag{696}$$

Assuming that for two nearby ships each one completely absorbs the power emitted from the other, we find that the two ships are attracted towards each other following

$$ma = m2\pi^2 \frac{h\alpha^2}{QT^2} \,. \tag{697}$$

Inserting typical values such as $Q = 2.5$, $T = 10\,\mathrm{s}$, $\alpha = 0.14\,\mathrm{rad}$ and a ship mass of 700 tons, we get about 1.9 kN. Long swells thus make ships attract each other. The intensity of the attraction is comparatively small and can indeed be overcome with a rowing boat. On the other hand, even the slightest wind will damp the oscillation amplitude and have other effects that will avoid the observation of the attraction.

Sound waves or noise in air can have the same effect. It is sufficient to suspend two metal plates in air and surround them by loudspeakers. The sound will induce attraction (or repulsion) of the plates, depending on whether the sound wavelength cannot (or can) be taken up by the other plate.

Ref. 990

In 1948, the Dutch physicist Hendrik Casimir made one of the most spectacular predictions of quantum theory: he predicted a similar effect for metal plates in vacuum. Casimir, who worked at the Dutch Electronics company Philips, wanted to understand why it was so difficult to build television tubes. Television screens are made by deposing small neutral particles on glass, but Casimir observed that the particles somehow attracted each other. Casimir got interested in understanding how neutral particles interact. During these theoretical studies he discovered that two neutral mirrors (or metal plates) would attract each other even in complete vacuum. This is the famous *Casimir effect*. Casimir also determined the attraction strength between a sphere and a plate, and between two spheres. In fact, all conducting bodies attract each other in vacuum, with a force depending on their geometry.

In all these situations, the role of the sea is taken by the zero-point fluctuations of the electromagnetic field, the role of the ships by the mirrors. Casimir understood that the space between two parallel mirrors, due to the geometrical constraints, had different zero-point fluctuations than the free vacuum. Like two ships, the result would be the attraction of the mirrors.

Casimir predicted that the attraction for two mirrors of mass m and surface A is given by

$$\frac{ma}{A} = \frac{\pi^3}{120} \frac{\hbar c}{d^4} \,. \tag{698}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The effect is a pure quantum effect; in classical electrodynamics, two neutral bodies do not attract. The effect is small; it takes some dexterity to detect it. The first experimental confirmation was by Derjaguin, Abrikosova and Lifshitz in 1956; the second experimental confirmation was by Marcus Sparnaay, Casimir's colleague at Philips, in 1958. Two beautiful high-precision measurements of the Casimir effect were performed in 1997 by Lamoreaux and in 1998 by Mohideen and Roy; they confirmed Casimir's prediction with a precision of 5 % and 1 % respectively. (Note that at very small distances, the dependence is not $1/d^4$, but $1/d^3$.)

Ref. 991 Ref. 992 Ref. 993 Ref. 994

In a cavity, spontaneous emission is suppressed, if it is smaller than the wavelength of the emitted light! This effect has also been observed. It confirms the old saying that spontaneous emission is emission stimulated by the zero point fluctuations.

The Casimir effect thus confirms the existence of the zero-point fluctuations of the electromagnetic field. It confirms that quantum theory is valid also for electromagnetism.

The Casimir effect between two spheres is proportional to $1/r^7$ and thus is much weaker than between two parallel plates. Despite this strange dependence, the fascination of the Casimir effect led many amateur scientists to speculate that a mechanism similar to the Casimir effect might explain gravitational attraction. Can you give at least three arguments why this is impossible, even if the effect had the correct distance dependence?

Challenge 1519 s

Like the case of sound, the Casimir effect can also produce repulsion instead of attraction. It is sufficient that one of the two materials be perfectly permeable, the other a perfect conductor. Such combinations repel each other, as Timothy Boyer discovered in 1974.

Ref. 995

The Casimir effect bears another surprise: between two metal plates, the speed of light changes and can be larger than c. Can you imagine what exactly is meant by 'speed of light' in this context?

Ref. 996 Challenge 1520 s

In 2006, the Casimir effect provided another surprise. The ship story just presented is beautiful, interesting and helps understanding the effect; but it seems that the story is based on a misunderstanding. Alas, the interpretation of the old naval text given by Sipko Boersma seems to be wishful thinking. There might be such an effect for ships, but it has never been observed nor put into writing by seamen, as Fabrizio Pinto has pointed out after carefully researching naval sources.

The Lamb shift

In the 1947, the measurements of the spectrum of hydrogen had yielded another effect due to virtual particles. Willis Lamb (1913–) found that the $2S_{1/2}$ energy level in atomic hydrogen lies slightly above the $2P_{1/2}$ level. This is in contrast to the calculation performed above, where the two levels are predicted to have the same energy. In reality, they have an energy difference of 1057.864 MHz or 4.3 μeV. This discovery had important consequences for the description of quantum theory and yielded Lamb a share of the 1955 Nobel Prize in Physics.

Page 1046

The reason for the level difference is an unnoticed approximation performed in the simple relativistic calculation of the hydrogen levels. There are two equivalent ways to explain it. One is to say that the calculation neglects the coupling terms between the Dirac equation and the Maxwell equations. This explanation lead to the first calculations

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of the Lamb shift, around the year 1950. The other explanation is to say that the calculation *neglects virtual particles*. In particular, the calculation neglects the virtual photons emitted and absorbed during the motion of the electron around the nucleus. This is the explanation in line with the modern vocabulary of quantum electrodynamics. QED is the perturbative approach to solve the coupled Dirac and Maxwell equations.

The QED Lagrangian

– CS – section on the QED Lagrangian to be added – CS –

Interactions and virtual particles

The electromagnetic interaction is exchange of virtual photons. So how can the interaction be attractive? At first sight, any exchange of virtual photons should drive the electrons from each other. However, this is not correct. The momentum of virtual photons does not have to be in the direction of its energy flow; it can also be in opposite direction.* Obviously, this is only possible within the limits provided by the indeterminacy principle.

Can one count virtual photons? No.

Vacuum energy

The strangest result of quantum field theory is the energy density of the vacuum.

– CS – More to be written – CS –

Moving mirrors

Mirrors also work when they or the light source is in motion; in contrast, walls do not produce echoes for all sound sources or for all wall speeds. For example, experiments show that walls do not produce echoes if the wall or the sound source moves faster than sound. On the other hand, mirrors always produce an image, whatever the involved speeds. These observations show that the speed of light is the *same* for all observers. Can you detail the argument?

Challenge 1521 s

Mirrors also differ from tennis rackets. (Rackets are a kind of portable walls, to continue the previous analogy.) We have seen that mirrors cannot be used to change the speed of the light they hit, in contrast to what tennis rackets can do with balls. This observation shows that the speed of light is a *limit* velocity. In short, the simple existence of mirrors is sufficient to derive special relativity.

But there are more interesting things to be learned from mirrors. We only have to ask whether mirrors work when they undergo *accelerated* motion. This issue yields a surprising result.

* One of the most beautiful booklets on quantum electrodynamics which makes this point remains the text by Richard Feynman, *QED: the Strange Theory of Light and Matter*, Penguin Books, 1990.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In the 1970s, quite a number of researchers found that there is no vacuum for accelerated observers. This effect is called *Fulling–Davies–Unruh effect* or sometimes the *dynamical Casimir effect*. As a consequence, a mirror in accelerated motion reflects the fluctuations it encounters and reflects them. In short, *an accelerated mirror emits light*. Unfortunately, the intensity is so weak that it has not been measured up to now. We will explore the issue in more detail below. Can you explain why accelerated mirrors emit light, but not matter?

Page 1207
Challenge 1522 s

Photons hitting photons

When virtual particles are taken into account, light beams can 'bang' onto each other. This result is in full contrast to classical electrodynamics. Indeed, QED shows that the appearance of virtual electron-positron pairs allow photons to hit each other. And such pairs are found in any light beam.

However, the cross-section for photons banging onto each other is small. In fact, the bang is extremely weak. When two light beams cross, most photons will pass undisturbed. The cross-section A is approximately

$$A \approx \frac{973}{10\,125\pi}\alpha^4\left(\frac{\hbar}{m_e c}\right)^2\left(\frac{\hbar\omega}{m_e c^2}\right)^6 \tag{699}$$

for the everyday case that the energy $\hbar\omega$ of the photon is much smaller than the rest energy $m_e c^2$ of the electron. This value is about 18 orders of magnitude smaller than what was measurable in 1999; the future will show whether the effect can be observed for visible light. However, for high energy photons these effects are observed daily in particle accelerators. In these cases one observes not only interaction through virtual electron–antielectron pairs, but also through virtual muon–antimuon pairs, virtual quark–antiquark pairs, and much more.

Everybody who consumes science fiction knows that matter and antimatter annihilate and transform into pure light. In more detail, a matter particle and an antimatter particle annihilate into two or more photons. More interestingly, quantum theory predicts that the opposite process is also possible: photons hitting photons can produce matter!

Ref. 997

In 1997, this was also confirmed experimentally. At the Stanford particle accelerator, photons from a high energy laser pulse were bounced off very fast electrons. In this way, the reflected photons acquired a large energy, when seen in the inertial frame of the experimenter. The original pulse, of 527 nm or 2.4 eV green light, had a peak power density of $10^{22}\,\mathrm{W/m^2}$, about the highest achievable so far. That is a photon density of $10^{34}\,/\mathrm{m^3}$ and an electric field of $10^{12}\,\mathrm{V/m}$, both of which were record values at the time. When this laser pulse was reflected off a 46.6 GeV electron beam, the returning photons had an energy of 29.2 GeV and thus had become intense gamma rays. These gamma rays then collided with other, still incoming green photons and produced electron–positron pairs by the reaction

Challenge 1523 e

$$\gamma_{29.2} + n\,\gamma_{\mathrm{green}} \to \mathrm{e}^+ + \mathrm{e}^- \tag{700}$$

for which both final particles were detected by special apparatuses. The experiment thus showed that light can hit light in nature, and above all, that doing so can produce matter.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This is the nearest one can get to the science fiction idea of light swords or of laser swords banging onto each other.

Is the vacuum a bath?

If the vacuum is a sea of virtual photons and particle–antiparticle pairs, vacuum could be suspected to act as a bath. In general, the answer is negative. Quantum field theory works because the vacuum is *not* a bath for single particles. However, there is always an exception. For dissipative systems made of many particles, such as electrical conductors, the vacuum *can* act as a viscous fluid. Irregularly shaped, neutral, but conducting bodies can emit photons when accelerated, thus damping such type of motion. This is due to the Fulling–Davies–Unruh effect, also called the *dynamical Casimir effect*, as described above. The damping depends on the shape and thus also on the direction of the body's motion.

Ref. 998

Page 287

In 1998, Gour and Sriramkumar even predicted that Brownian motion should also appear for an imperfect, i.e., partly absorbing mirror placed in vacuum. The fluctuations of the vacuum should produce a mean square displacement

Ref. 999

$$\langle d^2 \rangle = \hbar/mt \tag{701}$$

increasing linearly with time; however, the extremely small displacements produced this way seem out of experimental reach so far. But the result is not a surprise. Are you able to give another, less complicated explanation for it?

Challenge 1524 ny

Renormalization – why is an electron so light?

– CS – section on renormalization to be added – CS –

Sometimes it is claimed that the infinities appearing in quantum electrodynamics in the intermediate steps of the calculation show that the theory is incomplete or wrong. However, this type of statement would imply that classical physics is also incomplete or wrong, on the ground that in the definition of the velocity v with space x and time t, namely

$$v = \frac{\mathrm{d}x}{\mathrm{d}t} = \lim_{\Delta t \to 0} \frac{\Delta x}{\Delta t} = \lim_{\Delta t \to 0} \Delta x \frac{1}{\Delta t} \,, \tag{702}$$

one gets an infinity as intermediate step. Indeed, $\mathrm{d}t$ being vanishingly small, one could argue that one is dividing by zero. Both arguments show the difficulty to accept that the result of a limit process can be a finite quantity even if infinite quantities appear in it. The parallel with the definition of the velocity is closer than it seems; both 'infinities' stem from the assumption that space-time is continuous, i.e., infinitely divisible. The infinities necessary in limit processes for the definition of differentiation, of integration or for the renormalization scheme appear only when space-time is approximated as a complete set, or as physicists say, as a 'continuous' set.

On the other hand, the conviction that the appearance of an infinity might be a sign of incompleteness of a theory was an interesting development in physics. It shows how

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

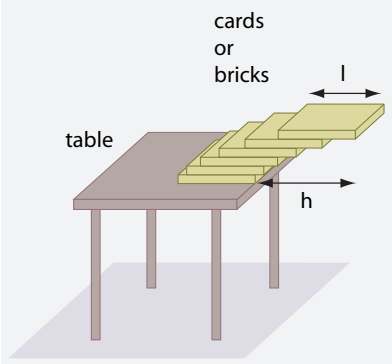

FIGURE 534 What is the maximum possible value of h/l?

uncomfortable many physicists had become with the use of infinity in our description of nature. Notably, this was the case for Dirac himself, who, after having laid in his youth the basis of quantum electrodynamics, has tried for the rest of his life to find a way, without success, to change the theory so that infinities are avoided.*

Ref. 1000

Renormalization is a procedure that follows from the requirement that continuous space-time and gauge theories must work together. In particular, it follows form the requirement that the particle concept is consistent, i.e., that perturbation expansions are possible.

Curiosities and fun challenges of quantum electrodynamics

Motion is an interesting topic, and when a curious person asks a question about it, most of the time quantum electrodynamics is needed for the answer. Together with gravity, quantum electrodynamics explains almost all of our everyday experience, including numerous surprises. Let us have a look at some of them.

* *

There is a famous riddle asking how far the last card (or the last brick) of a stack can hang over the edge of a table. Of course, only gravity, no glue or any other means is allowed to keep the cards on the table. After you solved the riddle, can you give the solution in case that the quantum of action is taken into account?

Challenge 1525 s

* *

Quantum electrodynamics explains why there are only a *finite* number of different atom types. In fact, it takes only two lines to prove that pair production of electron–antielectron pairs make it impossible that a nucleus has more than about 137 protons. Can you show this? The effect at the basis of this limit, the polarization of the vacuum, also plays a role in much larger systems, such as charged black holes, as we will see shortly.

Ref. 1007

Challenge 1526 s

Page 1211

* *

* Not long after his death, his wish has been fulfilled, although in a different manner that he envisaged. The final part of this mountain ascent will show the way out of the issue.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Taking 91 of the 92 electrons off an uranium atom allows researchers to check whether the innermost electron still is described by QED. The electric field near the uranium nucleus, 1 EV/m is near the threshold for spontaneous pair production. The field is the highest constant field producible in the laboratory, and an ideal testing ground for precision QED experiments. The effect of virtual photons is to produce a Lamb shift; even in these extremely high fields, the value fits with the predictions. Ref. 1008

* *

Is there a critical magnetic field in nature, like there is a critical electric field, limited by spontaneous pair production? Challenge 1527 ny

* *

In classical physics, the field energy of a point-like charged particle, and hence its mass, was predicted to be infinite. QED effectively *smears out* the charge of the electron over its Compton wavelength, so that in the end the field energy contributes only a small correction to its total mass. Can you confirm this? Page 781 Challenge 1528 ny

* *

Microscopic evolution can be pretty slow. Light, especially when emitted by single atoms, is always emitted by some metastable state. Usually, the decay times, being induced by the vacuum fluctuations, are much shorter than a microsecond. However, there are metastable atomic states with a lifetime of ten years: for example, an ytterbium ion in the $^2F_{7/2}$ state achieves this value, because the emission of light requires an octupole transition, in which the angular momentum changes by $3\hbar$; this is an extremely unlikely process. Ref. 1009

In radiocative decay, the slowness record is held by ^{209}Bi, with over 10^{19} years of half-life. Page 1348

* *

Microscopic evolution can be pretty fast. Can you imagine how to deduce or to measure the speed of electrons inside atoms? And inside metals? Challenge 1529 s

* *

Take a horseshoe. The distance between the two ends is not fixed, since otherwise their position and velocity would be known at the same time, contradicting the indeterminacy relation. Of course, this reasoning is also valid for any other solid object. In short, both quantum mechanics and special relativity show that rigid bodies do not exist, albeit for different reasons.

* *

Have you ever admired a quartz crystal or some other crystalline material? The beautiful shape and atomic arrangement has formed spontaneously, as a result of the motion of atoms under high temperature and pressure, during the time that the material was deep under the Earth's surface. The details of crystal formation are complex and interesting.

For example, are regular crystal lattices *energetically* optimal? This simple question leads to a wealth of problems. We might start with the much simpler question whether a

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

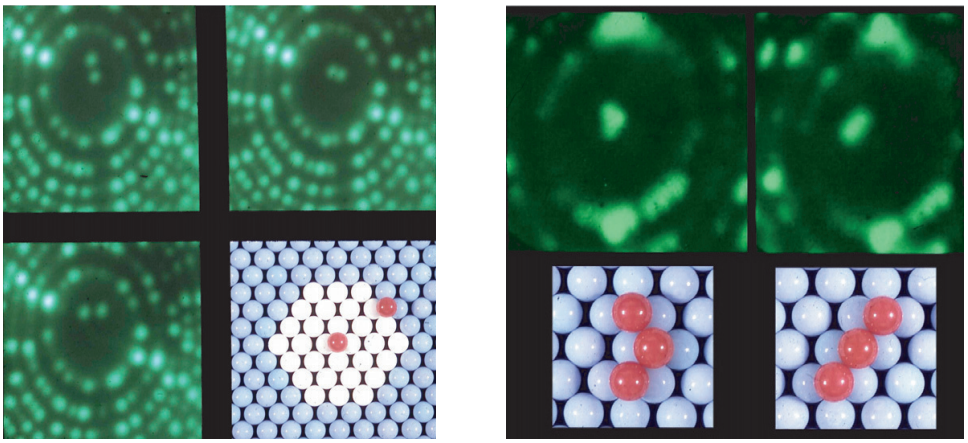

FIGURE 535 On tungsten tips, rhenium atoms, visible at the centre of the images, do not form dimers (left) but do form trimers (right) (© Hans-Werner Fink, APS, AIP from Ref. 1014)

Challenge 1530 s

regular dense packing of spheres is the most *dense* possible. Its density is $\pi/\sqrt{18}$, i.e., a bit over 74 %. Even though this was conjectured to be the maximum possible value already

Ref. 1012

in 1609 by Johannes Kepler, the statement was proven only in 1998 by Tom Hales. The proof is difficult because in small volumes it is possible to pack spheres up to almost 78 %. To show that over large volumes the lower value is correct is a tricky business.

Next, does a regular crystal of solid spheres, in which the spheres do *not* touch, have the lowest possible entropy? This simple problem has been the subject of research only in the 1990s. Interestingly, *for low temperatures*, regular sphere arrangements indeed show the largest possible entropy. At low temperatures, spheres in a crystal can oscillate around their average position and be thus more disordered than if they were in a liquid; in the liquid state the spheres would block each other's motion and would not allow to show disorder at all.

This many similar results deduced from the research into these so-called *entropic forces* show that the transition from solid to liquid is – at least in part – simply a geometrical effect. For the same reason, one gets the surprising result that even slightly

Ref. 1013

repulsing spheres (or atoms) can form crystals and melt at higher temperatures. These are beautiful examples of how classical thinking can explain certain material properties, using from quantum theory only the particle model of matter.

But the energetic side of crystal formation provides other interesting questions. Quantum theory shows that it is possible that *two* atoms repel each other, while *three* attract each other. This beautiful effect was discovered and explained by Hans-Werner Fink in

Ref. 1014

1984. He studied rhenium atoms on tungsten surfaces and showed, as observed, that they cannot form dimers – two atoms moving closeby – but readily form trimers. This is an example contradicting classical physics; the effect is impossible if one pictures atoms as immutable spheres, but becomes possible when one remembers that the electron clouds around the atoms rearrange depending on their environment.

For an exact study of crystal energy, the interactions between all atoms have to be included. The simplest question is to determine whether a regular array of alternatively charged spheres has lower energy than some irregular collection. Already such simple

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

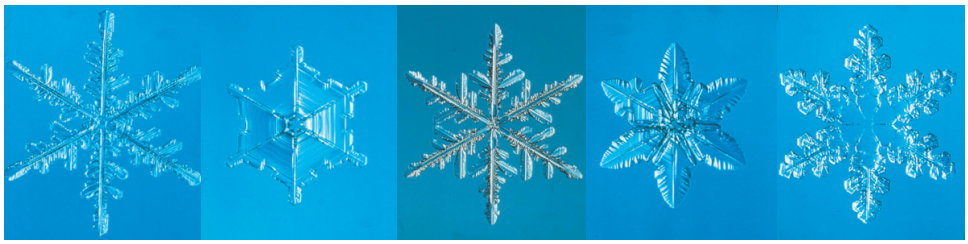

FIGURE 536 Some snow flakes (© Furukawa Yoshinori)

questions are still topic of research; the answer is still open.

Another question is the mechanism of face formation in crystals. Can you confirm Challenge 1531 s that crystal faces are those planes with the *slowest* growth speed, because all fast growing planes are eliminated? The finer details of the process form a complete research field in Ref. 1015 itself.

However, not always the slowest growing planes win out. Figure 536 shows some well-known exceptions. Explaining such shapes is possible today, and Furukawa Yoshinori is Ref. 1016 one of the experts in the field, heading a dedicated research team. Indeed, there remains the question of symmetry: why are crystals often symmetric, such as snowflakes, instead of asymmetric? This issue is a topic of self-organization, as mentioned already in the Page 302 section of classical physics. It turns out that the symmetry is an automatic result of the way molecular systems grow under the combined influence of diffusion and nonlinear processes. The details are still a topic of research.

* *

A similar breadth of physical and mathematical problems are encountered in the study Ref. 1017 of liquids and polymers. The ordering of polymer chains, the bubbling of hot water, the motion of heated liquids and the whirls in liquid jets show complex behaviour that can be explained with simple models. Turbulence and self-organization will be a fascinating research field for many years to come.

* *

The ways people handle single atoms with electromagnetic fields provide many beautiful examples of modern applied technologies. Nowadays it is possible to levitate, to trap, to Page 260 excite, to photograph, to deexcite and to move single atoms just by shining light onto Ref. 210 them. In 1997, the Nobel Prize in Physics has been awarded to the originators of the field.

* *

In 1997, a Czech group built a quantum version of the Foucault pendulum, using the Ref. 1018 superfluidity of helium. In this beautiful piece of research, they cooled a small ring of fluid helium below the temperature of 0.28 K, below which the helium moves without friction. In such situations it thus can behave like a Foucault pendulum. With a clever arrangement, it was possible to measure the rotation of the helium in the ring using phonon signals, and to show the rotation of the Earth.

* *

If an electrical wire is sufficiently narrow, its electrical conductance is quantized in steps of $2e^2/\hbar$. The wider the wire, the more such steps are added to its conductance. Can you Challenge 1532 s explain the effect? By the way, quantized conductance has also been observed for light Ref. 1019 and for phonons.

* *

An example of modern research is the study of hollow atoms, i.e., atoms missing a number of inner electrons. They have been discovered in 1990 by J.P. Briand and his group. They appear when a completely ionized atom, i.e., one without any electrons, is brought in contact with a metal. The acquired electrons then orbit on the outside, leaving the inner shells empty, in stark contrast with usual atoms. Such hollow atoms can also be Ref. 1020 formed by intense laser irradiation.

* *

In the past, the description of motion with formulae was taken rather seriously. Before computers appeared, only those examples of motion were studied which could be described with simple formulae. It turned out that Galilean mechanics cannot solve the three-body problem, special relativity cannot solve the two-body problem, general relativity the one-body problem and quantum field theory the zero-body problem. It took some time to the community of physicists to appreciate that understanding motion does not depend on the description by formulae, but on the description by clear equations based on space and time.

* *

The Casimir effect, as well as other experiments, imply that there is a specific and *finite* energy density that can be ascribed to the vacuum. Does this mean that we can apply the Challenge 1533 d Banach-Tarski effect to pieces of vacuum?

* *

Challenge 1534 s Can you explain why mud is not clear?

* *

Challenge 1535 ny Matter is hard, radiation is soft. Are you able to summarise why?

* *

Photons not travelling parallel to each other attract each other through gravitation and thus deflect each other. Could two such photons form a bound state, a sort of atom of light, in which they would circle each other, provided there were enough empty space Challenge 1536 s for this to happen?

* *

Challenge 1537 s Can the universe ever have been smaller than its own Compton wavelength?

In fact, quantum electrodynamics, or QED, provides a vast number of curiosities and every year there is at least one interesting new discovery. We now conclude the theme with a more general approach.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

How can one move on perfect ice? – The ultimate physics test

In our quest, we have encountered motion of many sorts. Therefore, the following test – not to be taken too seriously – is the ultimate physics test, allowing to check your understanding and to compare it with that of others.

Imagine that you are on a perfectly frictionless surface and that you want to move to its border. How many methods can you find to achieve this? Any method, so tiny its effect may be, is allowed.

Classical physics provided quite a number of methods. We saw that for rotating ourselves, we just need to turn our arm above the head. For translation motion, throwing a shoe or inhaling vertically and exhaling horizontally are the simplest possibilities. Can
Challenge 1538 s you list at least six additional methods, maybe some making use of the location of the surface on Earth? What would you do in space?

Electrodynamics and thermodynamics taught us that in vacuum, heating one side of the body more than the other will work as motor; the imbalance of heat radiation will push you, albeit rather slowly. Are you able to find at least four other methods from these
Challenge 1539 s two domains?

General relativity showed that turning one arm will emit gravitational radiation un-
Challenge 1540 s symmetrically, leading to motion as well. Can you find at least two better methods?

Quantum theory offers a wealth of methods. Of course, quantum mechanics shows that we actually are always moving, since the indeterminacy relation makes rest an impossibility. However, the average motion can be zero even if the spread increases with time. Are you able to find at least four methods of moving on perfect ice due to quantum
Challenge 1541 s effects?

Materials science, geophysics, atmospheric physics and astrophysics also provide ways
Challenge 1542 s to move, such as cosmic rays or solar neutrinos. Can you find four additional methods?

Self-organization, chaos theory and biophysics also provide ways to move, when the inner workings of the human body are taken into account. Can you find at least two
Challenge 1543 s methods?

Assuming that you read already the section following the present one, on the effects of semiclassical *quantum gravity*, here is an additional puzzle: is it possible to move by
Challenge 1544 s accelerating a pocket mirror, using the emitted Unruh radiation? Can you find at least two other methods to move yourself using quantum gravity effects? Can you find one from string theory?

If you want points for the test, the marking is simple. For students, every working method gives one point. Eight points is ok, twelve points is good, sixteen points is very good, and twenty points or more is excellent.For graduated physicists, the point is given only when a back-of-the-envelope estimate for the ensuing momentum or acceleration is provided.

A summary of quantum electrodynamics

The shortest possible summary of quantum electrodynamics is the following: *matter is made of charged particles which interact through photon exchange in the way described by Figure 537*.

No additional information is necessary. In a bit more detail, quantum electrodynamics starts with elementary *particles*, characterized by their mass, their spin and their charge,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

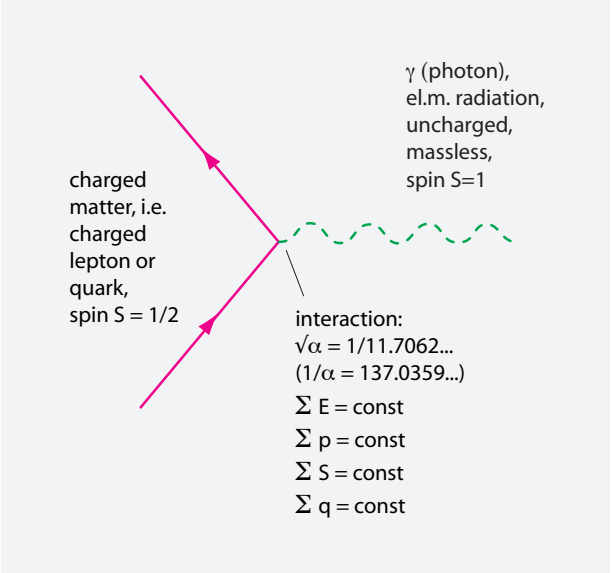

FIGURE 537 QED as perturbation theory in space-time

and with the *vacuum*, essentially a sea of virtual particle–antiparticle pairs. *Interactions* between charged particles are described as the exchange of virtual photons, and *decay* is described as the interaction with the virtual photons of the vacuum.

All physical results of QED can be calculated by using the single diagram of Figure 537. It contains the Lagrangian and the Hamiltonian of QED, as well as a method to calculate results for actual systems. As QED is a perturbative theory, the diagram directly describes the first order effects and its composites describe effects of higher order. QED is a perturbative theory.

QED describes all everyday properties of matter and radiation. It describes the *divisibility* down to the smallest constituents, the *isolability* from the environment and the *impenetrability* of matter. It also describes the *penetrability* of radiation. All these properties are due to electromagnetic interactions of constituents and follow from Figure 537. Matter is divisible because the interactions are of finite strength, matter is also divisible because the interactions are of finite range, and matter is impenetrable because interactions among the constituents increase in intensity when they approach each other, in particular because matter constituents are fermions. Radiation is divisible into photons, and is penetrable because photons are bosons and first order photon-photon interactions do not exist.

Both matter and radiation are made of elementary constituents. These elementary constituents, whether bosons or fermions, are indivisible, isolable, indistinguishable, and point-like.

To describe observations, it is necessary to use quantum electrodynamics in all those situations for which the characteristic dimensions d are of the order of the Compton wavelength

$$d \approx \lambda_C = \frac{h}{m\,c}\,. \tag{703}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In situations where the dimensions are of the order of the de Broglie wavelength, or equivalently, where the action is of the order of the Planck value, simple quantum mechanics is sufficient:

$$d \approx \lambda_{\mathrm{dB}} = \frac{h}{m\,v} \,. \tag{704}$$

For larger dimensions, classical physics will do.

Together with gravity, quantum electrodynamics explains almost all observations of motion on Earth; QED unifies the description of matter and radiation in daily life. All objects and all images are described by it, including their properties, their shape, their transformations and their other changes. This includes self-organization and chemical or biological processes. In other words, QED gives us full grasp of the effects and the variety of motion due to electromagnetism.

Open questions in QED

Even though QED describes motion without any discrepancy from experiment, that does not mean that we understand every detail of every example of electric motion. For example, nobody has described the motion of an animal with QED yet.* In fact, there is beautiful and fascinating work going on in many branches of electromagnetism.

Atmospheric physics still provides many puzzles and regularly delivers new, previ- Ref. 1022 ously unknown phenomena. For example, the detailed mechanisms at the origin of aurorae are still controversial; and the recent unexplained discoveries of discharges *above* Ref. 1023 clouds should not make one forget that even the precise mechanism of charge separation *inside* clouds, which leads to lightning, is not completely clarified. In fact, all examples of electrification, such as the charging of amber through rubbing, the experiment which gave electricity its name, are still poorly understood.

Materials science in all its breadth, including the study of solids, fluids, and plasmas, as well as biology and medicine, still provides many topics of research. In particular, the twenty-first century will undoubtedly be the century of the life sciences.

The study of the interaction of atoms with intense light is an example of present research in atomic physics. Strong lasers can strip atoms of many of their electrons; for such phenomena, there are not yet precise descriptions, since they do not comply to the weak field approximations usually assumed in physical experiments. In strong fields, new Ref. 1025 effects take place, such as the so-called Coulomb explosion.

But also the skies have their mysteries. In the topic of cosmic rays, it is still not clear Ref. 1024 how rays with energies of 10^{22} eV are produced outside the galaxy. Researchers are intensely trying to locate the electromagnetic fields necessary for their acceleration and to understand their origin and mechanisms.

In the theory of quantum electrodynamics, discoveries are expected by all those who Ref. 1026 study it in sufficient detail. For example, Dirk Kreimer has discovered that higher order interaction diagrams built using the fundamental diagram of Figure 537 contain relations to the theory of knots. This research topic will provide even more interesting results in the near future.

* On the other hand, there is beautiful work going on how humans move their limbs; it seems that humans Ref. 1021 move by combining a small set of fundamental motions.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Relations to knot theory appear because QED is a *perturbative* description, with the vast richness of its nonperturbative effects still hidden. Studies of QED at high energies, where perturbation is *not* a good approximation and where particle numbers are not conserved, promise a wealth of new insights. We will return to the topic later on.

High energies provide many more questions. So far, the description of motion was based on the idea that measurable quantities can be multiplied and added. This always happens at one space-time point. In mathematical jargon, observables form a *local* algebra. Thus the structure of an algebra contains, implies and follows from the idea that local properties *lead* to local properties. We will discover later on that this basic assumption is wrong at high energies.

Many other open issues of more practical nature have not been mentioned. Indeed, by far the largest numbers of physicists get paid for some form of applied QED. However, our quest is the description of the *fundamentals* of motion. So far, we have not achieved it. For example, we still need to understand motion in the realm of atomic nuclei. But before we do that, we take a first glimpse of the strange issues appearing when gravity and quantum theory meet.

Chapter 43

QUANTUM MECHANICS WITH GRAVITATION – THE FIRST APPROACH

Gravitation is a weak effect. Every seaman knows it: storms are the worst part of his life, not gravity. Despite its weakness, including gravity into quantum mechanics yields a list of important issues.

Does gravity act on quantum systems? Yes. In the chapter on general relativity we already mentioned that light frequency changes with height. Thus gravity has a simple and measurable effect on photons.

In 2004 it became possible to repeat Galileo's leaning tower experiment with atoms instead of steel balls. Single atoms do fall like stones. In particular, atoms of different mass fall with the same acceleration, within the experimental precision of one part in 6 million.

Ref. 1027

The phase of wave functions

Gravity also has an effect on wave functions: it changes their *phase*. Can you imagine why? The effect was first confirmed in 1975 with the help of neutron interferometers, where neutron beams are brought to interference after having climbed some height h at two different locations. The experiment is shown schematically in Figure 538; the predicted phase difference is

Challenge 1545 ny

$$\delta\varphi = \frac{mghl}{\hbar v} \,, \tag{705}$$

where l is the horizontal distance between the two climbs and v and m are the speed and mass of the neutrons. These beautifully simple experiments have confirmed the formula within experimental errors.

Ref. 1028

In the 1990s, similar experiments have even been performed with complete atoms. These interferometers are so sensitive that local gravity g can be measured with a precision of more than eight significant digits.

Ref. 1030

Playing table tennis with neutrons

The gravitational potential also has directly measurable effects on quantum particles. Classically, a table tennis ball (without spin) follows parabolic paths when bouncing over a table tennis table. How does a quantum particle behave in the same setting? The experiment was first performed in 2002.

Ref. 1031

In the gravitational field, the energy levels of the neutron are quantized. This leads to probability density that changes with height in discrete steps, as shown in Figure 539.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

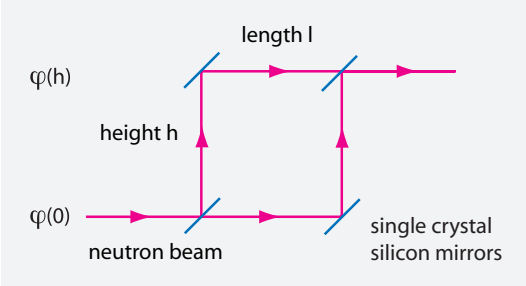

FIGURE 538 The weakness of gravitation

FIGURE 539 Table tennis and neutrons

— More to be added —

The best experimental procedure is to produce an intense beam of neutral particles, because neutral particles are not affected by stray electromagnetic fields. Neutrons are ideal, as they are produced in large quantities by nuclear reactors. Using a few clever tricks, the experimenters managed to slow down neutrons to the incredibly small value of 8 m/s, comparable to a table tennis ball. They then directed the neutrons onto a neutron mirror, the analogue of the table tennis table, and observed the neutrons jumping back up.

Why is the experiment so difficult? The lowest energy level for neutrons due to gravity is $2.3 \cdot 10^{-31}$ J, or 1.4 peV. To get an impression of it smallness, we can compare it to the value of $2.2 \cdot 10^{-18}$ J or 13.6 eV for the lowest state in the hydrogen atom. Nevertheless, the team managed to measure the first few discrete levels. The results confirmed the prediction of the Schrödinger equation to the achievable measurement precision.

In short, neutrons in gravity, atoms in gravity and photons in gravity show now surprises. The Dirac equation with gravity can thus be used, for example, to describe the processes inside trees.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The gravitational Bohr atom

A short calculation shows that an electron circling a proton due to gravity alone, without electrostatic attraction, would do so at a gravitational Bohr radius of

Challenge 1546 ny

$$r_{\text{gr.B.}} = \frac{\hbar^2}{G\, m_e^2\, m_p} = 1.1 \cdot 10^{29}\,\text{m} \tag{706}$$

which is about a thousand times the distance to the cosmic horizon. In fact, even in the normal hydrogen atom there is not a *single way* to measure gravitational effects. (Are you able to confirm this?)

Challenge 1547 ny

But why is gravity so weak? Or equivalently, why are the universe and normal atoms so much smaller than a gravitational Bohr atom? At the present point of our quest these questions cannot be answered. Worse, the weakness of gravity even means that with high probability, future experiments will provide little additional data helping to decide among competing answers. The only help is careful thought.

We might conclude from all this that gravity does not require a quantum description. Indeed, we stumbled onto quantum effects because classical electrodynamics implies, in stark contrast with reality, that atoms decay in about 0.1 ns. Classically, an orbiting electron would emit radiation until it falls into the nucleus. Quantum theory is thus necessary to explain the existence of matter.

When the same stability calculation is performed for the emission of gravitational radiation by orbiting electrons, one finds a decay time of around 10^{37} s. (True?) This extremely large value, trillions of times longer than the age of the universe, is a result of the low emission of gravitational radiation by rotating masses. Therefore, the existence of atoms does not require a quantum theory of gravity.

Challenge 1548 ny

Page 530

Indeed, quantum gravity is unnecessary in every single domain of everyday life. However, we will see later on that quantum gravity is necessary in domains which are more remote, but also more fascinating.

Page 1396

Gravitation and limits to disorder

> Die Energie der Welt ist constant.
> Die Entropie der Welt strebt einem Maximum zu.*
>
> Rudolph Clausius

We have already encountered the famous statement by Clausius, the father of the term 'entropy'. We have seen that the Boltzmann constant $k/2$ is the smallest entropy found in nature.

Page 598

What is the influence of gravitation on entropy, and thermodynamics in general? For a long time, nobody was interested in this question. In parallel, for many decades nobody asked whether there also exists a theoretical *maximum* for entropy. The situations changed dramatically in 1973, when Jacob Bekenstein discovered that the two issues are related.

Bekenstein was investigating the consequences gravity has for quantum physics. He

Ref. 1032

* 'The energy of the universe is constant. Its entropy tends towards a maximum.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

found that the entropy of an object of energy E and size L is bound by

$$S \leqslant EL\frac{k\pi}{\hbar c} \tag{707}$$

for all physical systems. In particular, he deduced that (nonrotating) black holes saturate
Challenge 1549 s the bound, with an entropy given by

$$S = \frac{kc^3}{G\hbar}\frac{A}{4} = \frac{kG}{\hbar c}4\pi M^2 \tag{708}$$

where A is now the area of the *horizon* of the black hole. It is given by $A = 4\pi R^2 = 4\pi(2GM/c^2)^2$. In particular, the result implies that every black hole has an entropy. Black holes are thus disordered systems described by thermostatics. *Black holes are the most disordered systems known.**

As an interesting note, the maximum entropy also gives a memory limit for memory
Challenge 1550 s chips. Can you find out how?

What are the different microstates leading to this macroscopic entropy? It took many years to convince physicists that the microstates are due to the various possible states of the black hole horizon itself, and that they are due to the diffeomorphism invariance
Ref. 1034 at this boundary. As Gerard 't Hooft explains, the entropy expression implies that the number of degrees of freedom of a black hole is about (but not exactly) one per Planck
Challenge 1551 s area of the horizon.

If black holes have entropy, they must have a temperature. What does this temperature mean? In fact, nobody believed this conclusion until two unrelated developments confirmed it within a short time. All these results were waiting to be discovered since the 1930s, even though, incredibly, nobody had thought about them for over 40 years.

Measuring acceleration with a thermometer – Fulling–Davies–Unruh radiation

Independently, Stephen Fulling in 1973, Paul Davies in 1975 and William Unruh in 1976
Ref. 1035 made the same theoretical discovery while studying quantum theory: if an inertial observer observes that he is surrounded by vacuum, a second observer *accelerated* with respect to the first does not: he observes black body radiation. The radiation has a spectrum corresponding to the temperature

$$T = a\frac{\hbar}{2\pi kc} \,. \tag{709}$$

* The precise discussion that black holes are the most disordered systems in nature is quite subtle. The
Ref. 1033 issue is summarized by Bousso. Bousso claims that the area appearing in the maximum entropy formula cannot be taken naively as the area at a given time, and gives four arguments why this should be not allowed. However, all four arguments are wrong in some way, in particular because they assume that lengths smaller than the Planck length or larger than the universe's size can be measured. Ironically, he brushes aside some of the arguments himself later in the paper, and then deduces an improved formula, which is exactly the same as the one he criticizes first, just with a different interpretation of the area A. Later in his careers, Bousso revised his conclusions; he now supports the maximum entropy bound. In short, the expression of black hole entropy is indeed the maximum entropy for a physical system with surface A.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The result means that there is no vacuum on Earth, because any observer on its surface can maintain that he is accelerated with $9.8\,\mathrm{m/s^2}$, thus leading to $T = 40\,\mathrm{zK}$! We can thus measure gravity, at least in principle, using a thermometer. However, even for the largest practical accelerations the temperature values are so small that it is questionable whether the effect will ever be confirmed experimentally. But if it will, it will be a great experiment. Ref. 1036

When this effect was predicted, people explored all possible aspects of the argument. For example, also an observer in rotational motion detects radiation following expression (709). But that was not all. It was found that the acceleration of a *mirror* leads to radiation *emission*! Mirrors are thus harder to accelerate than other bodies of the same mass.

When the acceleration is high enough, also *matter* particles can be emitted and detected. If a particle counter is accelerated sufficiently strongly across the vacuum, it will start counting particles! We see that the difference between vacuum and matter becomes fuzzy at large accelerations.

Black holes aren't black

In 1973 and 1974, Jacob Bekenstein, and independently, the English physicist Stephen Hawking, famous for the courage with which he fights a disease which forces him into the wheelchair, surprised the world of general relativity with a fundamental theoretical discovery. They found that if a virtual particle–antiparticle pair appeared in the vacuum near the horizon, there is a finite chance that one particle escapes as a real particle, while the virtual antiparticle is captured by the black hole. The virtual antiparticle is thus of negative energy, and reduces the mass of the black hole. The mechanism applies both to fermions and bosons. From far away this effect looks like the emission of a particle. A detailed investigation showed that the effect is most pronounced for photon emission. In short, Bekenstein and Hawking showed that black holes radiate as black bodies.

Black hole radiation confirms both the result on black hole entropy by Bekenstein and the effect for observers accelerated in vacuum found by Fulling, Davies and Unruh. When all this became clear, a beautiful Gedanken experiment was published by William Unruh and Robert Wald, showing that the whole result could have been deduced already 50 years earlier! Ref. 1037

Shameful as this delay of the discovery is for the community of theoretical physicists, the story itself remains beautiful. It starts in the early 1970s, when Robert Geroch studied the issue shown in Figure 540. Imagine a mirror box full of heat radiation, thus full of light. The mass of the box is assumed to be negligible, such as a box made of thin aluminium paper. We lower the box, with all its contained radiation, from a space station towards a black hole. On the space station, lowering the weight of the heat radiation allows to generate energy. Obviously, when the box reaches the black hole horizon, the heat radiation is red-shifted to infinite wavelength. At that point, the full amount of energy originally contained in the heat radiation has been provided to the space station. We can now do the following: we can open the box on the horizon, let drop out whatever is still inside, and wind the empty and massless box back up again. As a result, we have completely converted heat radiation into mechanical energy. Nothing else has changed: the black hole has the same mass as beforehand.

But this result contradicts the second principle of thermodynamics! Geroch con-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

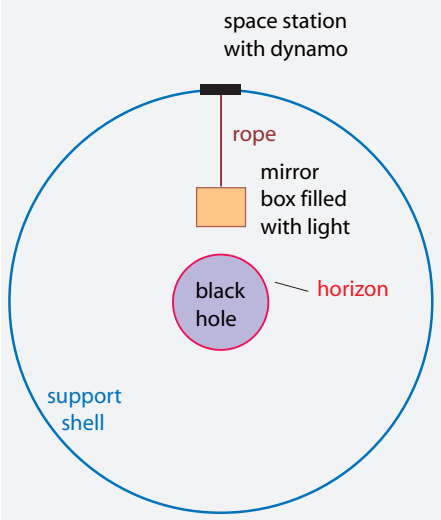

FIGURE 540 A *Gedanken experiment* allowing to deduce the existence of black hole radiation

cluded that something must be wrong. We must have forgotten an effect which makes this process impossible.

In the 1980s, Unruh and Wald showed that black hole radiation is precisely the forgotten effect that puts everything right. Because of black hole radiation, the box feels buoyancy, so that it cannot be lowered down to the horizon. It floats somewhat above it, so that the heat radiation inside the box has not yet *zero* energy when it falls out of the opened box. As a result, the black hole does increase in mass and thus in entropy. In summary, when the empty box is pulled up again, the final situation is thus the following: only part of the energy of the heat radiation has been converted into mechanical energy, part of the energy went into the increase of mass and thus of entropy of the black hole. The second principle of thermodynamics is saved.

Well, it is only saved if the heat radiation has precisely the right energy density at the horizon and above. Let us have a look. The centre of the box can only be lowered up to a hovering distance d above the horizon, where the acceleration due to gravity is $g = c^2/4GM$. The energy E gained by lowering the box is

$$E = mc^2 - mg\frac{d}{2} = mc^2\left(1 - \frac{dc^2}{8GM}\right) \tag{710}$$

The efficiency of the process is $\eta = E/mc^2$. To be consistent with the second law of thermodynamics, this efficiency must obey

$$\eta = \frac{E}{mc^2} = 1 - \frac{T_{\mathrm{BH}}}{T}e \tag{711}$$

We thus find a black hole temperature T_{BH} given by the hovering distance d. That hovering distance d is roughly given by the size of the box. The box size in turn must be

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 102 The principles of thermodynamics and those of horizon mechanics

Principle	Thermodynamics	Horizons
Zeroth principle	the temperature T is constant in a body at equilibrium	the surface gravity a is constant on the horizon
First principle	energy is conserved: $\mathrm{d}E = T\mathrm{d}S - p\mathrm{d}V + \mu\mathrm{d}N$	energy is conserved: $\mathrm{d}(mc^2) = \frac{ac^2}{8\pi G}\mathrm{d}A + \Omega\mathrm{d}J + \Phi\mathrm{d}q$
Second principle	entropy never decreases: $\mathrm{d}S \geqslant 0$	surface area never decreases: $\mathrm{d}A \geqslant 0$
Third principle	$T = 0$ cannot be achieved	$a = 0$ cannot be achieved

at least the wavelength of the thermal radiation; in first approximation, Wien's relation gives $d \approx \hbar c/kT$. A precise calculation, first performed by Hawking, gives the result

$$T_{\mathrm{BH}} = \frac{\hbar c^3}{8\pi kGM} = \frac{\hbar c}{4\pi k}\frac{1}{R} = \frac{\hbar}{2\pi kc}\, g_{\mathrm{surf}} \quad \text{with} \quad g_{\mathrm{surf}} = \frac{c^4}{4GM} \tag{712}$$

where R and M are the radius and the mass of the black hole. It is either called the black-hole temperature or Bekenstein-Hawking temperature. As an example, a black hole with the mass of the Sun would have the rather small temperature of 62 nK, whereas a smaller black hole with the mass of a mountain, say 10^{12} kg, would have a temperature of 123 GK. That would make quite a good oven. All known black hole candidates have masses in the range from a few to a few million solar masses. The radiation is thus extremely weak, the reason being that the emitted wavelength is of the order of the black hole radius, as you might want to check. The radiation emitted by black holes is often also called *Bekenstein-Hawking radiation*.

Challenge 1552 ny

Ref. 1038

Black hole radiation is thus so weak that we can speak of an academic effect. It leads to a luminosity that increases with decreasing mass or size as

Challenge 1553 ny

$$L \sim \frac{1}{M^2} \sim \frac{1}{R^2} \quad \text{or} \quad L = nA\sigma T^4 = n\frac{c^6\hbar}{G^2M^2}\frac{\pi^2}{15\cdot 2^7} \tag{713}$$

where σ is the Stefan–Boltzmann or *black body radiation constant*, n is the number of particle degrees of freedom that can be radiated; if only photons are radiated, we have $n = 2$. (For example, if neutrinos were massless, they would be emitted more frequently than photons.)

Page 793

Ref. 1039

Black holes thus shine, and the more the smaller they are. This is a genuine *quantum* effect, since classically, black holes, as the name says, cannot emit any light. Even though the effect is academically weak, it will be of importance later on. In actual systems, many other effects around black holes increase the luminosity far above this value; indeed, black holes are usually brighter than normal stars, due to the radiation emitted by the matter falling into them. But that is another story. Here we are only treating isolated black holes, surrounded only by vacuum.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Due to the emitted radiation, black holes gradually lose mass. Therefore their theoretical lifetime is *finite*. A calculation shows that it is given by

Challenge 1554 ny

$$t = M^3 \frac{20\,480\,\pi G^2}{\hbar c^4} \approx M^3\ 3.4 \cdot 10^{-16}\ \mathrm{s/kg^3} \tag{714}$$

as function of their initial mass M. For example, a black hole with mass of 1 g would have a lifetime of $3.4 \cdot 10^{-25}$ s, whereas a black hole of the mass of the Sun, $2.0 \cdot 10^{30}$ kg, would have a lifetime of about 10^{68} years. Obviously, these numbers are purely academic. In any case, *black holes evaporate*. However, this extremely slow process for usual black holes determines their lifetime only if no other, faster process comes into play. We will present a few such processes shortly. Hawking radiation is the weakest of all known effects. It is not masked by stronger effects only if the black hole is non-rotating, electrically neutral and with no matter falling into it from the surroundings.

So far, none of these quantum gravity effects has been confirmed experimentally, as the values are much too small to be detected. However, the deduction of a Hawking temperature has been beautifully confirmed by a theoretical discovery of Unruh, who found that there are configurations of fluids in which sound waves cannot escape, so-called '*silent holes*'. Consequently, these silent holes radiate sound waves with a temperature satisfying the same formula as real black holes. A second type of analogue system, namely *optical black holes*, are also being investigated.

Ref. 1040

Ref. 1042

Gamma ray bursts

In 1975, a much more dramatic radiation effect than black hole radiation was predicted for *charged* black holes by Damour and Ruffini. Charged black holes have a much shorter lifetime than just presented, because during their formation a second process takes place. In a region surrounding them the electric field is larger than the so-called vacuum polarization value, so that large numbers of electron-positron pairs are produced, which then almost all annihilate. This process effectively reduces the charge of the black hole to a value for which the field is below critical everywhere, while emitting large amounts of high energy light. It turns out that the mass is reduced by up to 30 % in a time of the order of seconds. That is quite shorter than 10^{68} years. This process thus produces an extremely intense *gamma ray burst*.

Ref. 1043

Such gamma ray bursts had been discovered in the late 1960s by military satellites which were trying to spot nuclear explosions around the world through their gamma ray emission. The satellites found about two such bursts per day, coming from all over the sky. Another satellite, the Compton satellite, confirmed that they were extragalactic in origin, and that their duration varied between a sixtieth of a second and about a thousand seconds. In 1996, the Italian-Dutch BeppoSAX satellite started mapping and measuring gamma ray bursts systematically. It discovered that they were followed by an *afterglow* in the X-ray domain of many hours, sometimes of days. In 1997 afterglow was discovered also in the optical domain. The satellite also allowed to find the corresponding X-ray, optical and radio sources for each burst. These measurements in turn allowed to determine the distance of the burst sources; red-shifts between 0.0085 and 4.5 were measured. In 1999 it also became possible to detect *optical* bursts corresponding to the

Ref. 1044

Ref. 1045

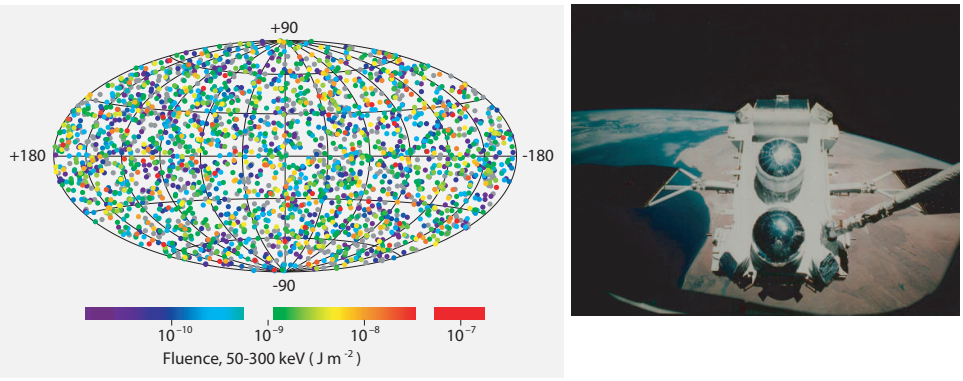

FIGURE 541 The location and energy of the 2704 gamma ray bursts observed in the sky between 1991 and 2000 by the BATSE experiment on board of the Compton Gamma Ray Observatory, a large satellite deployed by the space shuttle after over 20 years of planning and construction (NASA)

gamma ray ones.*

All this data together show that the gamma ray bursts have energies ranging from 10^{40} W to 10^{45} W. The larger value is about one hundredth of the brightness all stars of the whole visible universe taken together! Put differently, it is the same amount of energy that is released when converting several solar masses into radiation within a few seconds. In fact, the measured luminosity is near the theoretical maximum luminosity a body can have. This limit is given by

Challenge 1555 s

$$L < L_{\mathrm{Pl}} = \frac{c^5}{4G} = 0.9 \cdot 10^{52}\,\mathrm{W}\,, \tag{715}$$

as you might want to check yourself. In short, the sources of gamma ray bursts are the biggest bombs found in the universe. In fact, more detailed investigations of experimental data confirm that gamma ray bursts are 'primal screams' of black holes in formation.

Challenge 1556 e

Ref. 1045

With all this new data, Ruffini took up his 1975 model again in 1997 and with his collaborators showed that the gamma ray bursts generated by the annihilation of electron-positrons pairs created by vacuum polarization, in the region they called the *dyadosphere*, have a luminosity and a duration exactly as measured, if a black hole of about a few up to 30 solar masses is assumed. Charged black holes therefore reduce their charge and mass through the vacuum polarization and electron positron pair creation process. (The process reduces the mass because it is one of the few processes which is *reversible*; in contrast, most other attempts to reduce charge on a black hole, e.g. by throwing in a particle with the opposite charge, increase the mass of the black hole and are thus irreversible.) The left over remnant then can lose energy in various ways and also turns out to be responsible for the afterglow discovered by the BeppoSAX satellite. Among others, Ruffini's team speculates that the remnants are the sources for the high energy cosmic rays, whose origin had not been localized so far. All these exciting studies are still ongoing.

Ref. 1046

Recent studies distinguish two classes of gamma ray bursts. Short gamma ray bursts,

* For more about this fascinating topic, see the www.aip.de/~jcg/grb.html website by Jochen Greiner.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

with a duration between a millisecond and two seconds, differ significantly in energy and spectrum from long gamma ray bursts, with an average length of ten seconds, a higher energy content and a softer energy spectrum. It is often speculated that short bursts are due to merging neutron stars or merging black holes, whereas long bursts are emitted, as just explained, when a black hole is formed in a supernova or hypernova explosion. It also seems that gamma ray bursts are not of spherical symmetry, but that the emission takes place in a collimated beam. This puts the energy estimates given above somewhat into question. The details of the formation process are still subject to intense exploration.

Ref. 1048

Other processes leading to emission of radiation from black holes are also possible. Examples are matter falling into the black hole and heating up, matter being ejected from rotating black holes through the Penrose process, or charged particles falling into a black hole. These mechanisms are at the origin of *quasars*, the extremely bright quasi-stellar sources found all over the sky. They are assumed to be black holes surrounded by matter, in the development stage following gamma ray bursters. The details of what happens in quasars, the enormous voltages (up to 10^{20} V) and magnetic fields generated, as well as their effects on the surrounding matter are still object of intense research in astrophysics.

Page 611

Material properties of black holes

Once the concept of entropy of a black hole was established, people started to think about black holes like about any other material object. For example, black holes have a matter density, which can be defined by relating their mass to a fictitious volume defined by $4\pi R^3/3$. This density is given by

$$\rho = \frac{1}{M^2}\,\frac{3c^6}{32\pi G^3} \tag{716}$$

and can be quite low for large black holes. For the highest black holes known, with 1000 million solar masses or more, the density is of the order of the density of air. Nevertheless, even in this case, the density is the highest possible in nature for that mass.

Challenge 1557 e

By the way, the gravitational acceleration at the horizon is still appreciable, as it is given by

$$g_{\text{surf}} = \frac{1}{M}\,\frac{c^4}{4G} = \frac{c^2}{2R} \tag{717}$$

which is still 15 km/s^2 for an air density black hole.

Challenge 1558 ny

Obviously, the black hole temperature is related to the entropy S by its usual definition

$$\frac{1}{T} = \left.\frac{\partial S}{\partial E}\right|_{\rho} = \left.\frac{\partial S}{\partial (Mc^2)}\right|_{\rho} \tag{718}$$

All other thermal properties can be deduced by the standard relations from thermostatics.

In particular, it looks as if black holes are the matter states with the largest possible entropy. Can you confirm this statement?

Challenge 1559 ny

It also turns out that black holes have a *negative* heat capacity: when heat is added, they

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

cool down. In other words, black holes cannot achieve equilibrium with a bath. This is not a real surprise, since *any* gravitationally bound material system has negative specific heat. Indeed, it takes only a bit of thinking to see that any gas or matter system collapsing under gravity follows $dE/dR > 0$ and $dS/dR > 0$. That means that while collapsing, the energy and the entropy of the system shrink. (Can you find out where they go?) Since temperature is defined as $1/T = dS/dE$, temperature is always positive; from the temperature increase $dT/dR < 0$ during collapse one deduces that the specific heat dE/dT is negative.

Challenge 1560 ny
Challenge 1561 s
Ref. 1049

Black holes, like any object, oscillate when slightly perturbed. These vibrations have also been studied; their frequency is proportional to the mass of the black hole.

Ref. 1050

Nonrotating black holes have no magnetic field, as was established already in the 1960s by Russian physicists. On the other hand, black holes have something akin to a finite electrical conductivity and a finite viscosity. Some of these properties can be understood if the horizon is described as a membrane, even though this model is not always applicable. In any case, one can study and describe macroscopic black holes like any other macroscopic material body. The topic is not closed.

Ref. 1039
Ref. 1047

How do black holes evaporate?

When a nonrotating and uncharged black hole loses mass by radiating Hawking radiation, eventually its mass reaches values approaching the Planck mass, namely a few micrograms. Expression (714) for the lifetime, applied to a black hole of Planck mass, yields a value of over sixty thousand Planck times. A surprising large value. What happens in those last instants of evaporation?

A black hole approaching the Planck mass at some time will get smaller than its own Compton wavelength; that means that it behaves like an elementary particle, and in particular, that quantum effects have to be taken into account. It is still unknown how these final evaporation steps take place, whether the mass continues to diminish smoothly or in steps (e.g. with mass values decreasing as $\sqrt{n}$ when n approaches zero), how its internal structure changes, whether a stationary black hole starts to rotate (as the author predicts), how the emitted radiation deviates from black body radiation. There is still enough to study. However, one important issue *has* been settled.

The information paradox of black holes

When the thermal radiation of black holes was discovered, one question was hotly debated for many years. The matter forming a black hole can contain lots of information; e.g., imagine the black hole formed by a large number of books collapsing onto each other. On the other hand, a black hole radiates thermally until it evaporates. Since thermal radiation carries no information, it seems that information somehow disappears, or equivalently, that entropy increases.

An incredible number of papers have been written about this problem, some even claiming that this example shows that physics as we know it is incorrect and needs to be changed. As usual, to settle the issue, we need to look at it with precision, laying all prejudice aside. Three intermediate questions can help us finding the answer.

— What happens when a book is thrown into the Sun? When and how is the information radiated away?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— How precise is the sentence that black hole radiate *thermal* radiation? Could there be a slight deviation?
— Could the deviation be measured? In what way would black holes radiate information?

Challenge 1562 e You might want to make up your own mind before reading on.

Let us walk through a short summary. When a book or any other highly complex – or low entropy – object is thrown into the Sun, the information contained is radiated away. The information is contained in some slight deviations from black hole radiation, namely in slight correlations between the emitted radiation emitted over the burning time of the Sun. A short calculation, comparing the entropy of a room temperature book and the information contained in it, shows that these effects are extremely small and difficult to measure.

Ref. 1051 A clear exposition of the topic was given by Don Page. He calculated what information would be measured in the radiation if the system of black hole and radiation *together* would be in a *pure* state, i.e., a state containing specific information. The result is simple. Even if a system is large – consisting of many degrees of freedom – and in pure state, any smaller *sub*system nevertheless looks almost perfectly thermal. More specifically, if a total system has a Hilbert space dimension $N = nm$, where n and $m \leqslant n$ are the dimensions of two subsystems, and if the total system is in a pure state, the subsystem m Challenge 1563 ny would have an entropy S_m given by

$$S_m = \frac{1-m}{2n} + \sum_{k=n+1}^{mn} \frac{1}{k} \tag{719}$$

which is approximately given by

$$S_m = \ln m - \frac{m}{2n} \quad \text{for} \quad m \gg 1\,. \tag{720}$$

To discuss the result, let us think of n and m as counting degrees of freedom, instead of Hilbert space dimensions. The first term in equation (720) is the usual entropy of a mixed state. The second term is a small deviation and describes the amount of specific information contained in the original pure state; inserting numbers, one finds that it is extremely small compared to the first. In other words, the subsystem m is almost indistinguishable from a mixed state; it looks like a thermal system even though it is not.

A calculation shows that the second, small term on the right of equation (720) is indeed sufficient to radiate away, during the lifetime of the black hole, any information contained in it. Page then goes on to show that the second term is so small that not only it is lost in measurements; it is also lost in the usual, perturbative calculations for physical systems.

The question whether any radiated information could be measured can now be answered directly. As Don Page showed, even measuring half of the system only gives about Ref. 1052 1/2 bit of that information. It is necessary to measure the complete system to measure all the contained information. In summary, at a given instant, the amount of information radiated by a black hole is negligible when compared with the total black hole radiation, and is practically impossible to detect by measurements or even by usual calculations.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

More paradoxes

A black hole is a macroscopic object, similar to a star. Like all objects, it can interact with its environment. It has the special property to swallow everything that falls into them. This immediately leads us to ask if we can use this property to cheat around the usual everyday 'laws' of nature. Some attempts have been studied in the section on general relativity and above; here we explore a few additional ones.

Page 613

* *

Apart from the questions of entropy, we can look for methods to cheat around conservation of energy, angular momentum, or charge. Every Gedanken experiment comes to the same conclusions. No cheats are possible; in addition, the maximum number of degrees of freedom in a region is proportional to the surface area of the region, and *not* to its volume. This intriguing result will keep us busy for quite some time.

Challenge 1564 ny

* *

A black hole transforms matter into antimatter with a certain efficiency. Thus one might look for departures from particle number conservation. Are you able to find an example?

Challenge 1565 ny

* *

Black holes deflect light. Is the effect polarization dependent? Gravity itself makes no difference of polarization; however, if virtual particle effects of QED are included, the story might change. First calculations seem to show that such an effect exists, so that gravitation might produce rainbows. Stay tuned.

Ref. 1056

* *

If lightweight boxes made of mirrors can float in radiation, one gets a strange consequence: such a box might self-accelerate in free space. In a sense, an accelerated box could float on the Fulling–Davies–Unruh radiation it creates by its own acceleration.

Are you able to show the following: one reason why this is impossible is a small but significant difference between gravity and acceleration, namely the absence of tidal effects. (Other reasons, such as the lack of perfect mirrors, also make the effect impossible.)

Challenge 1566 ny

* *

In 2003, Michael Kuchiev has made the spectacular prediction that matter and radiation with a wavelength *larger* than the diameter of a black hole is partly reflected when it hits a black hole. The longer the wavelength, the more efficient the reflection would be. For stellar or even bigger black holes, only photons or gravitons are predicted to be reflected. Black holes are thus not complete trash cans. Is the effect real? The discussion is still ongoing.

Ref. 1057

Curiosities about quantum theory and gravity

Due to the influence of gravity on phases of wave functions, some people who do not believe in bath induced decoherence have even studied the influence of gravity on the decoherence process of usual quantum systems in flat space-time. Predictably, the calculated results do not reproduce experiments.

Ref. 1029

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Despite its weakness, gravitation provides many puzzles. Most famous are a number of curious coincidences that can be found when quantum mechanics and gravitation are combined. They are usually called 'large number hypotheses' because they usually involve large dimensionless numbers. A pretty, but less well known version connects the Planck length, the cosmic horizon, and the number of baryons:

Ref. 1053

$$(N_b)^3 \approx \left(\frac{R_0}{l_{Pl}}\right)^4 = \left(\frac{t_0}{t_{Pl}}\right)^4 \approx 10^{244} \tag{721}$$

in which $N_b = 10^{81}$ and $t_0 = 1.2 \cdot 10^{10}$ a were used. There is no known reason why the number of baryons and the horizon size R_0 should be related in this way. This coincidence is equivalent to the one originally stated by Dirac,* namely

$$m_p^3 \approx \frac{\hbar^2}{Gct_0} \,. \tag{723}$$

where m_p is the proton mass. This approximate equality seems to suggest that certain microscopic properties, namely the mass of the proton, is connected to some general properties of the universe as a whole. This has lead to numerous speculations, especially since the time dependence of the two sides differs. Some people even speculate whether relations (721) or (723) express some long-sought relation between local and global topological properties of nature. Up to this day, the only correct statement seems to be that they are *coincidences* connected to the time at which we happen to live, and that they should not be taken too seriously.

Ref. 1055

Quantum mechanics of gravitation

Let us take a conceptual step at this stage. So far, we looked at quantum theory *with* gravitation; now we have a glimpse at quantum theory *of* gravitation.

If we bring to our mind the similarity between the electromagnetic field and the gravitational 'field,' our next step should be to find the quantum description of the gravitational field. However, despite attempts by many brilliant minds for almost a century, this approach was not successful. Indeed, modern approaches take another direction, as will be explained later on. Let us see what was achieved and why the results are not sufficient.

Ref. 1054 Page 1437

* The equivalence can be deduced using $Gn_b m_p = 1/t_0^2$, which, as Weinberg explains, is required by several cosmological models. Indeed, this can be rewritten simply as

$$m_0^2/R_0^2 \approx m_{Pl}^2/R_{Pl}^2 = c^4/G^2 \,. \tag{722}$$

Together with the definition of the baryon density $n_b = N_b/R_0^3$ one gets Dirac's large number hypothesis, substituting protons for pions. Note that the Planck time and length are defined as $\sqrt{\hbar G/c^5}$ and $\sqrt{\hbar G/c^3}$ and are the natural units of length and time. We will study them in detail in the last part of the mountain ascent.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Do gravitons exist?

Quantum theory says that everything that moves is made of particles. What kind of particles are gravitational waves made of? If the gravitational field is to be treated quantum mechanically like the electromagnetic field, its waves should be quantized. Most properties of these quanta can be derived in a straightforward way.

The $1/r^2$ dependence of universal gravity, like that of electricity, implies that the quanta of the gravitational field have *vanishing* mass and move at light speed. The independence of gravity from electromagnetic effects implies a *vanishing* electric charge.

We observe that gravity is always attractive and never repulsive. This means that the field quanta have *integer* and *even* spin. Vanishing spin is ruled out, since it implies no coupling to energy. To comply with the property that 'all energy has gravity', spin $S = 2$ is needed. In fact, it can be shown that *only* the exchange of a massless spin 2 particle leads, in the classical limit, to general relativity.

Ref. 1059

The coupling strength of gravity, corresponding to the fine structure constant of electromagnetism, is given either by

$$\alpha_{G1} = \frac{G}{\hbar c} = 2.2 \cdot 10^{-15}\,\mathrm{kg}^{-2} \quad \text{or by} \quad \alpha_{G2} = \frac{Gmm}{\hbar c} = \left(\frac{m}{m_{Pl}}\right)^2 = \left(\frac{E}{E_{Pl}}\right)^2 \tag{724}$$

However, the first expression is not a pure number; the second expression is, but depends on the mass one inserts. These difficulties reflect the fact that gravity is not properly speaking an interaction, as became clear in the section on general relativity. It is often argued that m should be taken as the value corresponding to the energy of the system in question. For everyday life, typical energies are 1 eV, leading to a value $\alpha_{G2} \approx 1/10^{56}$. Gravity is indeed weak compared to electromagnetism, for which $\alpha_{em} = 1/137.04$.

If all this is correct, *virtual* field quanta would also have to exist, to explain static gravitational fields.

However, up to this day, the so-called *graviton* has not yet been detected, and there is in fact little hope that it ever will. On the experimental side, nobody knows yet how to build a graviton detector. Just try!

Challenge 1567 s

On the theoretical side, the problems with the coupling constant probably make it impossible to construct a *renormalizable* theory of gravity; the lack of renormalization means the impossibility to define a perturbation expansion, and thus to define particles, including the graviton. It might thus be that relations such as $E = \hbar\omega$ or $p = \hbar/2\pi\lambda$ are not applicable to gravitational waves. In short, it may be that the particle concept has to be changed before applying quantum theory to gravity. The issue is still open at this point.

Space-time foam

The indeterminacy relation for momentum and position also applies to the gravitational field. As a result, it leads to an expression for the indeterminacy of the metric tensor g in a region of size L, which is given by

$$\Delta g \approx 2\frac{{l_{Pl}}^2}{L^2}\,, \tag{725}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1568 ny where $l_{\mathrm{Pl}} = \sqrt{\hbar G/c^3}$ is the Planck length. Can you deduce the result? Quantum theory thus shows that like the momentum or the position of a particle, also the metric tensor g is a *fuzzy* observable.

But that is not all. Quantum theory is based on the principle that actions below $\hbar/2$ cannot be observed. This implies that the observable values for the metric g in a region of size L are bound by

$$g \geqslant \frac{2\hbar G}{c^3}\frac{1}{L^2} \,. \tag{726}$$

Can you confirm this? The result has far-reaching consequences. A minimum value for the metric depending inversely on the region size implies that it is impossible to say what happens to the shape of space-time at extremely small dimensions. In other words, at extremely high energies, the concept of space-time itself becomes fuzzy. John Wheeler introduced the term *space-time foam* to describe this situation. The term makes clear that space-time is not continuous nor a manifold in those domains. But this was the basis on which we built our description of nature so far! We are forced to deduce that our description of nature is built on sand. This issue will form the start of the third part Page 1398 of our mountain ascent.

Decoherence of space-time

General relativity taught us that the gravitational field and space-time are the same. If the gravitational field evolves like a quantum system, we may ask why no superpositions of different macroscopic space-times are observed.

Ref. 1058 The discussion is simplified for the simplest case of all, namely the superposition, in a vacuum region of size l, of a homogeneous gravitational field with value g and one with Page 1077 value g'. As in the case of a superposition of macroscopic distinct wave functions, such a superposition *decays*. In particular, it decays when particles cross the volume. A short Challenge 1569 ny calculation yields a decay time given by

$$t_{\mathrm{d}} = \left(\frac{2kT}{\pi m}\right)^{3/2}\frac{nl^4}{(g-g')^2} \,, \tag{727}$$

where n is the particle number density, kT their kinetic energy and m their mass. Inserting typical numbers, we find that the variations in gravitational field strength are Challenge 1570 ny *extremely* small. In fact, the numbers are so small that we can deduce that the gravitational field is the *first* variable which behaves classically in the history of the universe. Quantum gravity effects for space-time will thus be extremely hard to detect.

In short, matter not only tells space-time how to curve, it also tells it to behave with class.

Quantum theory as the enemy of science fiction

How does quantum theory change our ideas of space-time? The end of the twentieth century has brought several unexpected but strong results in semiclassical quantum gravity.

Ref. 1060 In 1995 Ford and Roman found that worm holes, which are imaginable in general rel-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ativity, cannot exist if quantum effects are taken into account. They showed that macroscopic worm holes require unrealistically large negative energies. (For microscopic worm holes the issue is still unclear.)

Ref. 1062 In 1996 Kay, Radzikowski and Wald showed that closed time-like curves do not exist in semiclassical quantum gravity; there are thus no time machines in nature.

Ref. 1061 In 1997 Pfenning and Ford showed that warp drive situations, which are also imaginable in general relativity, cannot exist if quantum effects are taken into account. Such situations require unrealistically large negative energies.

In short, the inclusion of quantum effects destroys all those fantasies which were started by general relativity.

No vacuum means no particles

Gravity has an important consequence for quantum theory. To count and define particles, Page 1055 quantum theory needs a defined vacuum state. However, the vacuum state cannot be defined when the curvature radius of space-time, instead of being larger than the Compton wavelength, becomes comparable to it. In such highly curved space-times, particles cannot be defined. The reason is the impossibility to distinguish the environment from the particle in these situations: in the presence of strong curvatures, the vacuum is full of spontaneously generated matter, as black holes show. Now we just saw that at small dimensions, space-time fluctuates wildly; in other words, space-time is highly curved at small dimensions or high energies. In other words, strictly speaking particles cannot be defined; the particle concept is only a low energy approximation! We will explore this strange conclusion in more detail in the final part of our mountain ascent.

Summary on quantum theory and gravity

Everyday gravitational fields can be included in quantum theory. However, the inclusion of strong gravitational fields into quantum theory leads to problems with the particle concept.

On the other hand, the inclusion of quantum effects into general relativity leads to space-time foam, space-time superpositions, and probably of gravitons. The inclusion also forbids the existence of wormholes, time-like curves and negative energy regions. Problems with the concept of space-time arises at high curvatures.

Since the combination of quantum theory and gravitation leads to problems with both the particle concept and the space-time concept, we are forced putting into question the foundations of our description of nature so far.

In fact, up to now we hid a simple fact: quantum theory and general relativity *contradict* each other. This contradiction was the real reason that we stepped back to special relativity before we started exploring quantum theory. By stepping back we avoided many problems, because quantum theory does not contradict *special* relativity. However, quantum theory does contradict *general* relativity. The issues are dramatic, changing everything from the basis of classical physics to the results of quantum theory. There will be surprising consequences for the nature of space-time, of particles and for motion itself. But before we study these issues, however, we complete the theme of the present, quantum part of the mountain ascent, namely exploring the essence of matter and interactions.

Chapter 44

THE STRUCTURE OF THE NUCLEUS – THE DENSEST CLOUDS

Nuclear physics was born in 1896 in France, but is now a small activity. ot many researchers are working on the topic now. The field produced ot more than one daughter, experimental high energy physics, which was born around 1930. But since 1985, also these activities are in strong decline, with the exception of the latest CERN experiment. Despite the short time of activity, the history is impressive; the two fields uncovered why stars shine, how powerful bombs work, how cosmic evolution produced the atoms we are made of and how medical doctors can dramatically improve their healing rate.

Ref. 1063

> Nuclear physics is just low-density astrophysics.
> Anonymous

A physical wonder – magnetic resonance imaging

Arguably, the most spectacular tool that physical research has produced in the twentieth century was magnetic resonance imaging, or MRI for short. This technique allows to image human bodies with a high resolution and with (almost) no damage, in strong contrast to X-ray imaging. Though the machines are still expensive – costing up to several million euro – there is hope that they will become cheaper in the future. Such a machine, shown in Figure 542, consists essentially of a large magnetic coil, a radio transmitter and a computer. Some results of putting part of a person into the coil are shown in Figure 543.

In these machines, a radio transmitter emits radio waves that are absorbed because hydrogen nuclei are small spinning magnets. The magnets can be parallel or antiparallel to the magnetic field produced by the coil. The transition energy E is absorbed from a radio wave whose frequency ω is tuned to the magnetic field B. The energy absorbed by a single hydrogen nucleus is given by

$$E = \hbar\omega = \hbar\gamma B \tag{728}$$

The material constant $\gamma/2\pi$ has a value of 42.6 MHz/T for hydrogen nuclei; it results from the non-vanishing spin of the proton. This is a quantum effect, as shown by the appearance of the quantum of action $\hbar$. Using some cleverly applied magnetic fields, typically with a strength between 0.3 and 7 T for commercial and up to 21 T for experimental machines, the machines are able to measure the absorption for each volume element separately. Interestingly, the precise absorption level depends on the chemical compound the nucleus is built into. Thus the absorption value will depend on the chemical environ-

FIGURE 544 Henri Becquerel (1852–1908)

1999.IndexWeijmar Schultz, Willibrord It is shown in Figure 545.

Each magnetic resonance image thus proves that atoms have spinning nuclei. Like for any other object, nuclei have size, shape, colour, composition and interactions. Let us explore them.

The size of nuclei

The magnetic resonance signal shows that hydrogen nuclei are quite sensitive to magnetic fields. The g-factor of protons, defined using the magnetic moment μ, their mass and charge as $g = \mu 4m/e\hbar$, is about 5.6. Using expression (626) that relates the g-factor and the radius of a composite object, we deduce that the radius of the proton is about 0.9 fm; this value is confirmed by experiment. Protons are thus much smaller than hydrogen atoms, the smallest of atoms, whose radius is about 30 pm. In turn, the proton is the smallest of all nuclei; the largest nuclei have radii 7 times the proton value.

Page 1038

The small size of nuclei is no news. It is known since the beginning of the twentieth century. The story starts on the first of March in 1896, when Henri Becquerel* discovered a puzzling phenomenon: minerals of uranium potassium sulphate blacken photographic plates. Becquerel had heard that the material is strongly fluorescent; he conjectured that fluorescence might have some connection to the X-rays discovered by Conrad Röngten the year before. His conjecture was wrong; nevertheless it led him to an important new discovery. Investigating the reason for the effect of uranium on photographic plates, Becquerel found that these minerals emit an undiscovered type of radiation, different from anything known at that time; in addition, the radiation is emitted by any substance containing uranium. In 1898, Bémont named the property of these minerals *radioactivity*.

Radioactive rays are also emitted from many elements other than uranium. The radiation can be 'seen': it can be detected by the tiny flashes of light that are emitted when the rays hit a scintillation screen. The light flashes are tiny even at a distance of several metre from the source; thus the rays must be emitted from point-like sources. Radioactivity has to be emitted from single atoms. Thus radioactivity confirmed unambiguously

magnetic and radio fields is also called *nuclear magnetic resonance*.

* Henri Becquerel (b. 1852 Paris, d. 1908 Le Croisic), important French physicist; his primary topic was the study of radioactivity. He was the thesis adviser of Marie Curie, the wife of Pierre Curie, and was central to bringing her to fame. The SI unit for radioactivity is named after him. For his discovery of radioactivity he received the 1903 Nobel Prize for physics; he shared it with the Curies.

FIGURE 545 The origin of human life (© Willibrord Weijmar Schultz)

that atoms do exist. In fact, radioactivity even allows to count them, as we will find out shortly.

The intensity of radioactivity cannot be influenced by magnetic or electric fields; it does not depend on temperature or light irradiation. In short, radioactivity does not depend on electromagnetism and is not related to it. Also the high energy of the emitted radiation cannot be explained by electromagnetic effects. Radioactivity must thus be due to another, new type of force. In fact, it took 30 years and a dozen of Nobel Prizes to fully understand the details. It turns out that several types of radioactivity exist; the types behave differently when they fly through a magnetic field or when they encounter matter. They are listed in Table 103. All have been studied in great detail, with the aim to understand the nature of the emitted entity and its interaction with matter.

In 1909, radioactivity inspired the 37 year old physicist Ernest Rutherford,* who had won the Nobel Prize just the year before, to another of his brilliant experiments. He asked his collaborator Hans Geiger to take an emitter of alpha radiation – a type of radioactivity which Rutherford had identified and named 10 years earlier – and to point the radiation at a thin metal foil. The quest was to find out where the alpha rays would end up. The research group followed the path of the particles by using scintillation screens; later on they used an invention by Charles Wilson: the cloud chamber. A *cloud chamber*, like its

* Ernest Rutherford (1871–1937), important New Zealand physicist. He emigrated to Britain and became professor at the University of Manchester. He coined the terms alpha particle, beta particle, proton and neutron. A gifted experimentalist, he discovered that radioactivity transmutes the elements, explained the nature of alpha rays, discovered the nucleus, measured its size and performed the first nuclear reactions. Ironically, in 1908 he received the Nobel price for chemistry, much to the amusement of himself and of the world-wide physics community; this was necessary as it was impossible to give enough physics prizes to the numerous discoverers of the time. He founded a successful research school of nuclear physics and many famous physicists spent some time at his institute. Ever an experimentalist, Rutherford deeply disliked quantum theory, even though it was and is the only possible explanation for his discoveries.

successor, the bubble chamber, produces white traces along the path of charged particles; the mechanism is the same as the one than leads to the white lines in the sky when an aeroplane flies by.

The radiation detectors gave a strange result: most alpha particles pass through the metal foil undisturbed, whereas a few are reflected. In addition, those few which are reflected are not reflected by the surface, but in the inside of the foil. (Can you imagine how they showed this?) Rutherford deduced from this scattering experiment that first of all, atoms are mainly transparent. Only transparency explains why most alpha particles pass the foil without disturbance, even though it was over 2000 atoms thick. But some particles were scattered by large angles or even reflected. Rutherford showed that the reflections must be due to a single scattering point. By counting the particles that were reflected (about 1 in 20000 for his 0.4 μm gold foil), Rutherford was also able to deduce

Challenge 1571 s

FIGURE 546 Marie Curie (1867–1934)

the size of the reflecting entity and to estimate its mass. He found that it contains almost all of the mass of the atom in a diameter of around 1 fm. He thus named it the *nucleus*. Using the knowledge that atoms contain electrons, Rutherford then deduced from this experiment that atoms consist of an electron cloud that determines the size of atoms – of the order of 0.1 nm – and of a tiny but heavy nucleus at the centre. If an atom had the size of a basketball, its nucleus would have the size of a dust particle, yet contain 99.9 % of the basketball's mass. Atoms resemble thus candy floss around a heavy dust particle. Even though the candy floss – the electron cloud – around the nucleus is extremely thin and light, it is strong enough to avoid that two atoms interpenetrate; thus it keeps the neighbouring nuclei at constant distance. For the tiny and massive alpha particles however, the candy floss is essentially empty space, so that they simply fly through the electron clouds until they exit on the other side or hit a nucleus.

The density of the nucleus is impressive: about $5.5 \cdot 10^{17}\,\mathrm{kg/m^3}$. At that density, the mass of the Earth would fit in a sphere of 137 m radius and a grain of sand would have a mass larger than the largest existing oil tanker. (True?) Now we know that oil tankers are complex structures. What then is the structure of a nucleus?

Challenge 1572 e

> I now know how an atom looks like!
> Ernest Rutherford

Nuclei are composed

The magnetic resonance images also show that nuclei are composed. Images can be taken also using heavier nuclei instead of hydrogen, such as certain fluorine or oxygen nuclei. The g-factors of these nuclei also depart from the value 2 characteristic of point particles; the more massive they are, the bigger the departure. Such objects have a finite size; indeed, the size of nuclei can be measured directly and confirm the values predicted by the g-factor. Both the values of the g-factor and the non-vanishing sizes show that nuclei are composed.

Page 1037

Interestingly, the idea that nuclei are composed is older than the concept of nucleus itself. Already in 1815, after the first mass measurements of atoms by John Dalton and others, researchers noted that the mass of the various chemical elements seem to be almost perfect multiples of the weight of the hydrogen atom. William Prout then formulated the hypothesis that all elements are composed of hydrogen. When the nucleus was discov-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ered, knowing that it contains almost all mass of the atom, it was therefore first thought that all nuclei are made of hydrogen nuclei. Being at the origin of the list of constituents, the hydrogen nucleus was named *proton*, from the greek term for 'first' and reminding the name of Prout at the same time. Protons carry a positive unit of electric charge, just the opposite of that of electrons, but are almost 2000 times as heavy.

However, the charge and the mass numbers of the other nuclei do not match. On average, a nucleus that has n times the charge of a proton, has a mass that is about 2.6 n times than of the proton. Additional experiments then confirmed an idea formulated by Werner Heisenberg: all nuclei heavier than hydrogen nuclei are made of positively charged protons and neutral *neutrons*. Neutrons are particles a tiny bit more massive than protons (the difference is less than a part in 700), but without any electrical charge. Since the mass is almost the same, the mass of nuclei – and thus that of atoms – is still an (almost perfect) integer multiple of the proton mass. But since neutrons are neutral, the mass and the charge number of nuclei differ. Being neutral, neutrons do not leave tracks in clouds chambers and are more difficult to detect. For this reason, they were discovered much later than other subatomic particles.

Today it is possible to keep single neutrons suspended between suitably shaped coils, with the aid of teflon 'windows'. Such traps were proposed in 1951 by Wolfgang Paul. They work because neutrons, though they have no charge, do have a small magnetic moment. (By the way, this implies that neutrons are composed of charged particles.) With a suitable arrangement of magnetic fields, neutrons can be kept in place, in other words, they can be levitated. Obviously, a trap only makes sense if the trapped particle can be observed. In case of neutrons, this is achieved by the radio waves absorbed when the magnetic moment switches direction with respect to an applied magnetic field. The result of these experiments is simple: the lifetime of free neutrons is around 888(1) s. Nevertheless, inside most nuclei we are made of, neutrons do not decay, as the result does not lead to a state of lower energy. (Why not?)

Challenge 1573 s

Magnetic resonance images also show that some elements have different types of atoms. These elements have atoms that with the same number of protons, but with different numbers of neutrons. One says that these elements have several isotopes.* This also explains why some elements radiate with a mixture of different decay times. Though chemically they are (almost) indistinguishable, isotopes can differ strongly in their nuclear properties. Some elements, such as tin, caesium, or polonium, have over thirty isotopes each. Together, the about 100 known elements have over 2000 *nuclides*.**

The motion of protons and neutrons inside nuclei allows to understand the spin and the magnetic moment of nuclei. Since nuclei are so extremely dense despite containing numerous positively charged protons, there must be a force that keeps everything together against the electrostatic repulsion. We saw that the force is not influenced by electromagnetic or gravitational fields; it must be something different. The force must be short range; otherwise nuclei would not decay by emitting high energy alpha rays. The new force is called the strong nuclear interaction. We shall study it in detail shortly.

* The name is derived from the Greek words for 'same' and 'spot', as the atoms are on the same spot in the periodic table of the elements.

** Nuclides is the standard expression for a nucleus with a given number of neutrons and protons.

Nuclei can move alone – cosmic rays

In everyday life, nuclei are mostly found inside atoms. But in some situations, they move all by themselves. The first to discover an example was Rutherford, who had shown that alpha particles are helium nuclei. Like all nuclei, alpha particles are small, so that they are quite useful as projectiles.

Then, in 1912, Viktor Heß* made a completely unexpected discovery. Heß was in-

* Viktor Franz Heß, (1883–1964), Austrian nuclear physicist, received the Nobel Prize for physics in 1936 for his discovery of cosmic radiation. Heß was one of the pioneers of research into radioactivity. Heß' discovery also explained why the atmosphere is always somewhat charged, a result important for the formation and behaviour of clouds. Twenty years after the discovery of cosmic radiation, in 1932 Carl Anderson discovered the first antiparticle, the positron, in cosmic radiation; in 1937 Seth Neddermeyer and Carl Anderson discovered the muon; in 1947 a team led by Cecil Powell discovered the pion; in 1951, the Λ^0 and the kaon K^0 are discovered. All discoveries used cosmic rays and most of these discoveries led to Nobel Prizes.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 548 Viktor Heß (1883–1964)

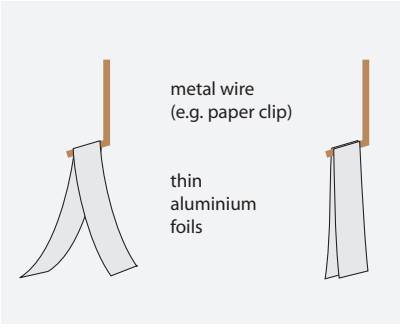

FIGURE 549 An electroscope (or electrometer) (© Harald Chmela) and its charged (middle) and uncharged state (right)

Page 675

trigued by electroscopes (also called electrometers). These are the simplest possible detectors of electric charge. They mainly consist of two hanging, thin metal foils, such as two strips of aluminium foil taken from a chocolate bar. When the electroscope is charged, the strips repel each other and move apart, as shown in Figure 549. (You can build one easily yourself by covering an empty glass with some transparent cellophane foil and suspending a paper clip and the aluminium strips from the foil.) An electroscope thus measures electrical charge. Like many before him, Heß noted that even for a completely isolated electroscope, the charge disappears after a while. He asked: why? By careful study he eliminated one explanation after the other, he and others were left with only one possibility: that the discharge could be due to charged rays, such as those of the recently discovered radioactivity. He thus prepared a sensitive electrometer and took it with him on a balloon flight.

Challenge 1574 e

As expected, the balloon flight showed that the discharge effect diminished with height, due to the larger distance from the radioactive substances on the Earth's surface. But above about 1000 m of height, the discharge effect increased again, and the higher he flew, the stronger it became. Risking his health and life, he continued upwards to more than 5000 m; there the discharge effect was several times stronger than on the surface of the Earth. This result is exactly what is expected from a radiation coming from outer space and absorbed by the atmosphere. In one of his most important flights, performed during an (almost total) solar eclipse, Heß showed that most of the 'height radiation' did not come from the Sun, but from further away. He – and Millikan – thus called the radiation *cosmic rays*. During the last few centuries, many people have drunk from a glass

TABLE 104 The main types of cosmic radiation

PARTICLE	ENERGY	ORIGIN	DETECTOR	SHIELD
At high altitude, the primary particles:				
Protons (90 %)	10^9 to 10^{22} eV	stars, supernovae, extragalactic, unknown	scintillator	in mines
Alpha rays (9 %)	typ. $5 \cdot 10^6$ eV	stars, galaxy	ZnS, counters	1 mm of any material
Other nuclei, such as Le, Be, B, Fe (1 %)	10^9 to 10^{19} eV	stars, novae	1 mm of any material	counters, films
Neutrinos	MeV, GeV	Sun, stars	chlorine, gallium, water	none
Electrons (0.1 %)	10^6 to $> 10^{12}$ eV	supernova remnants		
Gammas (10^{-6})	1 eV to 50 TeV	stars, pulsars, galactic, extragalactic	semiconductor detectors	in mines
At sea level, secondary particles are produced in the atmosphere:				
Muons	3 GeV, $150/\mathrm{m^2 s}$	protons hit atmosphere, produce pions which decay into muons	drift chamber, bubble chamber, scintillation detector	15 m of water or 2.5 m of soil
Oxygen, radiocarbon and other nuclei	varies	e.g., $n + {}^{16}\mathrm{O} \to \mathrm{p} + {}^{14}\mathrm{C}$	soil	
Positrons	varies		counters	soil
Neutrons	varies	reaction product when proton hits ^{16}O nucleus	counters	soil
Pions	varies	reaction product when proton hits ^{16}O nucleus	counters	soil
In addition, there are slowed down primary beam particles.				

and eaten chocolate; but only Heß combined these activities with such careful observation and deduction that he earned a Nobel Prize.*

Today, the most impressive detectors for cosmic rays are Geiger–Müller counters and spark chambers. Both share the same idea; a high voltage is applied between two metal parts kept in a thin and suitably chosen gas (a wire and a cylindrical mesh for the Geiger-Müller counter, two plates or wire meshes in the spark chambers). When a high energy ionizing particle crosses the counter, a spark is generated, which can either be observed through the generated spark (as you can do yourself in the entrance hall of the CERN

* In fact, Hess used gold foils in his electrometer.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 550 A Geiger–Müller counter with the detachable detection tube, the connection cable to the counter electronics, and, for this model, the built-in music player (© Joseph Reinhardt)

main building), or detected by the sudden current flow. Historically, the current was first amplified and sent to a loudspeaker, so that the particles can be heard by a 'click' noise. With a Geiger counter, one cannot see atoms or particles, but one can hear them. Finally, ionized atoms could be counted. Finding the right gas mixture is tricky; it is the reason that the counter has a double name. One needs a gas that extinguishes the spark after a while, to make the detector ready for the next particle. Müller was Geiger's assistant; he made the best counters by adding the right mixture of alcohol to the gas in the chamber. Nasty rumours maintained that this was discovered when another assistant tried, without success, to build counters while Müller was absent. When Müller, supposedly a heavy drinker, came back, everything worked again. However, the story is apocryphal. Today, Geiger–Müller counters are used around the world to detect radioactivity; the smallest fit in mobile phones and inside wrist watches.

The particle energy in cosmic rays spans a large range between 10^3 eV and at least 10^{20} eV; the latter is the same energy as a tennis ball after serve. Understanding the origin of cosmic rays is a science by its own. Some are galactic in origin, some are extragalactic. For most energies, supernova remnants – pulsars and the like – seem the best candidates. However, the source of the highest energy particles is still unknown.

In other words, cosmic rays are probably the only type of radiation discovered without the help of shadows. But shadows have been found later on. In a beautiful experiment performed in 1994, the shadow thrown by the Moon on high energy cosmic rays (about 10 TeV) was studied. When the position of the shadow is compared with the actual position of the Moon, a shift is found. Indeed, due to the magnetic field of the Earth, the cosmic ray Moon shadow is expected to be shifted westwards for protons and eastwards for antiprotons. The data are consistent with a ratio of antiprotons between 0 % and 30 %. By studying the shadow's position, the experiment thus showed that high energy cosmic rays are mainly positively charged and thus consist mainly of matter, and only in small part, if at all, of antimatter.

Ref. 1065

Detailed observations showed that cosmic rays arrive on the surface of the Earth as a mixture of many types of particles, as shown in Table 104. They arrive from outside the atmosphere as a mixture of which the largest fraction are protons, alpha particles,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 551 An aurora borealis, produced by charged particles in the night sky (© Jan Curtis)

iron and other nuclei. Nuclei can thus travel alone over large distances. The number of charged cosmic rays depends on their energy. At the lowest energies, charged cosmic rays hit the human body many times a second. The measurements also show that the rays arrive in irregular groups, called *showers*. The neutrino flux is many orders of magnitude higher, but does not have any effect on human bodies.

Page 1285

The distribution of the incoming direction of cosmic rays shows that many rays must be extragalactic in origin. The typical nuclei of cosmic radiation are ejected from stars and accelerated by supernova explosions. When they arrive on Earth, they interact with the atmosphere before they reach the surface of the Earth. The detailed acceleration mechanisms are still a topic of research.

Cosmic rays have several effects on everyday life. Through the charges they produce in the atmosphere, they are probably responsible for the jagged, non-straight propagation of lightning. (Lightning advances in pulses, alternating fast propagation for about 30 m with slow propagation, until they hit connect. The direction they take at the slow spots depends on the wind and the charge distribution in the atmosphere.) Cosmic rays are also important in the creation of rain drops and ice particles inside clouds, and thus indirectly in the charging of the clouds. Cosmic rays, together with ambient radioactivity, also start the Kelvin generator.

Page 671

If the Moon would not exist, we would die from cosmic rays. The Moon helps to give the Earth a high magnetic field via a dynamo effect, which then diverts most rays towards the magnetic poles. Also the upper atmosphere helps animal life to survive, by shielding life from the harmful effects of cosmic rays. Indeed, aeroplane pilots and airline employees have a strong radiation exposure that is not favourable to their health. Cosmic rays are one of several reasons that long space travel, such as a trip to mars, is not an option for humans. When cosmonauts get too much radiation exposure, the body weakens and eventually they die. Space heroes, including those of science fiction, would not survive much longer than two or three years.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

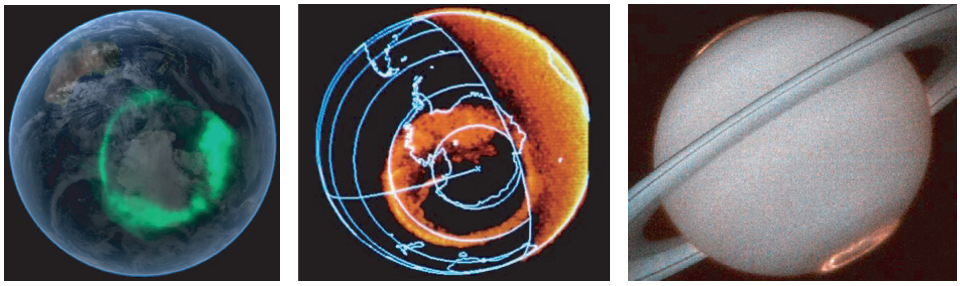

FIGURE 552 Two aurorae australes on Earth, seen from space (a composed image with superimposed UV intensity, and a view in the X-ray domain) and a double aurora on Saturn (all NASA)

Cosmic rays also produce beautifully coloured flashes inside the eyes of cosmonauts; they regularly enjoy these events in their trips. But cosmic rays are not only dangerous and beautiful. They are also useful. If cosmic rays would not exist at all, we would not exist either. Cosmic rays are responsible for mutations of life forms and thus are one of the causes of biological evolution. Today, this effect is even used artificially; putting cells into a radioactive environment yields new strains. Breeders regularly derive new mutants in this way.

Cosmic rays cannot be seen directly, but their cousins, the 'solar' rays, can. This is most spectacular when they arrive in high numbers. In such cases, the particles are inevitably deviated to the poles by the magnetic field of the Earth and form a so-called *aurora borealis* (at the North Pole) or an *aurora australis* (at the South pole). These slowly moving and variously coloured curtains of light belong to the most spectacular effects in the night sky. (Have a look at www.nasa.gov/mov/105423main_FUV_2005-01_v01.mov.) Visible light and X-rays are emitted at altitudes between 60 and 1000 km. Seen from space, the aurora curtains typically form a circle with a few thousand kilometres diameter around the magnetic poles.*

Cosmic rays are mainly free nuclei. With time, researchers found that nuclei appear without electron clouds also in other situations. In fact, the vast majority of nuclei in the universe have no electron clouds at all: in the inside of stars no nucleus is surrounded by bound electrons; similarly, a large part of intergalactic matter is made of protons. It is known today that most of the matter in the universe is found as protons or alpha particles inside stars and as thin gas between the galaxies. In other words, in contrast to what the Greeks said, matter is not usually made of atoms; it is mostly made of nuclei. Our everyday environment is an exception when seen on cosmic scales. In nature, atoms are rare.

By the way, nuclei are in no way forced to move; nuclei can also be stored with almost no motion. There are methods – now commonly used in research groups – to superpose electric and magnetic fields in such a way that a single nucleus can be kept floating in mid-air; we discussed this possibility in the section on levitation earlier on.

Page 782

* In the solar system, aurorae due to core magnetic fields have been observed on Jupiter, Saturn, Uranus, Neptune, Earth, Io and Ganymede. Aurorae due to other mechanisms have been seen on Venus and Mars.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Nuclei decay

Not all nuclei are stable over time. The first measurement that provided a hint was the way radioactivity changes with time. The number N of atoms decreases with time. More precisely, radioactivity follows an exponential decay:

$$N(t) = N(0)e^{-t/\tau} \tag{729}$$

The parameter τ, the so-called *life time*, depends on the type of nucleus emitting the rays. It can vary from much less than a microsecond to millions of millions of years. The expression has been checked for as long as 34 multiples of the duration τ; its validity and precision is well-established by experiments. Radioactivity is the decay of unstable nuclei. Formula (729) is an approximation for large numbers of atoms, as it assumes that $N(t)$ is a continuous variable. Despite this approximation, deriving this expression
Page 1139 from quantum theory is not a simple exercise, as we saw in the section on atomic physics. Though the quantum Zeno effect can appear for small times t, for the case of radioactivity it has not been observed so far.

Most of all, the expression (729) allows to count the number of atoms in a given mass of material. Imagine to have measured the mass of radioactive material at the beginning of your experiment; you have chosen an element that has a lifetime of about a day. Then you put the material inside a scintillation box. After a few weeks the number of flashes has become so low that you can count them; using the formula you can then determine how many atoms have been in the mass to begin with. Radioactivity thus allows us to determine the number of atoms, and thus their size, in addition to the size of nuclei.

The decay (729) and the release of energy is typical of metastable systems. In 1903, Rutherford and Soddy discovered what the state of lower energy is for alpha and beta emitters. In these cases, radioactivity changes the emitting atom; it is a spontaneous transmutation of the atom. An atom emitting alpha or beta rays changes its chemical nature.
Page 295 Radioactivity confirms what statistical mechanics of gases had concluded long time before: atoms have a structure that can change. In alpha decay, the radiating nucleus emits a (doubly charged) helium nucleus. The kinetic energy is typically a handful of MeV. After the emission, the nucleus has changed to one situated two places earlier in the periodic system of the elements.

In beta decay, a neutron transforms itself into a proton, emitting an electron and an antineutrino. Also beta decay changes the chemical nature of the atom, but to the place following the original atom in the periodic table of the elements. A variation is the beta+ decay, in which a proton changes into a neutron and emits a neutrino and a positron. We
Page 1275 will study these important decay processes below.

In gamma decay, the nucleus changes from an excited to a lower energy state by emitting a high energy photon. In this case, the chemical nature is not changed. Typical energies are in the MeV range. Due to the high energy, such rays ionize the material they encounter; since they are not charged, they are not well absorbed by matter and penetrate deep into materials. Gamma radiation is thus by far the most dangerous type of (outside) radioactivity.

By the way, in every human body about nine thousand radioactive decays take place every second, mainly 4.5 kBq (0.2 mSv/a) from ^{40}K and 4 kBq from ^{14}C (0.01 mSv/a).

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1575 s Why is this not dangerous?

All radioactivity is accompanied by emission of energy. The energy emitted by an atom trough radioactive decay or reactions is regularly a million time large than that emitted by a chemical process. That is the reason for the danger of nuclear weapons. More than a decay, a radioactive process is thus an explosion.

What distinguishes those atoms that decay from those which do not? An exponential decay law implies that the probability of decay is independent of the age of the atom. Page 1053 Age or time plays no role. We also know from thermodynamics, that all atoms are exactly identical. So how is the decaying atom singled out? It took around 40 years to discover that decays are triggered by the statistical fluctuations of the vacuum, as described by quantum theory. Indeed, radioactivity is one of the clearest observations that classical physics is not sufficient to describe nature. Radioactivity, like all decays, is a pure quantum effect. Only a finite quantum of action makes it possible that a system remains unchanged until it suddenly decays. Indeed, in 1928 George Gamow explained alpha decay with the tunnelling effect. The tunnelling effect explains the relation between the lifetime and the range of the rays, as well as the measured variation of lifetimes – between 10 ns and 10^{17} years – as the consequence of the varying potentials to be overcome.

By the way, massless particles cannot decay. There is a simple reason for it: massless particles do not experience time, as their paths are 'null'. A particle that does not experience time cannot have a half-life. (Can you find another argument?) Challenge 1576 s

As a result of the chemical effects of radioactivity, the composition ratio of certain elements in minerals allows to determine the age of the mineral. Page 1244 Using radioactive decay to deduce the age of a sample is called radiometric dating. With this technique, geologists determined the age of mountains, the age of sediments and the age of the continents. They determined the time that continents moved apart, the time that mountains formed when the continents collided and the time when igneous rocks were formed. The times found in this way are consistent with the relative time scale that geologists had defined independently for centuries before the technique appeared. With the appearance of radiometric dating, all fell into place. Equally successful was the *radiocarbon method*; with it, historians determined the age of civilizations and the age of human artefacts.* Many false beliefs were shattered. In some communities the shock is still not over, even though over hundred years have passed since these results became known. Ref. 1066

With the advent of radiometric dating, for the first time it became possible to reliably date the age of rocks, to compare it with the age of meteorites and, when space travel became fashionable, with the age of the Moon. The result of the field of *radiometric dating* was beyond all estimates and expectations: the oldest rocks and the oldest meteorites studied independently using different dating methods, are 4570(10) million years old. But if the Earth is that old, why did the Earth not cool down in its core in the meantime?

Why is hell hot?

The lava seas and streams found in and around volcanoes are the origin of the images that many cultures ascribe to hell: fire and suffering. Because of the high temperature of

* In 1960, the developer of the radiocarbon dating technique, Willard Libby, received the Nobel Prize for chemistry.

FIGURE 553 The lava sea in the volcano Erta Ale in Ethiopia (© Marco Fulle)

lava, hell is inevitably depicted as a hot place. A striking example is the volcano Erta Ale, shown in Figure 553. But why is lava still hot, after 4570 million years?

A straightforward calculation shows that if the Earth had been a hot sphere in the beginning, it should have cooled down and solidified already long time ago. The Earth should be a solid object, like the moon: the Earth should not contain any lava and hell would not be hot.

Challenge 1577 ny

The solution to the riddle is provided by radioactivity: the centre of the Earth contains an oven fuelled by radioactive potassium ^{40}K, radioactive uranium ^{235}U and ^{238}U and radioactive thorium ^{232}Th. The radioactivity of these elements, and to minor degree a few others, keeps the centre of the Earth glowing. More precise investigations, taking into account the decay times and material concentrations, show that this mechanism indeed explains the internal heat of the Earth. (By the way, the decay of potassium is the origin for the 1 % of argon found in the Earth's atmosphere.)

Ref. 1067

Page 1246

This brings up a challenge: why is the radioactivity of lava and of the Earth in general not dangerous to humans?

Challenge 1578 s

Nuclei can form composites

Nuclei are highly unstable when they contain more than about 280 nucleons. Higher mass values inevitably decay into smaller fragments. But when the mass is above 10^{57} nucleons, nuclear composites are stable again: such systems are then called neutron stars. This is the most extreme example of pure nuclear matter found in nature. Neutron stars are left overs of (type II) supernova explosions. They do not run any fusion reactions any more, as other stars do; in first approximation they are simply a large nucleus.

Neutron stars are made of degenerate matter. Their density of 10^{18} kg/m^3 is a few times that of a nucleus, as gravity compresses the star. This density value means that tea spoon of such a star has a mass of several 100 million tons. Neutron stars are about 10 km in diameter. They are never much smaller, as such stars are unstable. They are never much

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

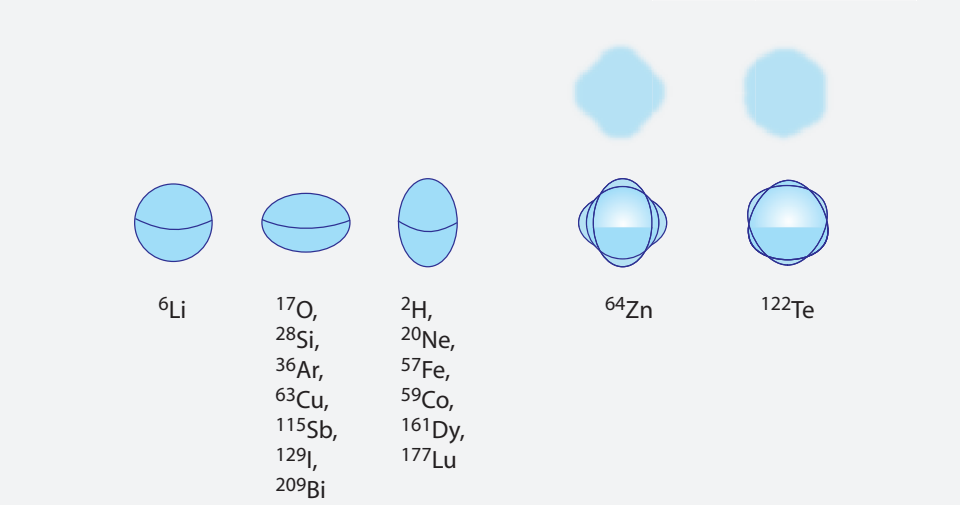

FIGURE 554 Various nuclear shapes – fixed: spherical, oblate, prolate (left) and oscillating (right), shown realistically as clouds (above) and simplified as geometric shapes (below)

larger, because more massive neutron stars turn into black holes.

Nuclei have colours and shapes

In everyday life, the colour of objects is determined by the wavelength of light that is least absorbed, or if they shine, by the wavelength that is emitted. Also nuclei can absorb photons of suitably tuned energies and get into an excited state. In this case, the photon energy is converted into a higher energy of one or several of the nucleons whirling around inside the nucleus. Many radioactive nuclei also emit high energy photons, which then are called gamma rays, in the range of 1 keV (or 0.2 fJ) to about 20 MeV (or 3.3 pJ). The process is similar to the emission of light by electrons in atoms. From the energy, the number and the lifetime of the excited states – they range from 1 ps to 300 d – researchers can deduce how the nucleons move inside the nucleus.

The photon energies define the 'colour' of the nucleus. It can be used, like all colours, to distinguish nuclei from each other and to study their motion. In particular, the colour of the γ-rays emitted by excited nuclei can be used to determine the chemical composition of a piece of matter. Some of these transition lines are so narrow that they can been used to study the change due to the chemical environment of the nucleus, to measure their motion or to detect the gravitational Doppler effect.

The study of γ-rays also allows to determine the shape of nuclei. Many nuclei are spherical; but many are prolate or oblate ellipsoids. Ellipsoids are favoured if the reduction in average electrostatic repulsion is larger than the increase in surface energy. All nuclei – except the lightest ones such as helium, lithium and beryllium – have a constant mass density at their centre, given by about 0.17 fermions per fm^3, and a skin thickness of about 2.4 fm, where their density decreases. Nuclei are thus small clouds, as shown in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Figure 554.

We know that molecules can be of extremely involved shape. In contrast, nuclei are mostly spheres, ellipsoids or small variations of these. The reason is the short range, or better, the fast spatial decay of nuclear interactions. To get interesting shapes like in molecules, one needs, apart from nearest neighbour interactions, also next neighbour interactions and next next neighbour interactions. The strong nuclear interaction is too short ranged to make this possible. Or does it? It might be that future studies will discover that some nuclei are of more unusual shape, such as smoothed pyramids. Some predictions have been made in this direction; however, the experiments have not been performed yet. Ref. 1068

The shape of nuclei does not have to be fixed; nuclei can also oscillate in shape. Such oscillations have been studied in great detail. The two simplest cases, the quadrupole and octupole oscillations, are shown in Figure 554. Obviously, nuclei can also rotate. Rapidly spinning nuclei, with a spin of up to $60\hbar$ and more, exist. They usually slow down step by step, emitting a photon and reducing their angular momentum at each step. Recently it was discovered that nuclei can also have bulges that rotate around a fixed core, a bit like tides rotate around the Earth. Ref. 1069

The four types of motion in the nuclear domain

Nuclei are small because the nuclear interactions are short-ranged. Due to this short range, nuclear interactions play a role only in types of motion: scattering, bound motion, decay and a combination of these three called *nuclear reactions*. The history of nuclear physics showed that the whole range of observed phenomena can be reduced to these four fundamental processes. In each motion type, the main interest is what happens at the start and at the end; the intermediate situations are less interesting. Nuclear interactions thus lack the complex types of motion which characterize everyday life. That is the reason for the shortness of this chapter.

Scattering is performed in all accelerator experiments. Such experiments repeat for nuclei what we do when we look at an object. Seeing is a scattering process, as seeing is the detection of scattered light. Scattering of X-rays was used to see atoms for the first time; scattering of high energy alpha particles was used to discover and study the nucleus, and later the scattering of electrons with even higher energy was used to discover and study the components of the proton.

Bound motion is the motion of protons and neutrons inside nuclei or the motion of quarks inside mesons and baryons. Bound motion determines shape and shape changes of compounds.

Decay is obviously the basis of radioactivity. Decay can be due to the electromagnetic, the strong or the weak nuclear interaction. Decay allows to study the conserved quantities of nuclear interactions.

Nuclear reactions are combinations of scattering, decay and possibly bound motion. Nuclear reactions are for nuclei what the touching of objects is in everyday life. Touching an object we can take it apart, break it, solder two objects together, throw it away, and much more. The same can be done with nuclei. In particular, nuclear reactions are responsible for the burning of the Sun and the other stars; they also tell the history of the nuclei inside our bodies.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Quantum theory showed that all four types of motion can be described in the same way. Each type of motion is due to the exchange of virtual particles. For example, scattering due to charge repulsion is due to exchange of virtual photons, the bound motion inside nuclei due to the strong nuclear interaction is due to exchange of virtual gluons, beta decay is due to the exchange of virtual W bosons, and neutrino reactions are due to the exchange of virtual Z bosons. The rest of this chapter explains these mechanisms in more details.

Nuclei react

Page 1056

The first man thought to have made transuranic elements, the Italian genius Enrico Fermi, received the Nobel Prize for the discovery. Shortly afterwards, Otto Hahn and his collaborators Lise Meitner and Fritz Strassmann showed that Fermi was wrong, and that his prize was based on a mistake. Fermi was allowed to keep his prize, the Nobel committee gave Hahn and Strassman the Nobel Prize as well, and to make the matter unclear to everybody and to women physicists in particular, the prize was not given to Lise Meitner. (After her death, a new element was named after her.)

When protons or neutrons were shot into nuclei, they usually remained stuck inside them, and usually lead to the transformation of an element into a heavier one. After having done this with all elements, Fermi used uranium; he found that bombarding it with neutrons, a new element appeared, and concluded that he had created a transuranic element. Alas, Hahn and his collaborators found that the element formed was well-known: it was barium, a nucleus with less than half the mass of uranium. Instead of remaining stuck as in the previous 91 elements, the neutrons had split the uranium nucleus. Hahn, Meitner and Strassmann had observed reactions such as:

$$^{235}\mathrm{U} + \mathrm{n} \to {}^{143}\mathrm{Ba} + {}^{90}\mathrm{Kr} + 3n + 170\,\mathrm{MeV}\ . \tag{730}$$

Meitner called the splitting process *nuclear fission*. A large amount of energy is liberated in fission. In addition, several neutrons are emitted; they can thus start a chain reaction. Later, and (of course) against the will of the team, the discovery would be used to make nuclear bombs.

Reactions and decays are transformations. In each transformation, already the Greek taught us to search, first of all, for conserved quantities. Besides the well-known cases of energy, momentum, electric charge and angular momentum conservation, the results of nuclear physics lead to several new conserved quantities. The behaviour is quite constrained. Quantum field theory implies that particles and antiparticles (commonly denoted by a bar) must behave in compatible ways. Both experiment and quantum field theory show for example that every reaction of the type $\mathrm{A} + \mathrm{B} \to \mathrm{C} + \mathrm{D}$ implies that the reactions $\mathrm{A} + \overline{\mathrm{C}} \to \overline{\mathrm{B}} + \mathrm{D}$ or $\overline{\mathrm{C}} + \overline{\mathrm{D}} \to \overline{\mathrm{A}} + \overline{\mathrm{B}}$ or, if energy is sufficient, $\mathrm{A} \to \mathrm{C} + \mathrm{D} + \overline{\mathrm{B}}$, are also possible. Particles thus behave like conserved mathematical entities.

Experiments show that antineutrinos differ from neutrinos. In fact, all reactions confirm that the so-called *lepton number* is conserved in nature. The lepton number L is zero for nucleons or quarks, is 1 for the electron and the neutrino, and is -1 for the positron and the antineutrino.

In addition, all reactions conserve the so-called *baryon number*. The baryon number

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

B is 1 for protons and neutrons (and 1/3 for quarks), and −1 for antiprotons and antineutrons (and thus −1/3 for antiquarks). So far, no process with baryon number violation has ever been observed. Baryon conservation is one reason for the danger of radioactivity, fission and fusion.

Bombs and nuclear reactors

Uranium fission is triggered by a neutron, liberates energy and produces several additional neutrons. It can trigger a chain reaction which can lead to an explosion or a controlled generation of heat. Once upon a time, in the middle of the twentieth century, these processes were studied by quite a number of researchers. Most of them were interested in making weapons or in using nuclear energy, despite the high toll these activities place on the economy, on human health and on the environment.

Most stories around this topic are absurd. The first nuclear weapons were built during the second world war with the smartest physicists that could be found. Everything was ready, including the most complex physical models, factories and an organization of incredible size. There was just one little problem: there was no uranium of sufficient quality. The mighty United States thus had to go around the world to shop for good uranium. They found it in the Belgian colony of Congo, in central Africa. In short, without the support of Belgium, which sold the Congolese uranium to the USA, there would have been no nuclear bomb, no early war end and no superpower status.

Congo paid a high price for this important status. It was ruled by a long chain of military dictators up to this day. But the highest price was paid by the countries that actually built nuclear weapons. Some went bankrupt, others remained underdeveloped, still other countries have amassed huge debts and have a large underprivileged population. There is no exception. The price of nuclear weapons has also been that some regions of our planet became uninhabitable, such as numerous islands, deserts and marine environments. But it could have been worse. When the most violent physicist ever, Edward Teller, made his first calculations about the hydrogen bomb, he predicted that the bomb would set the atmosphere into fire. Nobel Prize winner Hans Bethe* corrected the mistake and showed that nothing of this sort would happen. Nevertheless, the military preferred to explode the hydrogen bomb in the Bikini atoll, the most distant place from their homeland they could find. Today it is even dangerous simply to fly over that island. It was then noticed that nuclear test explosions increased ambient radioactivity in the atmosphere all over the world. Of the produced radioactive elements, ^{3}H is absorbed by humans in drinking water, ^{14}C and ^{90}Sr through food, and ^{137}Cs in both ways. In the meantime, all countries have agreed to perform their nuclear tests underground.

Ref. 1070

But even peaceful nuclear reactors are dangerous. The reason was discovered in 1934 by Frédéric Joliot and his wife Irène, the daughter of Pierre and Marie Curie: *artificial radioactivity*. The Joliot–Curies discovered that materials irradiated by alpha rays become

* Hans Bethe (b. 1906 Strasbourg, d. 2005) was one of the great physicists of the twentieth century, even though he was head of the theory department that lead to the construction of the first atomic bombs. He worked on nuclear physics and astrophysics, helped Richard Feynman in developing quantum electrodynamics, and worked on solid state physics. When he got older and wiser, he became a strong advocate of arms control; he also was essential in persuading the world to stop atmospheric nuclear test explosions and saved many humans from cancer in doing so.

TABLE 105 Some radioactivity measurements

MATERIAL	ACTIVITY IN BQ/KG
Air	$c.\,10^{-2}$
Sea water	10^{1}
Human body	$c.\,10^{2}$
Cow milk	max. 10^{3}
Pure ^{238}U metal	$c.\,10^{7}$
Highly radioactive α emitters	$> 10^{7}$
Radiocarbon: ^{14}C (β emitter)	10^{8}
Highly radioactive β and γ emitters	$> 10^{9}$
Main nuclear fallout: ^{137}Cs, ^{90}Sr (α emitter)	$2 \cdot 10^{9}$
Polonium, one of the most radioactive materials (α)	10^{24}

radioactive in turn. They found that alpha rays transformed aluminium into radioactive phosphorus:

$$^{27}_{13}\mathrm{Al} + {}^{4}_{2}\alpha \rightarrow {}^{31}_{15}\mathrm{P}\ . \tag{731}$$

In fact, almost all materials become radioactive when irradiated with alpha particles, neutrons or gamma rays. As a result, radioactivity itself can only be contained with difficulty. After a time which depends on the material and the radiation, the box that contains radioactive material has itself become radioactive.

The dangers of natural and artificial radioactivity are the reason for the high costs of nuclear reactors. After about thirty years of operation, reactors have to be dismantled. The radioactive pieces have to be stored in specially chosen, inaccessible places, and at the same time the workers' health must not be put in danger. The world over, many dismantlings are now imminent. The companies performing the job sell the service at high price. All operate in a region not far from the border to criminal activity, and since radioactivity cannot be detected by the human senses, many crossed it. In fact, an important nuclear reactor is (usually) not dangerous to humans: the Sun. We explore it shortly.

CURIOSITIES AND CHALLENGES ON RADIOACTIVITY

Not all γ-rays are due to radioactivity. In the year 2000, an Italian group discovered that thunderstorms also emit γ-rays, of energies up to 10 MeV. The mechanisms are still being investigated. Ref. 1074

* *

Chain reactions are quite common in nature. *Fire* is a chemical chain reaction, as are exploding fireworks. In both cases, material needs heat to burn; this heat is supplied by a neighbouring region that is already burning.

* *

Radioactivity can be extremely dangerous to humans. The best example is plutonium.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 106 Human exposure to radioactivity and the corresponding doses

Exposure	Dose
Daily human exposure:	
Average exposure to cosmic radiation in Europe	
at sea level	0.3 mSv/a
at a height of 3 km	1.2 mSv/a
Average (and maximum) exposure from the soil, not counting radon effects	0.4 mSv/a (2 mSv/a)
Average (and maximum) inhalation of radon	1 mSv/a (100 mSv/a)
Average exposure due to internal radionuclides	0.3 mSv/a
natural content of ^{40}K in human muscles	10^{-4} Gy and 4500 Bq
natural content of Ra in human bones	$2 \cdot 10^{-5}$ Gy and 4000 Bq
natural content of ^{14}C in humans	10^{-5} Gy
Total average (and maximum) human exposure	2 mSv/a (100 mSv/a)
Common situations:	
Dental X-ray	*c.* 10 mSv equivalent dose
Lung X-ray	*c.* 0.5 mSv equivalent dose
Short one hour flight (see www.gsf.de/epcard)	*c.* 1 µSv
Transatlantic flight	*c.* 0.04 mSv
Maximum allowed dose at work	30 mSv/a
Deadly exposures:	
Ionization	0.05 C/kg can be deadly
Dose	100 Gy=100 J/kg is deadly in 1 to 3 days
Equivalent dose	more than 3 Sv/a leads to death

Only 1 µg of this alpha emitter inside the human body are sufficient to cause lung cancer.

* *

Why is nuclear power a dangerous endeavour? The best argument is Lake Karachay near Mayak, in the Urals in Russia. In less than a decade, the nuclear plants of the region have transformed it into the most radioactive place on Earth. Walking on the shore of the lake for an hour leads to death on the shore. The radioactive material in the lake was distributed over lage areas in several catastrophic explosions in the 1950s and 1960s, leading to widespread death and illness. Several of these accidents were comparable to the Chernobyl accident of 1986. The lake is now covered in concrete.

* *

All lead is slightly radioactive, because it contains the ^{210}Pb isotope, a beta emitter. This lead isotope is produced by the uranium and thorium contained in the rock from where the lead is extracted. For sensitive experiments, such as for neutrino experiments, one

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

needs radioactivity shields. The best shield material is lead, but obviously it has to be low radioactivity lead. Since the isotope ^{210}Pb has a half-life of 22 years, one way to do it is to use old lead. In a precision neutrino experiment in the Gran Sasso in Italy, the research team uses lead mined during Roman times in order to reduce spurious signals.

* *

Not all nuclear reactors are human made. Natural reactors have been predicted in 1956 by Paul Kuroda. In 1972 the first example was found. In Oklo, in the African country of Gabon, there is a now famous geological formation where uranium is so common that two thousand million years ago a natural nuclear reactor has formed spontaneously – albeit a small one, with an estimated power generation of 100 kW. It has been burning for over 150 000 years, during the time when the uranium 235 percentage was 3% or more, as required for chain reaction. (Nowadays, the uranium 235 content on Earth is 0.7%.) The water of a nearby river was periodically heated to steam during an estimated 30 minutes; then the reactor cooled down again for an estimated 2.5 hours, since water is necessary to moderate the neutrons and sustain the chain reaction. The system has been studied in great detail, from its geological history up to the statements it makes about the constancy of the 'laws' of nature. The studies showed that 2000 million years ago the mechanisms were the same as those used today.

* *

High energy radiation is dangerous to humans. In the 1950s, when nuclear tests were still made above ground by the large armies in the world, the generals overruled the orders of the medical doctors. They positioned many soldiers nearby to watch the explosion, and worse, even ordered them to walk to the explosion site as soon as possible after the explosion. One does not need to comment on the orders of these generals. Several of these unlucky soldiers made a strange observation: during the flash of the explosion, they were able to see the bones in their own hand and arms. How can this be?

Challenge 1579 ny

* *

The SI units for radioactivity are now common; in the old days, 1 Sievert, or 1 Sv, was called 100 rem or 'Röntgen equivalent man'; the SI unit for dose, 1 Gray, defined as 1 Gy = 1 J/kg, replaces what used to be called 100 rd or Rad. The SI unit for exposition, 1 C/kg, replaces the older unit 'R öntgen', with the relation $1\,\mathrm{R} = 2.58 \cdot 10^{-4}\,\mathrm{C/kg}$.

* *

Nuclear bombs are terrible weapons. To experience their violence but also the criminal actions of many military people during the tests, have a look at the pictures of explosions. In the 1950 and 60s, nuclear tests were performed by generals who refused to listen to doctors and scientists. Generals ordered to explode these weapons in the air, making the complete atmosphere of the world radioactive, hurting all mankind in doing so; worse, they even obliged soldiers to visit the radioactive explosion site a few minutes after the explosion, thus doing their best to let their own soldiers die from cancer and leukaemia.

Ref. 1075

* *

The technique of radiometric dating has deeply impacted astronomy, geology, evolu-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tionary biology, archaeology and history. (And it has reduced the number of violent believers.) Half-lives can usually be measured to within one or two per cent of accuracy, and they are known both experimentally and theoretically not to change over geological time scales. As a result, radiometric dating methods can be be surprisingly precise. But how does one measure half-lives of thousands of millions of years to high precision?

Ref. 1066

Challenge 1580 s

* *

The beta decay of the radioactive carbon isotope ^{14}C has a decay time of 5568 a. This isotope is continually created in the atmosphere through the influence of cosmic rays. This happens through the reaction $^{14}N + n \to p + {}^{14}C$. As a result, the concentration of radiocarbon in air is relatively constant over time. Inside living plants, the metabolism thus (unknowingly) maintains the same concentration. In dead plants, the decay sets in. The decay time of a few thousand years is particularly useful to date historic material. The method, called radiocarbon dating, has been used to determine the age of mummies, the age of prehistoric tools and the age of religious relics. The original version of the technique measured the radiocarbon content through its radioactive decay and the scintillations it produced. A quality jump was achieved when accelerator mass spectroscopy became commonplace. It was not necessary any more to wait for decays: it is now possible to determine the ^{14}C content directly. As a result, only a tiny amount of carbon, as low as 0.2 mg, is necessary for a precise dating. This technique showed that numerous religious relics are forgeries, such as a cloth in Turin, and several of their wardens turned out to be crooks.

* *

Researchers have developed an additional method to date stones using radioactivity. Whenever an alpha ray is emitted, the emitting atom gets a recoil. If the atom is part of a crystal, the crystal is damaged by the recoil. The damage can be seen under the microscope. By counting the damaged regions it is possible to date the time at which rocks have been crystallized. In this way it has been possible to determine when material from volcanic eruptions has become rock.

* *

Several methods to date wine are used, and more are in development. A few are given in Table 107.

* *

In 1958, six nuclear bombs were made to explode in the stratosphere by a vast group of criminals. A competing criminal group performed similar experiments in 1961, followed by even more explosions by both groups in 1962. (For reports and films, see http://en.wikipedia.org/wiki/High_altitude_nuclear_explosion.) As a result of most of these explosions, an *artificial aurora* was triggered the night following each of them. In addition, the electromagetic pulse from the blasts destroyed satellites, destroyed electronics on Earth, disturbed radio communications, injured people on the surface of the Earth, caused problems with power plants, and distributed large amounts of radioactive material over the Earth – during 14 years following the blasts. The van Allen radiation belts around the Earth were strongly affected; it is expected that the lower van Allen belt will recover from

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the blasts only in a few hundred years. Fortunately for the human race, after 1962, this activity was stopped.

* *

Selected radioactive decay times can be changed by external influence. Electron capture, as observed in beryllium-7, is one of the rare examples were the decay time can change, by up to 1.5%, depending on the chemical environment. The decay time for the same isotope has also been found to change by a fraction of a per cent under pressures of 27 GPa. On the other hand, these effects are predicted (and measured) to be negligible for nuclei of larger mass.

* *

The non-radioactive isotopes ^{2}H and ^{18}O can be used for measuring energy production in humans in an easy way. Give a person a glass of doubly labelled water to drink and collect his urine samples for a few weeks. Using a mass spectrometer one can determine his energy consumption. Why? Doubly labelled water $^{2}H_2{}^{18}O$ is processed by the body in three main ways. The oxygen isotope is expired as $C^{18}O_2$ or eliminated as $H_2{}^{18}O$; the hydrogen isotope is eliminated as $^{2}H_2O$. Measurements on the urine allow to determine carbon dioxyde production, therefore to determine how much has food been metabolized, and thus to determine energy production.

Measurements showed that high altitude climbers with 20 000 kJ/d and bicycle riders with up to 30 000 kJ/d are the most extreme sportsmen. Average humans produce 6 000 kJ/d.

Summary on nuclei

Nuclei are composed of protons and neutrons. Their radius is between one and a few femtometres and they rotate. Their rotation allows to produce magnetic resonance images. Nuclei can be spherical or ellipsoidal, they can be excited to higher energy states, and they can oscillate in shape. Nuclei can break up and can react among each other. The last property is the reason we exist, as we will show now.

Chapter 45

THE SUN, THE STARS AND THE BIRTH OF MATTER

> Lernen ist Vorfreude auf sich selbst.*
>
> Peter Sloterdijk

Nuclear physics is the most violent part of physics. But despite this bad image, nuclear physics has something to offer which is deeply fascinating: the understanding of the Sun, the stars and the early universe.

Ref. 1071

Since protons are positively charged, inside nuclei they must be bound by a force strong enough to keep them together against their electromagnetic repulsion. This is the strong nuclear interaction; it is needed to avoid that nuclei explode. The interaction is the strongest of all known ones; nevertheless, we do not experience it in everyday life, because its range is limited to distances of a few femtometres, or a few diameters of a proton. Despite this limitation, the strong interaction tells a good story about the flesh and blood we are made of.

The Sun

The Sun emits 385 YW of light. Where does this energy come from? If it came by burning coal, the Sun would stop burning after a few thousands of years. When radioactivity was discovered, researchers tested the possibility that this process was at the heart of the Sun's shining. However, even though radioactivity can produce more energy than chemical burning, the composition of the Sun – mostly hydrogen and helium – makes this impossible. The origin of the energy in the Sun was settled in 1939 by Hans Bethe: the Sun burns by hydrogen *fusion*. Fusion is the composition of a large nucleus from smaller ones. In the Sun, the fusion reaction

Ref. 1072

$$4\,{}^1\mathrm{H} \to {}^4\mathrm{He} + 2\,e^+ + 2\,\nu + 4.4\,\mathrm{pJ} \tag{732}$$

is the result of a continuous cycle of three separate nuclear reactions:

$$\begin{aligned} {}^1\mathrm{H} + {}^1\mathrm{H} &\to {}^2\mathrm{H} + e^+ + \nu \quad \text{(a weak nuclear reaction)} \\ {}^2\mathrm{H} + {}^1\mathrm{H} &\to {}^3\mathrm{He} + \gamma \quad \text{(a strong nuclear reaction)} \\ {}^3\mathrm{He} + {}^3\mathrm{He} &\to {}^4\mathrm{He} + 2\,{}^1\mathrm{H} + \gamma\,. \end{aligned} \tag{733}$$

* 'Learning is anticipated joy about yourself.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In total, four protons are thus fused to one helium nucleus; if we include the electrons, four hydrogen atoms are fused to one helium atom with the emission of neutrinos and light with a total energy of 4.4 pJ (26.7 MeV). Most of the energy is emitted as light; around 10 % is carried away by neutrinos. The first of the three reaction of equation 733 is due to the weak nuclear interaction; this avoids that it happens too rapidly and ensures that the Sun will shine still for some time. Indeed, in the Sun, with a luminosity of 385 YW, there are thus about 10^{38} fusions per second. This allows to deduce that the Sun will last another handful of Ga (Gigayears) before it runs out of fuel.

Ref. 1073

The fusion reaction (733) takes place in the centre of the Sun. The energy carried away by the photons arrives at the Sun's surface about two hundred thousand years later; this delay is due to the repeated scattering of the photon by the constituents inside the Sun. After two-hundred thousand years, the photons take another 8.3 minutes to reach the Earth and to sustain the life of all plants and animals.

Why do the stars shine?

> Don't the stars shine beautifully? I am the only person in the world who knows why they do.
>
> Friedrich (Fritz) Houtermans

All stars shine because of fusion. When two light nuclei are fused to a heavier one, some energy is set free, as the average nucleon is bound more strongly. This energy gain is possible until the nuclei of iron ^{56}Fe are made. For nuclei beyond this nucleus, the binding energies per nucleon then decrease again; thus fusion is not energetically possible.*

The different stars observed in the sky** can be distinguished by the type of fusion nuclear reaction that dominates. Most stars, in particular young or light stars, run hydrogen fusion. In fact, there are at least two main types of hydrogen fusion: the direct hydrogen–hydrogen (p-p) cycle and the CNO cycle(s).

The hydrogen cycle was described above and can be summarized as

Page 1248

$$4\,{}^{1}\mathrm{H} \to {}^{4}\mathrm{He} + 2\,e^{+} + 2\,\nu + 4.4\,\mathrm{pJ}\,. \tag{734}$$

This simple description does not fully purvey the fascination of the process. On average, protons in the Sun's centre move with 600 km/s. Only if they hit each other precisely head-on can a nuclear reaction occur; in all other cases, the electrostatic repulsion between the protons keeps them apart. For an average proton, a head-on collision happens once every 7 thousand million years. Nevertheless, there are so many proton collisions in the Sun that every second four million tons of hydrogen are burned to helium.

Fortunately for us, the photons generated in the Sun's centre are 'slowed' down by the outer parts of the Sun. In this process, gamma photons are progressively converted to visible photons. As a result, the sunlight of today was in fact generated at the time of the Neandertalers: a typical estimate is about 200 000 years ago. In other words, the effective speed of light right at the centre of the Sun is estimated to be around 10 km/year.

Ref. 1076

* Thus fission becomes interesting as energy source for heavy nuclei.

** To find out which stars are in the sky above you at present, see the www.surveyor.in-berlin.de/himmel website.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

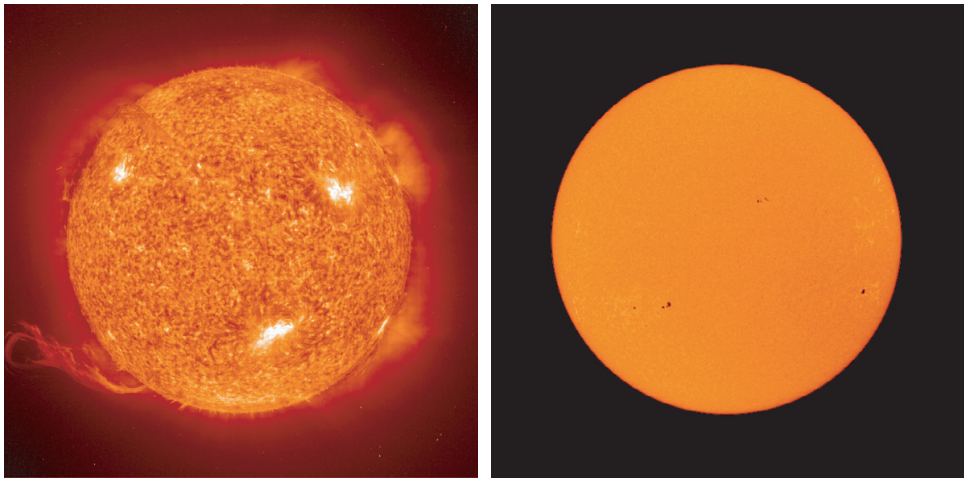

FIGURE 555 Photographs of the Sun at wavelengths of 30.4 nm (in the extreme ultraviolet, left) and around 677 nm (visible light, right, at a different date), by the SOHO mission (ESA and NASA)

If a star has heavier elements inside it, the hydrogen fusion uses these elements as catalysts. This happens through the so-called CNO cycle, which runs as

$$\begin{aligned} {}^{12}\mathrm{C} + {}^{1}\mathrm{H} &\to {}^{13}\mathrm{N} + \gamma \\ {}^{13}\mathrm{N} &\to {}^{13}\mathrm{C} + \mathrm{e}^{+} + \nu \\ {}^{13}\mathrm{C} + {}^{1}\mathrm{H} &\to {}^{14}\mathrm{N} + \gamma \\ {}^{14}\mathrm{N} + {}^{1}\mathrm{H} &\to {}^{15}\mathrm{O} + \gamma \\ {}^{15}\mathrm{O} &\to {}^{15}\mathrm{N} + \mathrm{e}^{+} + \nu \\ {}^{15}\mathrm{N} + {}^{1}\mathrm{H} &\to {}^{12}\mathrm{C} + {}^{4}\mathrm{He} \end{aligned} \tag{735}$$

The end result of the cycle is the same as that of the hydrogen cycle, both in nuclei and in energy. The CNO cycle is faster than hydrogen fusion, but requires higher temperatures, as the protons must overcome a higher energy barrier before reacting with carbon or nitrogen than when they react with another proton. (Why?) Due to the comparatively low temperature of a few tens of million kelvin inside the Sun, the CNO cycle is less important than the hydrogen cycle. (This is also the case for the other CNO cycles that exist.)

Challenge 1581 s

These studies also explain why the Sun does not collapse. The Sun is a ball of hot gas, and the high temperature of its constituents prevents their concentration into a small volume. For some stars, the radiation pressure of the emitted photons prevents collapse; for others it is the Pauli pressure; for the Sun, like for the majority of stars, it is the usual thermal motion of the gas.

The nuclear reaction rates at the interior of a star are extremely sensitive to temperature T. The carbon cycle reaction rate is proportional to between T^{13} for hot massive O stars and T^{20} for stars like the Sun. In red giants and supergiants, the triple alpha reaction rate is proportional to T^{40}; these strong dependencies imply that stars usually shine with constancy over times of thousands and millions of years, since any change in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

temperature would be damped by a very efficient feedback mechanism. (Of course, there are exceptions: variable stars get brighter and darker with periods of a few days; the Sun shows small oscillations in the minute range; and some stars change in brightness every few years.)

How can the Sun's surface have a temperature of 6000 K, whereas the corona around it, the thin gas emanating from the Sun, reaches two million Kelvin? In the latter part of the twentieth century it was shown, using satellites, that the magnetic field of the Sun is the cause; through the violent flows in the Sun's matter, magnetic energy is transferred to the corona in those places were flux tubes form knots, above the bright spots in the left of Figure 555 or above the dark spots in the right photograph. As a result, the particles of the corona are accelerated and heat the whole corona.

When the Sun erupts, as shown in the lower left corner in Figure 555, matter is ejected far into space. When this matter reaches the Earth,* after being diluted by the journey, it affects the environment. Solar storms can deplete the higher atmosphere and can thus possibly trigger usual Earth storms. Other effects of the Sun are the formation of auroras and the loss of orientation of birds during their migration; this happens during exceptionally strong solar storms, as the magnetic field of the Earth is disturbed in these situations. The most famous effect of a solar storm was the loss of electricity in large parts of Canada in March of 1989. The flow of charged solar particles triggered large induced currents in the power lines, blew fuses and destroyed parts of the network, shutting down the power system. Millions of Canadians had no electricity, and in the most remote places it took two weeks to restore the electricity supply. Due to the coldness of the winter and a train accident resulting from the power loss, over 80 people died. In the meantime the network has been redesigned to withstand such events.

The proton cycle and the CNO cycles are not the only options. Heavier and older stars than the Sun can also shine through other fusion reactions. In particular, when hydrogen is consumed, such stars run *helium burning*:

$$3\,{}^4\mathrm{He} \to {}^{12}\mathrm{C}\,. \tag{736}$$

This fusion reaction is of low probability, since it depends on three particles being at the same point in space at the same time. In addition, small amounts of carbon disappear rapidly via the reaction $\alpha + {}^{12}\mathrm{C} \to {}^{16}\mathrm{O}$. Nevertheless, since ${}^8\mathrm{Be}$ is unstable, the reaction with 3 alpha particles is the only way for the universe to produce carbon. All these negative odds are countered only by one feature: carbon has an excited state at 7.65 MeV, which is 0.3 MeV above the sum of the alpha particle masses; the excited state resonantly enhances the low probability of the three particle reaction. Only in this way the universe is able to produce the atoms necessary for pigs, apes and people. The prediction of this resonance by Fred Hoyle is one of the few predictions in physics that used the simple experimental observation that humans exist. The story has lead to a huge outflow of metaphysical speculations, most of which are unworthy of being even mentioned.

Page 868

* It might even be that the planets affect the solar wind; the issue is not settled and is still under study.

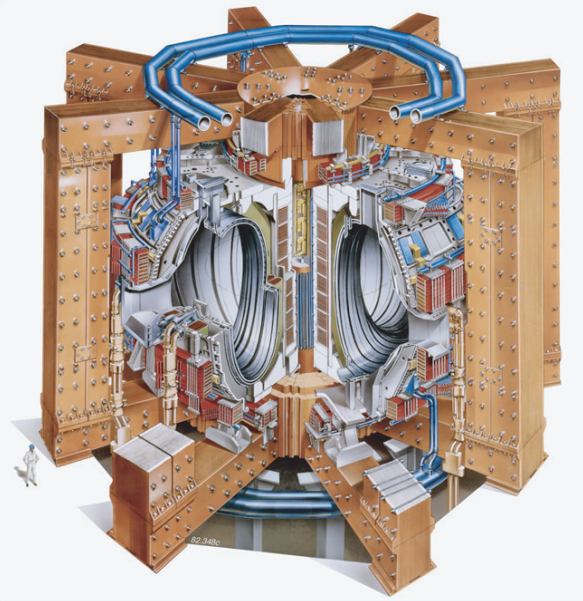

FIGURE 556 A simplified drawing of the Joint European Torus in operation at Culham, showing the large toroidal chamber and the magnets for the plasma confinement (© EFDA-JET)

Why are fusion reactors not common yet?

Across the world, for over 50 years, a large number of physicists and engineers have tried to build fusion reactors. Fusion reactors try to copy the mechanism of energy release used by the Sun. The first machine that realized macroscopic energy production was the Joint European Torus* (JET for short) located in Culham in the United Kingdom.

Ref. 1077 The idea of JET is to produce an extremely hot plasma that is as dense as possible. At high enough temperature and density, fusion takes place; the energy is released as a particle flux that is transformed (like in a fission reactor) into heat and then into electricity. To achieve ignition, JET used the fusion between deuterium and tritium, because this reaction has the largest cross section and energy gain:

$$\mathrm{D} + \mathrm{T} \to \mathrm{He}^4 + \mathrm{n} + 17.6\,\mathrm{MeV}\ . \tag{737}$$

Because tritium is radioactive, most research experiments are performed with the much less efficient deuterium–deuterium reactions, which have a lower cross section and a lower energy gain:

$$\begin{aligned} \mathrm{D} + \mathrm{D} &\to \mathrm{T} + \mathrm{H} + 4\,\mathrm{MeV} \\ \mathrm{D} + \mathrm{D} &\to \mathrm{He}^3 + \mathrm{n} + 3.3\,\mathrm{MeV}\ . \end{aligned} \tag{738}$$

Fusion takes place when deuterium and tritium (or deuterium) collide at high energy. The high energy is necessary to overcome the electrostatic repulsion of the nuclei. In

* See www.jet.edfa.org.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

other words, the material has to be hot. To release energy from deuterium and tritium, one therefore first needs energy to heat it up. This is akin to the ignition of wood: in order to use wood as a fuel, one first has to heat it with a match.

Following the so-called Lawson criterium, published in 1957 by the English engineer John Lawson, (but already known to Russian researchers) a fusion reaction releases energy only if the triple product of density n, reaction (or containment) time τ and temperature T exceeds a certain value. Nowadays this criterium is written as

Ref. 1078

$$n\tau T > 3 \cdot 10^{28}\,\mathrm{s\,K/m^3}\ . \tag{739}$$

In order to realize the Lawson criterium, JET uses temperatures of 100 to 200 MK, particle densities of 2 to $3 \cdot 10^{20}\ \mathrm{m^{-3}}$, and confinement times of 1 s. The temperature is much higher than the 20 MK at the centre of the Sun, because the densities and the confinement times are lower for JET.

Matter at these temperatures is in form of plasma: nuclei and electrons are completely separated. Obviously, it is impossible to pour a plasma at 100 MK into a container: the walls would instantaneously evaporate. The only option is to make the plasma float in a vacuum, and to avoid that the plasma touches the container wall. The main challenge of fusion research in the past has been to find a way to keep a hot gas mixture of deuterium and tritium suspended in a chamber so that the gas never touches the chamber walls. The best way is to suspend the gas using a magnetic field. This works because in the fusion plasma, charges are separated, so that they react to magnetic fields. The most successful geometric arrangement was invented by the famous Russian physicists Igor Tamm and Andrei Sakharov: the *tokamak*. Of the numerous tokamaks around the world, JET is the largest and most successful. Its concrete realization is shown in Figure 556. JET manages to keep the plasma from touching the walls for about a second; then the situation becomes unstable: the plasma touches the wall and is absorbed there. After such a *disruption*, the cycle consisting of gas injection, plasma heating and fusion has to be restarted. As mentioned, JET has already achieved ignition, that is the state were more energy is released than is added for plasma heating. However, so far, no sustained commercial energy production is planned or possible, because JET has no attached electrical power generator.

The successor project, *ITER*, an international tokamak built with European, Japanese, US-American and Russian funding, aims to pave the way for commercial energy generation. Its linear reactor size will be twice that of JET; more importantly, ITER plans to achieve 30 s containment time. ITER will use superconducting magnets, so that it will have extremely cold matter at 4 K only a few metres from extremely hot matter at 100 MK. In other words, ITER will be a high point of engineering. The facility will be located in Cadarache in France and is planned to start operation in the year 2016.

Like many large projects, fusion started with a dream: scientists spread the idea that fusion energy is safe, clean and inexhaustible. These three statements are still found on every fusion website across the world. In particular, it is stated that fusion reactors are not dangerous, produce much lower radioactive contamination than fission reactors, and use water as basic fuel. 'Solar fusion energy would be as clean, safe and limitless as the Sun.' In reality, the only reason that we do not feel the radioactivity of the Sun is that we are far away from it. Fusion reactors, like the Sun, are highly radioactive. The management of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 557 The comparison between measured nuclide abundances in the solar system and the calculated values predicted by the r-process.

radioactive fusion reactors is much more complex than the management of radioactive fission reactors.

Fusion fuels are almost inexhaustible: deuterium is extracted from water and the tritium – a short-lived radioactive element not found in nature in large quantities – is produced from lithium. The lithium must be enriched, but since material is not radioactive, this is not problematic. However, the production of tritium from lithium is a dirty process that produces large amounts of radioactivity. Fusion energy is thus inexhaustible, but not safe and clean.

In short, of all technical projects ever started by mankind, fusion is by far the most challenging and ambitious. Whether fusion will ever be successful – or whether it ever should be successful – is another issue.

Where do our atoms come from?

People consist of electrons and various nuclei. Electrons, hydrogen and helium nuclei are formed during the big bang. All other nuclei are formed in stars. Young stars run hydrogen burning or helium burning; heavier and older stars run neon-burning or even silicon-burning. These latter processes require high temperatures and pressures, which are found only in stars with a mass at least eight times that of the Sun. However, all fusion processes are limited by photodissociation and will not lead to nuclei heavier than ^{56}Fe.

Page 589
Ref. 1079

Heavier nuclei can only be made by neutron capture. There are two main processes; the s-process (for 'slow') runs inside stars, and gradually builds up heavy elements until the most heavy, lead, from neutron flying around. The rapid r-process occurs in stellar explosions. Many stars die this violent death. Such an explosion has two main effects: on one hand it distributes most of the matter of the star, such as carbon, nitrogen or oxygen, into space in the form of neutral atoms. On the other hand, new elements are synthesized during the explosion. The abundances of the elements in the solar system can be precisely measured. These several hundred data points correspond exactly with what is expected

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

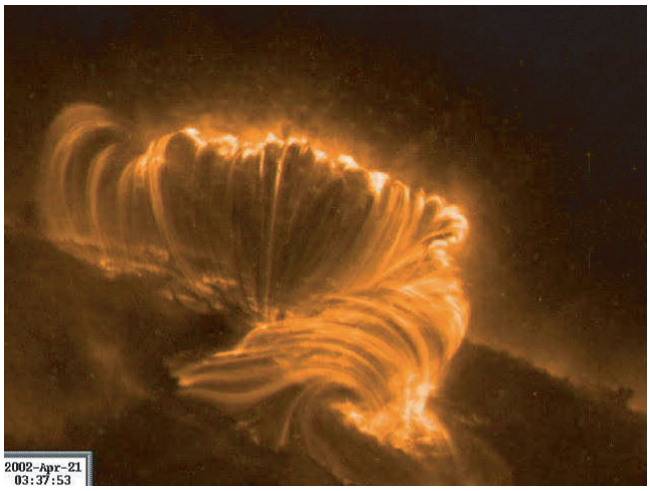

FIGURE 558 The evolution of a solar flare, as observed by the TRACE satellite (mpg film courtesy NASA)

from the material ejected by a (type II) supernova explosion. In other words, the solar system formed from the remnants of a supernova, as did, somewhat later, life on Earth.* We all are recycled stardust.

Curiosities about the stars

It is still not clear whether the radiation of the Sun is constant over long time scales. There is an 11 year periodicity, the famous solar cycle, but the long term trend is still unknown. Precise measurements cover only the years from 1978 onwards, which makes only about 3 cycles. A possible variation of the solar constant might have important consequences for climate research; however, the issue is still open.

* *

The sun is not a static object. An impressive way to experience the violent processes it contains is to watch the film shown in Figure 558, showing the evolution of a solar flare.

* *

In the 1960s and 70s, it was discovered that the Sun pulsates with a frequency of 5 minutes. The amplitude is small, only 3 kilometres out of 1.4 million; nevertheless, it is measurable. In the meantime, helioseismologists have discovered numerous additional oscillations of the Sun, and in 1993, even on other stars. Such oscillations allow to study what is happening inside stars, even separately in each of the layers they consist of.

* *

Some stars shine like a police siren: their luminosity increases and decreases regularly.

* By chance, the composition ratios between carbon, nitrogen and oxygen inside the Sun are the same as inside the human body.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Such stars, called *Cepheids*, are important because their period depends on their average (absolute) brightness. Measuring their period and their brightness on Earth thus allows astronomers to determine their distance.

* *

The first human-made hydrogen bomb explosion took place the Bikini atoll. But nature is much better at this. The most powerful nuclear explosions take place on the surface of neutron stars in X-ray binaries. The matter falling into such a neutron star from the companion star, mostly hydrogen, will heat up until the temperature allows fusion. The resulting explosions can be observed in telescopes as light or X-ray flashes of about 10 s duration; the explosions are millions of times more powerful that those of human-made hydrogen bombs.

* *

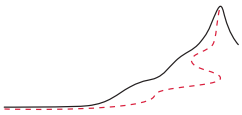
Nucleosynthesis is mainly regulated by the strong interaction. However, if the electromagnetic interaction would be much stronger or much weaker, stars would either produce too little oxygen or too little carbon, and we would not exist This famous argument is due to Fred Hoyle. Can you fill in the details?

Challenge 1582 d

Summary on stars

Stars and the Sun burn because of nuclear fusion. When stars at the end of their lifetime explode, they distribute nuclei around them. In the distant past, such nuclei recollected because of gravity and formed the Sun, the Earth and humans.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 46

THE STRONG INTERACTION

Both radioactivity and medical images show that nuclei are composed. But quantum theory makes an additional prediction: protons and neutrons themselves must be composed. There are two reasons: first, nucleons have a finite size and second, their magnetic moments do not match the value predicted for point particles.

The prediction of components inside the protons was confirmed in the late 1960s when Kendall, Friedman and Taylor shot high energy electrons into hydrogen atoms. They found that a proton contains *three* constituents with spin 1/2, which they called called *partons*. The experiment was able to 'see' the constituents through large angle scattering of electrons, in the same way that we see objects through large angle scattering of photons. These constituents correspond in number and (most) properties to the so-called *quarks* predicted in 1964 by George Zweig and also by Murray Gell-Mann.*

Ref. 1080

Ref. 1083

The feeble side of the strong interaction

It turns out that the interaction keeping the protons together in a nucleus, which was first described by Yukawa Hideki,** is only a feeble shadow of the interaction that keeps quarks together in a proton. Both are called by the same name. The two cases correspond

* The physicist George Zweig (b. 1937 Moscow , d.) proposed the quark idea – he called them *aces* – in 1963, with more clarity than Gell-Mann. Zweig stressed the reality of aces, whereas Gell-Mann, in the beginning, did not believe in the existence of quarks. Zweig later moved on to a more difficult field: neurobiology.

Murray Gell-Mann (b. 1929 New York, d.) received the Nobel Prize for physics in 1969. He is the originator of the term 'quark'. (The term has two origins: officially, it is said to be taken from *Finnegans Wake*, a novel by James Joyce; in reality, he took it from a Yiddish and German term meaning 'lean soft cheese' and used figuratively in those languages to mean 'silly idea'.)

Ref. 1081

Gell-Mann was the central figure of particle physics in the 20th century; he introduced the concept of strangeness, the renormalization group, the flavour SU(3) symmetry and quantum chromodynamics. A disturbing story is that he took the idea, the data, the knowledge, the concepts and even the name of the V–A theory of the weak interaction from the bright physics student George Sudarshan and published it, together with Richard Feynman, as his own. The wrong attribution is still found in many textbooks.

Gell-Mann is also known for his constant battle with Feynman about who deserved to be called the most arrogant physicist of their university. A famous anecdote is the following. Newton's once used a common saying of his time in a letter to Hooke: 'If I have seen further than you and Descartes, it is by standing upon the shoulders of giants.' Gell-Mann is known for saying: 'If I have seen further than others, it is because I am surrounded by dwarfs.'

** Yukawa Hideki (1907–1981), important Japanese physicist specialized in nuclear and particle physics. He founded the journal Progress of Theoretical Physics and together with his class mate Tomonaga he was an example to many scientists in Japan. He received the 1949 Nobel Prize for physics for this theory of mesons.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

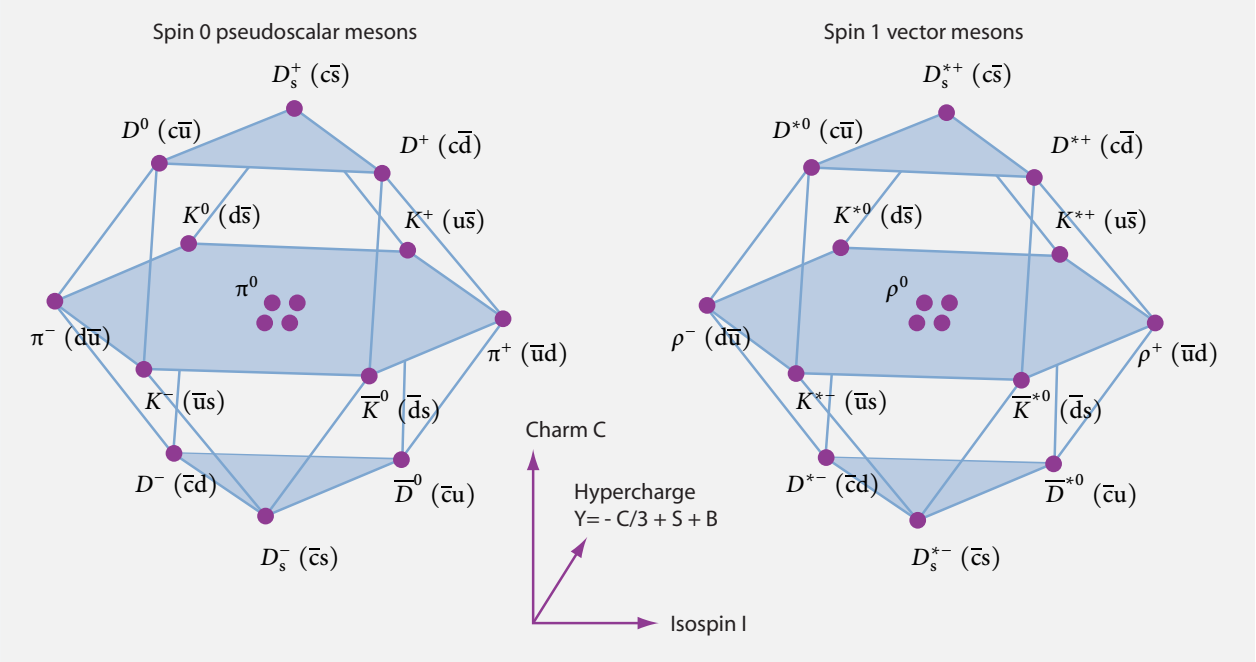


FIGURE 559 The least massive pseudoscalar and vector mesons that can be built as $q\bar{q}$ composites of the first four quark flavours

somewhat to the two cases of electromagnetism found in atomic matter. Neon atoms show the two cases most clearly: the strongest aspect of electromagnetism is responsible for the attraction of the electrons to the neon nuclei; its feeble 'shadow', the Van-der-Waals interaction, is responsible for the attraction of neon atoms in liquid neon and for processes like evaporation. Both attractions are electromagnetic, but the strengths differ markedly. Similarly, the strongest aspect of the strong interaction leads to the formation of the proton and the neutron through quark binding; the feeble aspect leads to the formation of nuclei and to alpha decay. Obviously, most information can be gathered by studying the strongest aspect.

Bound motion, the particle zoo and the quark model

Physicists are simple people. To understand the constituents of matter, and of nuclei in particular, they had no better idea than to take all particles they could get hold of and to smash them into each other. Many played this game for several decades. (Obviously, this is not a fair comment; in fact, quantum theory forbids any other method. Can you explain why?)

Ref. 1082

Challenge 1583 s

Imagine that you want to study how cars are built just by crashing them into each other. Before you get a list of all components, you must perform and study a non-negligible number of crashes. Most give the same result, and if you are looking for a particular part, you might have to wait for a long time. If the part is tightly attached to others, the crashes have to be especially energetic. Compared to car crashes, quantum

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

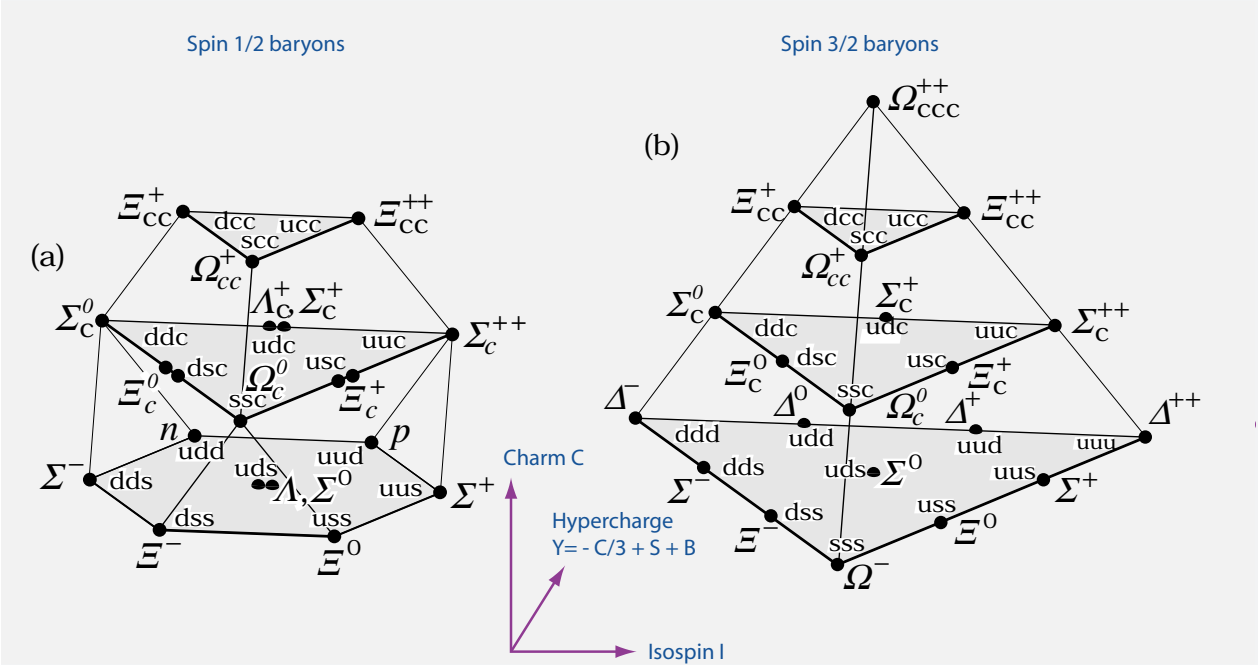

FIGURE 560 A selection of baryons and their classification as bound states of quarks (from Ref. 1087)

theory adds the possibility for debris to transform, to react, to bind and to get excited. Therefore the required diligence and patience is even greater than for car crashes. Despite these difficulties, researchers have collected an ever increasing number of debris, also called *hadrons*, for many decades. The list, part of which is given in Appendix E, is overwhelmingly long; the official full list, several hundred pages of fine print, is found at pdg.web.cern.ch and contains hundreds of hadrons.

Then came the quark model. Using the ingenuity of many experimentalists and theoreticians, the model explained the whole catalogue as a consequence of only 6 types of bound quarks. Typically, a large part of the catalogue could be ordered in tables such as the ones given in Figure 559 and Figure 560. These tables were the beginning of the end of high energy physics. They explained all quantum numbers of the debris, and allowed to understand their mass ratios as well as their decays.

Debris were divided into two types: *mesons* consist of a quark and an antiquark; *baryons* consist of three quarks. In particular, the proton and the neutron are seen as combinations of two quark types, called *up* (u) and *down* (d): the proton is a *uud* state, the neutron a *udd* state. The discovery of other hadrons lead to the addition of four additional types of quarks. Their names are somewhat confusing: they are called *strange* (s), *charm* (c), *bottom* (b) – also called 'beauty' in the old days – and *top* (t) – called 'truth' in the past. The quark types are called *flavours*; in total, there are thus 6 quark flavours in nature.

All quarks have spin one half; their electric charges are multiples of 1/3 of the electron charge. In addition, quarks carry a strong charge, called, again confusingly, *colour*. In

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

contrast to electromagnetism, which has only positive, negative, and neutral charges, the strong interaction has red, blue, green quarks on one side, and anti-red, anti-blue and anti-green on the other. The neutral state is called 'white'. All baryons and mesons are white, in the same way that all atoms are neutral.

The theory describing the bound states of quarks is called *quantum chromodynamics*, or QCD, and was formulated in its final form in 1973 by Fritzsch, Gell-Mann and Ref. 1084 Leutwyler. In the same way that in atoms, electrons and protons are held together by the exchange of virtual photons, in protons, quarks are held together by the exchange of virtual gluons. *Gluons* are the quanta of the strong interaction, and correspond to photons, the quanta of the electromagnetic interactions.

The Lagrangian of quantum chromodynamics

Ref. 1085 Quantum chromodynamics describes all motion due to the strong interaction with the three fundamental processes shown in Figure 561: two gluons can scatter, a gluon can emit or absorb another, and a quark can emit or absorb a gluon. In electrodynamics, only the last diagram is possible; in the strong interaction, the first two appear as well. Among others, the first two diagrams are responsible for the confinement of quarks, and thus for the lack of free quarks in nature.

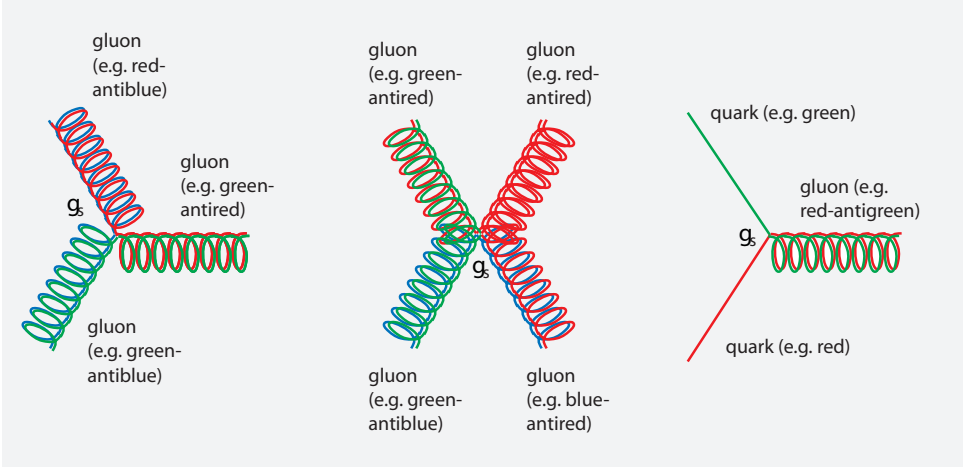

FIGURE 561 The essence of the QCD Lagrangian

QCD is a gauge theory: the fields of the strong interaction show gauge invariance under the Lie group SU(3). In the case of electrodynamics, the gauge group is U(1), and Abelian, or commutative. In contrast, SU(3) is non-Abelian; QCD is a non-abelian gauge theory, a so-called *Yang-Mills theory*.

Due to the SU(3) gauge symmetry, there are 8 gluons; they are called red-antigreen, blue-antired, etc. Since SU(3) is non-abelian, gluons interact among themselves, as shown in the first two processes in Figure 561. Out of the combinations red-antired, blue-antiblue, green-antigreen, only two gluons are linearly independent, thus giving a total of $3^2 - 1 = 8$ gluons.

The three fundamental processes of the strong interaction, together with its SU(3) gauge symmetry and the observed number of six quarks, completely determine the Lagrangian density of the strong interaction. Indeed, the Lagrangian density of the strong interaction can be seen as a complicated rewriting of Figure 561.

The Lagrangian density of quantum chromodynamics is

$$\mathcal{L}_{QCD} = -\tfrac{1}{4} F^{(a)}_{\mu\nu} F^{(a)\mu\nu} - c^2 \sum_q m_q \overline{\psi}^k_q \psi_{qk} + i\hbar c \sum_q \overline{\psi}^k_q \gamma^\mu (D_\mu)_{kl} \psi^l_q \qquad (740)$$

where the gluon field strength and the gauge covariant derivative are

$$F^{(a)}_{\mu\nu} = \partial_\mu A^a_\nu - \partial_\nu A^a_\mu + g_s f_{abc} A^b_\mu A^c_\nu$$

$$(D_\mu)_{kl} = \delta_{kl} \partial_\mu - i \frac{g_s}{2} \sum_a \lambda^a_{k,l} A^a_\mu \,.$$

We remember from the section on the principle of least action that Lagrangians are always sums of scalar products; this is clearly seen in the expression. The index $a = 1 \ldots 8$ numbers the eight types of gluons and the index $k = 1, 2, 3$ numbers the three colours, all due to SU(3). The index $q = 1 \ldots 6$ numbers the six quark flavours. The fields $A^a_\mu(x)$ are the eight gluon fields, represented by the coiled lines in Figure 561. The fields $\psi^k_q(x)$ are

Page 218

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

those of the quarks of flavour q and colour k, represented by the straight line in the figure. The six times three quark fields, like those of any elementary fermion, are 4-component Dirac spinors with masses m_q.*

The Lagrangian (740) is that of a *local* field theory: observables are functions of position. In other words, QCD can be applied in the same way usual quantum theory, and be compared to experiment in the same way.

The first term of the Lagrangian (740) represents the kinetic energy of the radiation (gluons), the second or mass term the kinetic energy of the matter particles (the quarks) and the third term the interaction between the two.

The mass term in the Lagrangian is the only term that spoils or *breaks flavour symmetry*, i.e., the symmetry under exchange of quark types. (In particle physics, this symmetry is also called *chiral symmetry*, for historical reasons.) Obviously, the mass term also breaks space-time conformal symmetry.

The interaction term thus corresponds to the third diagram in Figure 561. The strength of the strong interaction is described by the *strong coupling constant* g_s. The constant is independent of flavour and colour, as observed in experiment. The Interaction term does not mix different quarks; as observed in experiments, flavour is conserved in the strong interaction, as is baryon number. The strong interaction also conserves spatial parity P and charge conjugation parity C. The strong interaction does not transform matter.

In QCD, the eight gluons are massless; also this property is taken from experiment. Therefore no gluon mass term appears in the Lagrangian. It is easy to see that massive gluons would spoil gauge invariance. In contrast to electromagnetism, where the gauge group U(1) is Abelian, the gauge group SU(3) of the strong interactions is non-Abelian. As a consequence, the colour field itself is charged, i.e., carries colour, and thus the index a appears on the fields A and F. As a result, gluons can interact with each other, in contrast to photons, which pass each other undisturbed. The first two diagrams of Figure 561 are thus reflected in the somewhat complicated definition of the field $F^{(a)}_{\mu\nu}$. In contrast to electrodynamics, the definition has an extra term that is *quadratic* in the fields A; it is described by by the so-called structure constants f_{abc} and the interaction strength g_s. These are the structure constants of the SU(3) Lie algebra. The structure constants of SU(3) describe the detailed interaction between the quarks and the gluons and the interaction between gluons themselves.

Challenge 1584 ny

The behaviour of the gauge transformations and of the gluon field is described by the eight matrices $\lambda^a_{k,l}$. They are a fundamental, 3-dimensional representation of the generators of the SU(3) algebra and can be associated to the eight gluon types. The matrices λ_a, $a = 1..8$, and the structure constants f_{abc} obey the relations

$$[\lambda_a, \lambda_b] = 2i f_{abc} \lambda_c$$
$$\{\lambda_a, \lambda_b\} = 4/3 \delta_{ab} I + 2 d_{abc} \lambda_c \tag{742}$$

* In their simplest form, the matrices γ_μ can be written as

$$\gamma_0 = \begin{pmatrix} I & 0 \\ 0 & -I \end{pmatrix} \quad \text{and} \quad \gamma_n = \begin{pmatrix} 0 & \sigma^i \\ -\sigma^i & 0 \end{pmatrix} \quad \text{for } n = 1, 2, 3 \tag{741}$$

Page 882 where the σ^i are the Pauli spin matrices.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where I is the unit matrix. The structure constants f_{abc}, which are odd under permutation of any pair of indices, and d_{abc}, which are even, are

abc	f_{abc}	abc	d_{abc}	abc	d_{abc}
123	1	118	$1/\sqrt{3}$	355	$1/2$
147	$1/2$	146	$1/2$	366	$-1/2$
156	$-1/2$	157	$1/2$	377	$-1/2$
246	$1/2$	228	$1/\sqrt{3}$	448	$-1/(2\sqrt{3})$
257	$1/2$	247	$-1/2$	558	$-1/(2\sqrt{3})$
345	$1/2$	256	$1/2$	668	$-1/(2\sqrt{3})$
367	$-1/2$	338	$1/\sqrt{3}$	778	$-1/(2\sqrt{3})$
458	$\sqrt{3}/2$	344	$1/2$	888	$-1/\sqrt{3}$
678	$\sqrt{3}/2$				

(743)

All other elements vanish. A fundamental 3-dimensional representation of the generators λ_a is given, for example, by the set of the *Gell-Mann matrices*

$$\lambda_1 = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_2 = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_3 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$
$$\lambda_4 = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \lambda_5 = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad \lambda_6 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$
$$\lambda_7 = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad \lambda_8 = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix} . \tag{744}$$

There are eight matrices, one for each gluon type, with 3×3 elements, corresponding to the three colours of the strong interactions. There is no ninth gluon, because that gluon would be colourless, or 'white'.

Only quarks and gluons appear in the Lagrangian of QCD, because only quarks and gluons interact via the strong force. This can be also expressed by saying that only quarks and gluons carry colour; *colour* is the source of the strong force in the same way that electric charge is the source of the electromagnetic field. In the same way as electric charge, colour charge is *conserved* in all interactions. Electric charge comes in two types, positive and negative; in contrast, colour comes in three types, called *red*, *green* and *blue*. The neutral state, with no colour charge, is called *white*. Protons and neutrons, but also electrons or neutrinos, are thus 'white', thus *neutral* for the strong interaction.

Experimental consequences of the quark model

How can we pretend that quarks and gluons exist, even though they are never found alone? There are a number of arguments in favour.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

The quark model explains the non-vanishing magnetic moment of the neutron and explains the magnetic moments μ of the baryons. By describing the proton as a uud state and the neutron a udd state with no orbital angular momentum, we get

$$\mu_u = \tfrac{1}{5}(4\mu_p + \mu_n)\mu_0 \qquad \mu_d = \tfrac{1}{5}(4\mu_n + \mu_p)\mu_0 \qquad \text{where} \qquad \mu_0 = \hbar^2/Mc \tag{745}$$

This means that $m_u = m_d = 330\,\text{MeV}$, a bit more than a third of the nucleon, whose mass is *c.* 940 MeV. If we assume that the quark magnetic moment is proportional to their charge, the quark model predicts a ratio of the magnetic moments of the proton and the neutron of

$$\mu_p/\mu_n = -1.5. \tag{746}$$

This prediction differs from measurements only by 3 %. Furthermore, using the same values for the magnetic moment of the quarks, magnetic moment values of over half a dozen of other baryons can be predicted. The results typically deviate from measurements by around 10 %; the sign is always correctly calculated.

* *

The quark model describes all quantum numbers of mesons and baryons. P-parity, C-parity, and the absence of certain meson parities are all reproduced. The observed conservation of electric charge, baryon number, isospin, strangeness etc. is reproduced. Diagrams such as those shown in Figure 559 and in Figure 560 describe all existing states completely; the states not listed are not observed. The quark model thus produces a complete and correct classification of all hadrons as bound states of quarks.

* *

The quark model also explains the mass spectrum of mesons and baryons. The best predictions are made by QCD lattice calculations. With months of computer time, researchers were able to reproduce the masses of proton and neutron to within a few per cent. Interestingly, if one sets the u and d quark masses to zero, the resulting proton and neutron mass differ from experimental values only by 10 %. The mass of protons and neutrons is almost completely due to the binding.

Ref. 1092
Ref. 1093

* *

The number of colours of quarks must be taken into account to get correspondence of theory and calculation. For example, the measured decay time of the neutral pion is 83 as. The calculation without colour gives 750 as; if each quark is assumed to appear in 3 colours the value must be divided by 9, and then matches the measurement.

* *

In particle colliders, collisions of electrons and positrons sometimes lead to the production of hadrons. The calculated production rates also fit experiments only if quarks have three colours. In more detail, if one compares the ratio of muon–antimuon production and of hadron production, a simple estimate relates them to their charges:

Challenge 1585 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$R = \frac{\sum q_{\text{hadrons}}}{\sum q_{\text{muons}}} \tag{747}$$

Between 2 and 4 GeV, when only three quarks can appear, this argument thus predicts $R = 2$ if colours exist, or $R = 2/3$ if they don't. Experiments yield a value of $R = 2.2$, thus confirming the number of colours.

Many other such *branching ratios* can be calculated in this way. They agree with experiments only if the number of colours is three.

* *

Ref. 1094 In 1979, the first clear decays of gluons have been observed at the PETRA accelerator in Hamburg. The occurrence of certain events, called *gluon jets*, are due to the decay of high-energy gluons into narrow beams of particles. Gluon jets appear in coplanar three-jet events. The observed rate and the other properties of these events confirmed the predictions of QCD. Experiments at PETRA also determined the spin $S = 1$ of the gluon and the running of the strong coupling constant. The hero of those times was the project manager Gustav-Adolf Voss, who completed the accelerator on budget and six months ahead of schedule.

Confinement of quarks – and elefants

Many of the particlesquark confinement which are not part of the diagrams of Figure 559 and Figure 560 can be explained as *rotational excitations* of the fundamental mesons. The idea of rotational excitations leads to quantitative predictions, as shown by Tullio Regge in 1957. Regge assumed that mesons and baryons are quarks connected by strings, like rubber bands, and that the force or tension k between the quarks is thus constant over distance.

We assume that the strings, whose length we call $2r_0$, rotate around their centre of mass as rapidly as possible, as shown in Figure 563. Then we have

$$v(r) = c\frac{r}{r_0} \,. \tag{748}$$

The quark masses are assumed negligible. For the total energy this implies the relation

$$E = mc^2 = 2\int_0^{r_0} \frac{k}{\sqrt{1 - v(r)/c^2}} \mathrm{d}r = kr_0\pi \tag{749}$$

and for angular momentum the relation

$$J = \frac{2}{\hbar c^2}\int_0^{r_0} \frac{krv(r)}{\sqrt{1 - v(r)/c^2}} \mathrm{d}r = \frac{kr_0^2}{2\hbar c} \,. \tag{750}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

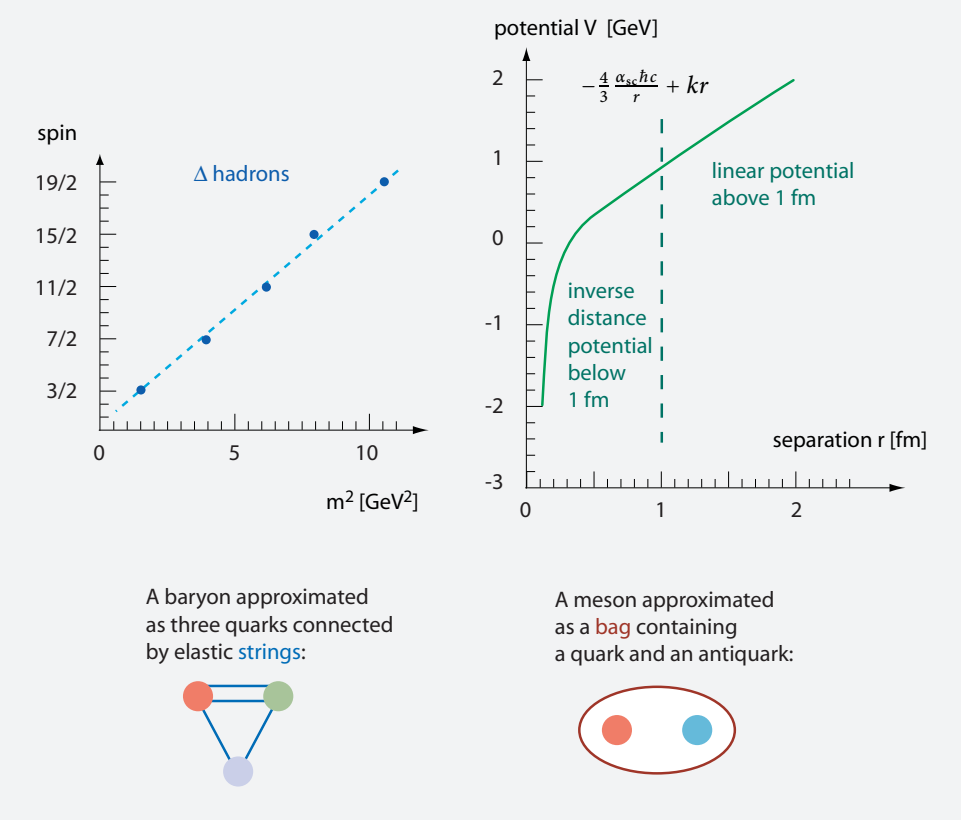

FIGURE 562 A Regge trajectory, or Chew-Frautschi plot, due to the confinement of quarks, the quark confinement potential, and two approximate ways to describe the confinement: the string model and the bag model of hadrons

Including the spin of the quarks, we thus get

$$J = \alpha_0 + \alpha' m^2 \quad \text{where} \quad \alpha' = \frac{c^3}{2\pi k\hbar} \,. \tag{751}$$

Regge thus deduced a simple expression that relates the mass m of excited hadrons to their total spin J. For bizarre historical reasons, this relation is called a *Regge trajectory*.

The value of the constant α' is predicted to be of the quark–antiquark pairing. A few years later, as shown in Figure 562, such linear relations were found in experiments: the *Chew-Frautschi plots*. For example, the three lowest lying states of Δ are the spin 3/2 $\Delta(1232)$ with m^2 of 1.5 GeV^2, the spin 7/2 $\Delta(1950)$ with m^2 of 3.8 GeV^2, and the spin 11/2 $\Delta(2420)$ with m^2 of 5.9 GeV^2. The value of the constant α' is found experimentally to be around 0.93 GeV^{-2} for almost all mesons and baryons, whereas the value for α_0 varies from particle to particle. The string tension is thus found to be k =0.87 GeV/fm=0.14 MN. In other words, two quarks in a hadron attract each other with a force equal to the weight of two elephants: 15 tons.

Ref. 1085

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

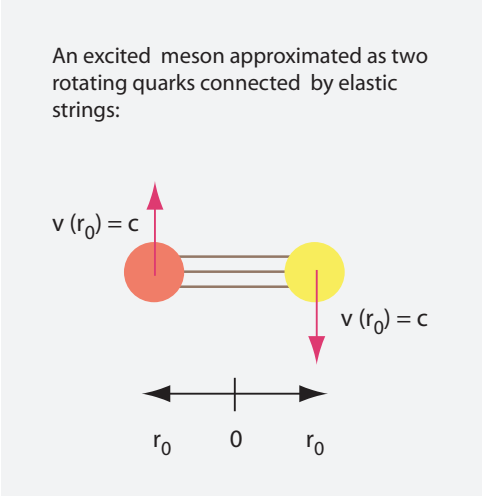

FIGURE 563 Calculating masses of excited hadrons

Experiments are thus clear: the observed Chew-Frautschi plots, as well as several other observations not discussed here, are best described by a quark–quark potential that grows linearly with distance above 1 fm. As a result, quarks never appear as free particles: quarks are always *confined* in hadrons. This is in contrast with QED, where the force between charges goes to zero for large distances; electric charges are thus not confined, but can exist as free particles. At low distances, the potential decreases with the inverse of the distance. In total, experiments lead to a potential given by

Ref. 1082

$$V = -\frac{4}{3}\frac{\alpha_{sc}\hbar c}{r} + kr \tag{752}$$

where k is the mentioned 0.87 GeV/fm, α_{sc} is 0.2, and $\hbar c$ is 0.1975 GeV/fm. It is shown in Figure 562

Even though experiments are clear, theoreticians face a problem. So far, neither the quark-quark potential nor the quark bound states can be deduced from the QCD Lagrangian with a *simple* approximation method. Nevertheless, complicated non-perturbative calculations show that the QCD Lagrangian does predict a force between two coloured particles that levels off at a constant value (corresponding to a linearly increasing potential). These calculations show that the old empirical approximations of hadrons as quarks connected by strings or a quarks in bags, shown in Figure 562, can indeed be deduced from the QCD Lagrangian. However, the calculations are too complex to be summarized in a few lines. Independently, the constant force value has also been reproduced in computer calculations, in which one simplifies space-time to a lattice and then approximates QCD by so-called *lattice QCD* or *lattice gauge theory*. Lattice calculations have also reproduced the masses of most mesons and baryons with reasonable accuracy. Using the most powerful computers available, these calculations have given predictions of the mass of the proton and other baryons within a few per cent. Discussing these complex and fascinating calculations lies outside the scope of this

Ref. 1088

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

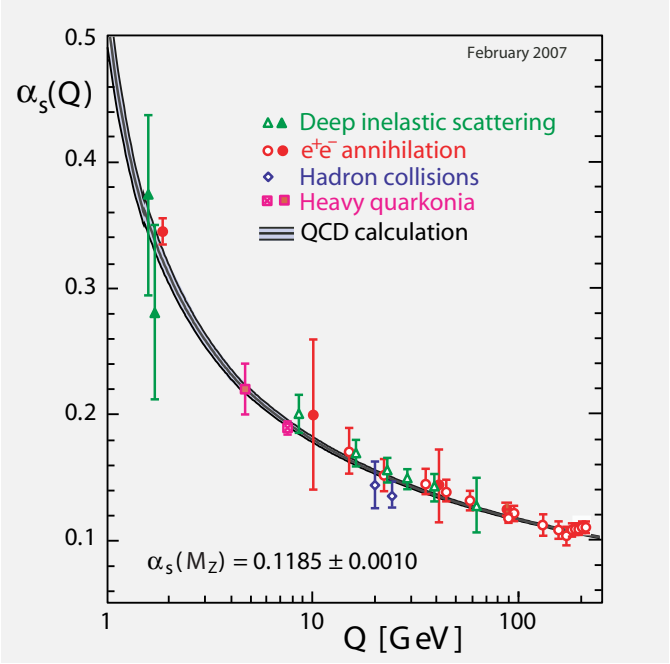

FIGURE 564 The measured and the calculated variation of the strong coupling with energy, showing the precision of the QCD Lagrangian and the asymptotic freedom of the strong interaction (© Siegfried Bethke, updated from Ref. 1089)

text, however.

In fact, the challenge of explaining confinement in simple terms is so difficult that the brightest minds have been unable to solve it yet. This is not a surprise, as its solution probably requires the unification of the interactions and, most probably, also the unification with gravity. We therefore leave this issue for later in our adventure.

Asymptotic freedom

QCD has another property that sets it apart form QED: the behaviour of its coupling with energy. In fact, there are three equivalent ways to describe the strong coupling. The quantity appearing in the QCD Lagrangian, g_s, is often used to define the equivalent quantity $\alpha_s = g_s^2/4\pi$. Both α_s and g_s depend on the energy Q of the experiment. If they are known for one energy, they are known for all of them. Presently, the best experimental value is $\alpha_s(M_Z) = 0.1185 \pm 0.0010$.

Ref. 1085, Ref. 1087

The energy dependence of the strong coupling can be calculated with the standard renormalization procedures and is expected to be

$$\alpha_s(Q^2) = \frac{12\pi}{33-2n_f}\frac{1}{L}\left(1 - \frac{(918-114n_f)\ln L}{(33-2n_f)^2 L} + \dots\right) \quad \text{where} \quad L = \ln\frac{Q^2}{\Lambda^2(n_f)} \qquad (753)$$

where n_f is the number of quarks with mass below the energy scale Q, thus a number between 3 and 6. (The expression has been expanded to many additional terms with help of computer algebra.) The third way to describe the strong coupling is thus the en-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.net Copyright © Christoph Schiller November 1997–January 2009

ergy parameter $\Lambda(n_f)$. Experiments yield $\Lambda(3)$ =230(60) GeV, $\Lambda(4)$ =180(50) GeV and $\Lambda(5)$ =120(30) GeV.

The accelerator experiments that measure the coupling are extremely involved, and hundreds of people across the world have worked for many years to gather the relevant data. The comparison of QCD and experiment, shown in Figure 564, does not show any contradiction between the two.

Figure 564 and expression (753) also illustrate what is called *asymptotic freedom*: α_s decreases at high energies. In other words, at high energies quarks are *freed* from the strong interaction; they behave as free particles.* As a result of asymptotic freedom, in QCD, a perturbation expansion can be used only at energies much larger than Λ. Historically, the discovery of asymptotic freedom was essential to establish QCD as a theory of the strong interaction.

Asymptotic freedom can be understood qualitatively if the situation is compared to QED. The electron coupling increases at small distances, because the screening due to the virtual electron-positron pairs has less and less effect. In QCD, the effective colour coupling also changes at small distances, due to the smaller number of virtual quark-antiquark pairs. However, the gluon properties lead to the opposite effect, an *antiscreening*: the effective coupling decreases at small distances.

The sizes and masses of quarks

The size of quarks, like that of all elementary particles, is predicted to vanish by qcd, as in all quantum field theory. So far, no experiment has found any effect due to a finite quark size. Measurements show that quarks are surely smaller than 10^{-19} m. No size conjecture has been given by any hypothetical theory. Quarks are assumed point-like, or at most Planck-sized, in all descriptions so far.

Ref. 1095

We noted in several places that a neutral compound of charged particles is always less massive than its components. But when the mass values for quarks are looked up in most tables, the masses of u and d quarks are only of the order of a few MeV/c^2, whereas the proton's mass is 938 MeV/c^2. What is the story here?

It turns out that the definition of the mass is more involved for quarks than than for other particles. Quarks are never found as free particles, but only in bound states. As a result, the concept of quark mass depends on the theoretical framework one is using.

Due to *asymptotic freedom*, quarks behave almost like free particles only at high energies. The mass of such a 'free' quark is called the *current quark mass*; for the light quarks it is only a few MeV/c^2, as shown in Table 108.

At low energy, for example inside a proton, quarks are *not* free, but must carry along a large amount of energy due to the confinement process. As a result, bound quarks have a much larger effective, so-called *constituent quark mass*, which takes into account this confinement energy. To give an idea of the values, take a proton; the indeterminacy relation for a particle inside a sphere of radius 0.9 fm gives a momentum indeterminacy of around 190 MeV/c. In three dimensions this gives an energy of $\sqrt{3}$ times that value, or an effective, constituent quark mass of about 330 MeV/c^2. Three confined quarks are thus

* Asymptotic freedom was discovered in 1972 by Gerard 't Hooft; since he had received the Nobel Prize already, the 2004 Prize was then given to the next people who highlighted it: David Gross, David Politzer and Frank Wilczek, who studied it extensively in 1973.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

heavier than a proton, whose mass is 938 MeV/c^2; we can thus still say that a compound proton is less massive than its constituents.

In short, the mass of the proton and the neutron is (almost exclusively) the kinetic energy of the quarks inside them, as their rest mass is almost negligible. As Frank Wilczek says, some people put on weight even though they never eat anything heavy.

Ref. 1086

But also the small current quark mass values for the up, down, strange and charmed quarks that appear in the QCD Lagrangian are framework dependent. The values of Table 108 are those for a renormalization scale of 2 GeV. For half that energy, the mass values increase by 35%. The heavy quark masses are those used in the so-called $\bar{M}S$ scheme, a particular way to perform perturbation theory.

Ref. 1087

The mass, shape and colour of protons

Frank Wilczek mentions that one of the main results of QCD, the theory of strong interactions, is to explain mass relations such as

Ref. 1086

$$m_{\text{proton}} \sim e^{-k/\alpha} m_{\text{Planck}} \quad \text{and} \quad k = 11/2\pi \,,\ \alpha_{\text{unif}} = 1/25 \,. \tag{754}$$

Here, the value of the coupling constant α_{unif} is taken at the unifying energy, a factor of 1000 below the Planck energy. (See the section of unification below.) In other words, a general understanding of masses of bound states of the strong interaction, such as the proton, requires almost purely a knowledge of the unification energy and the coupling constant at that energy. The approximate value $\alpha_{\text{unif}} = 1/25$ is an extrapolation from the low energy value, using experimental data. The proportionality factor k in expression (754) is not easy to calculate. It is usually determined on computers using lattice QCD.

Page 1295

But the mass is not the only property of the proton. Being a cloud of quarks and gluons, it also has a shape. Surprisingly, it took a long time before people started to become interested in this aspect. The proton, being made of two up quarks and one down quark, resembles a ionized H_2^+ molecule, where one electron forms a cloud around two protons. Obviously, the H_2^+ molecule is elongated, or prolate.

Is the proton prolate? There is no spectroscopically measurable non-sphericty – or quadrupole moment – of the proton. However, the proton has an *intrinsic* quadrupole moment. The quadrupole moments of the proton and of the neutron are predicted to be positive in all known calculation methods, implying an *prolate* shape. Recent measurements at Jefferson Laboratories confirm this prediction. A prolate shape is predicted for all $J = 1/2$ baryons, in contrast to the oblate shape predicted for the $J = 3/2$ baryons. The spin 0 pseudoscalar mesons are predicted to be prolate, whereas the spin 1 vector mesons are expected to be oblate.

Ref. 1090

The shape of any molecule will depend on whether other molecules surround it. Recent research showed that similarly, both the size and the shape of the proton in nuclei is slightly variable; both seem to depend on the nucleus in which the proton is built-in.

Ref. 1091

Apart from shapes, molecules also have a colour. The colour of a molecule, like that of any object, is due to the energy absorbed when it is irradiated. For example, the H_2^+ molecule can absorb certain light frequencies by changing to an excited state. Molecules change mass when they absorb light; the excited state is heavier than the ground state. In the same way, protons and neutrons can be excited. In fact, their excited states have been

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

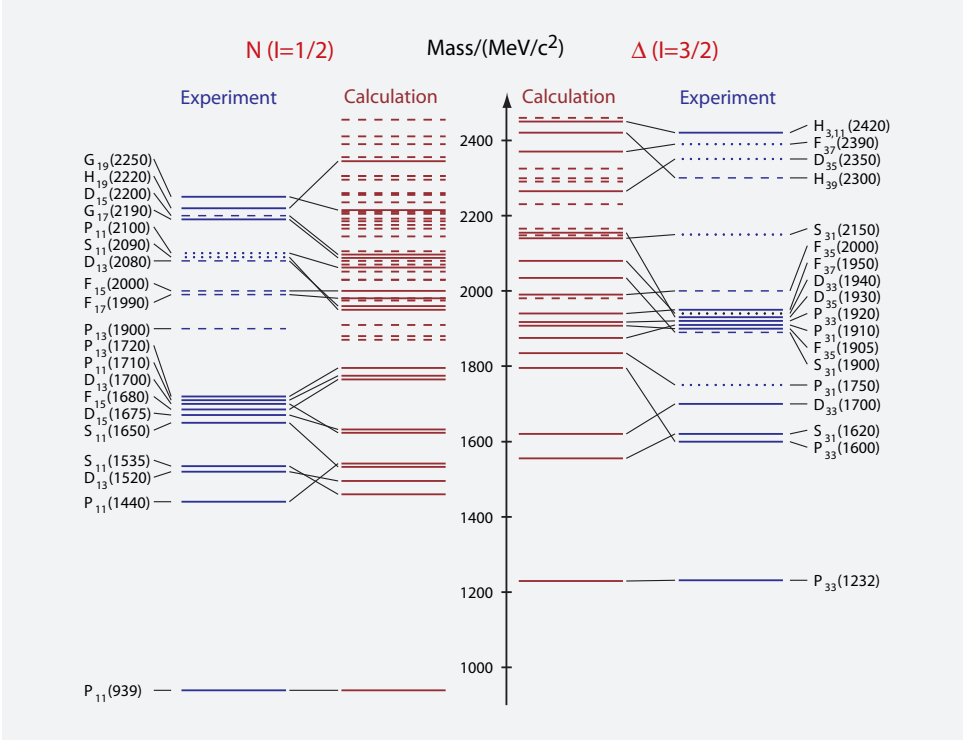

FIGURE 565 The mass spectrum of the excited states of the proton: experimental and calculated values (from Ref. 1087)

Ref. 1087

studied in detail; a summary, also showing the limitation of the approach, is shown in Figure 565. Many excitations can be explained as excited quarks states, but many more are predicted. The calculated masses agree with observations to about 10%. The quark model and QCD thus structure and explain a large part of the baryon spectrum; but the agreement is not yet perfect.

Obviously, in our everyday environment the energies necessary to excite nucleons do not appear – in fact, they do not even appear inside the Sun – and these excited states can be neglected. They only appear in particle accelerators and in cosmic radiation. In a sense, we can say that in our corner of the universe, the colour of protons usually is not visible.

Curiosities about the strong interactions

The computer calculations necessary to extract particle data from the Lagrangian of quantum chromodynamics are among the most complex calculations ever performed. They beat weather forecasts, fluid simulations and the like by orders of magnitude. Nobody knows whether this will be necessary also in the future: the race for a simple approximation method for finding solutions is still open.

* *

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Even though gluons are massless, like photons and gravitons, there is no colour radiation. Gluons carry colour and couple to themselves; as a result, free gluons were predicted to directly decay into quark–antiquark pairs. This decay has indeed been observed in experiments at particle accelerators.

* *

Something similar to colour radiation, but still stranger might have been found in 1997. It might be that a scalar meson with a mass of 1.5 GeV/c^2 is a *glueball*. This is a hypothetical meson composed of gluons only. Numerical results from lattice gauge theory seem to
Ref. 1096 confirm the possibility of a glueball in that mass range.

* *

There is a growing consensus that most light scalar mesons below 1 GeV/c^2, are
Ref. 1097 tetraquarks. In 2003, experiments provided also candidates for heavier tetraquarks, namely the X(3872), Ds(2317) and Ds(2460). The coming years will show whether this interpretation is correct.

* *

Do particles made of five quarks, so-called *pentaquarks*, exist? So far, they seem to exist only in a few laboratories in Japan, whereas in other laboratories across the world they are not seen. The issue is still open, though most researchers do not believe in them any
Ref. 1098 more.

* *

Whenever we look at a periodic table of the elements, we look at a manifestation of the strong interaction. The Lagrangian of the strong interaction describes the origin and properties of the presently known 115 elements.

Nevertheless one central aspect of nuclei is determined by the electromagnetic interaction. Why are there around 115 different elements? Because the electromagnetic coupling constant α is around 1/137.036. In more detail, the answer is the following. If the charge of a nucleus were much higher than around 130, the electric field around nuclei would lead to spontaneous electron–positron pair generation; the generated electron would fall into the nucleus and transform one proton into a neutron, thus inhibiting a larger proton number. The finite number of the elements is thus due to the electromagnetic interaction.

* *

The instability of the vacuum also yields a (trivial) limit on the fine structure constant. The fine structure constant value of around 1/137.036 cannot be explained by quantum
Ref. 1099 electrodynamics. However, it can be deduced that it must be lower than 1 to lead to a consistent theory. Indeed, if its value were larger than 1, the vacuum would become unstable and would spontaneously generate electron-positron pairs.

* *

To know more about radioactivity, its effects, its dangers and what a government can do about it, see the English and German language site of the Federal Office for Radiation Protection at www.bfs.de.

* *

From the years 1990 onwards, it has regularly been claimed that extremely poor countries are building nuclear weapons. Why is this highly unlikely? Challenge 1586 s

* *

Historically, nuclear reactions provided the first test of the relation $E = \gamma mc^2$. This was achieved in 1932 by Cockcroft and Walton. They showed that by shooting protons into lithium one gets the reaction

$$^{7}_{3}\mathrm{Li} + ^{1}_{1}\mathrm{H} \to ^{8}_{4}\mathrm{Be} \to ^{4}_{2}\mathrm{He} + ^{4}_{2}\mathrm{He} + 17\,\mathrm{MeV}\ . \tag{755}$$

The measured energy on the right is exactly the value that is derived from the differences in total mass of the nuclei on both sides.

* *

A large minority of researchers say that QCD is defined by two parameters. Apart from the coupling constant, they count also the strong CP parameter. Indeed, it might be that the strong interaction violates CP invariance. This violation would be described by a second term in the Lagrangian; its strength would be described by a second parameter, a phase usually called θ_{CP}. However, many high-precision experiments have been performed to search for this effect, and no CP violation in the strong interaction has ever been detected.

* *

In a well-known analogy, QCD can be compared to superconductivity. Table 109 gives an overview of the correspondence.

A SUMMARY OF QCD

Quantum chromodynamics, the non-abelian gauge theory based on the SU(3) symmetric Lagrangian, describes the properties of gluons and quarks, the properties of the proton, the neutron and all other hadrons, the properties of atomic nuclei, the working of the stars and the origin of the atoms inside us and around us. Without the strong inter-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

action, we would not have flesh and blood. And all these aspects of nature follow from a single number, the strong coupling constant.

QCD and experiment agree wherever comparisons have been made. The limitations of QCD are only conceptual. Like in all of quantum field theory, also in the case of QCD the mathematical form of the Lagrangian is almost uniquely defined by requiring renormalizability, Lorentz invariance, and gauge invariance – SU(3) in this case. We say 'almost', because the Lagrangian contains a few parameters that remain unexplained:

— The number, 6, and the masses m_q of the quarks are not explained by QCD.
— The coupling constant of the strong interaction g_s, or equivalently, α_s or Λ, is unexplained. QCD predicts its energy dependence, but not its absolute value.
— Experimentally, the strong interaction is found to be CP conserving. This is not obvious; the QCD Lagrangian assumes that any possible CP-violating term vanishes, even though there exist CP-violating Lagrangian terms that are Lorentz-invariant, gauge-invariant and renormalizable.
— The properties of space-time, in particular its Lorentz invariance, its continuity and the number of its dimensions are obviously all unexplained in QCD and assumed from the outset.
— It is also not known how QCD has to be modified in strong gravity, thus in strongly curved space-time.

Before we explore ways to overcome these limits, we have a look at the other nuclear interaction.

Chapter 47

THE WEAK NUCLEAR INTERACTION AND THE HANDEDNESS OF NATURE

No interaction is as weird as the weak interaction. It transforms elementary particles into each other, it is extremely weak, its radiation particles have mass, and it violates parity. These properties make it fascinating in many ways.

Transformation of elementary particles

Radioactivity, in particular the so-called β decay, is a bizarre phenomenon. Experiments in the 1910s showed that when beta sources emit electrons, atoms change from one chemical element to another. For example, one observed that tritium decays into Helium as

$$ {}^{3}_{1}\mathrm{H} \to {}^{3}_{2}\mathrm{He} + e^- + \overline{\nu}_e \,. \tag{756}$$

In the 1930s it became clear that this process is due to a neutron in the nucleus changing into a proton (and more):

$$ n \to p + e^- + \overline{\nu}_e \,. \tag{757}$$

In the 1960s, the quark model showed that beta decay is due to an up quark changing to a down quark:

$$ d \to u + e^- + \overline{\nu}_e \,. \tag{758}$$

Elementary particles are thus not immutable. The dream of Democritus and Leucippus about immutable basic building blocks is definitely *not* realized in nature.

Experiments show that quark transformation is not possible to achieve with electromagnetic fields, nor with gluon fields, nor with gravitation. There must be another type of radiation in nature, and thus another interaction. Fortunately, such transformations are rare, otherwise we would not be running around: the interaction is *weak*.

The weak nuclear interaction transforms quarks into each other. But where does the energy go in beta decay? Measurements in 1911 showed that the energy spectrum of the emitted electron is continuous. Then, in 1930, Wolfgang Pauli had the courage and genius to explain this observation in with a daring hypothesis: the energy of the decay is split between the electron and a new, truly astonishing particle, the *neutrino* – more precisely, the electron anti-neutrino $\bar{\nu}_w$. Experiments showed that the neutrino must be uncharged, must not interact strongly, and must be of very low mass. As a result, neutrinos interact with ordinary matter only extremely rarely, and usually fly through the Earth without being affected. This property makes detection very difficult, but not impossible; the particle

was detected in 1952.

THE WEAKNESS OF THE WEAK NUCLEAR INTERACTION

'Weak radiation' consists of massive particles; there are two types, the neutral Z boson with a mass of 91.2 GeV – that is the mass of a silver atom – and the electrically charged W boson with a mass of 80.4 GeV. The masses are so large that free radiation exists only

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 111 The intermediate vector bosons of the weak interaction (the Z boson is its own antiparticle; the W boson has an antiparticle of opposite charge)

Boson	Mass m	Spin J	Colour; weak behaviour	Charge Q, isospin I, strangeness S, charm C, beauty B', topness T	Lepton number L, baryon number B
Z boson	91.1876(21) GeV/c^2	1	white; 'triplet'	0, 0, 0, 0, 0, 0	0, 0
W boson	80.398(25) GeV/c^2	1	white; 'triplet'	1, 0, 0, 0, 0, 0	0, 0

for an extremely short time, about 0.1 ys; then the particles decay. The large mass is the reason that the weak interaction is extremely short range and weak; any exchange of virtual particles scales with the negative exponential of the intermediate particle's mass. In fact, the weak interaction is so weak that neutrinos, particles which interact only weakly, have an overwhelming probability to fly through the Sun without any interaction.

The existence of a massive charged intermediate vector boson, today called the W, was already deduced in the 1940s; but theoretical physicists did not accept the idea until the Dutch physicist Gerard 't Hooft proved that it was possible to have such a mass without having problems in the rest of the theory. For this proof he later received the Nobel Prize in Physics.

Experimentally, the Z boson was first observed as a virtual particle in 1973 at CERN in Geneva. In 1983, CERN groups produced and detected the first real W and Z bosons. This experiment was a five-year effort by thousands of people working together. The energetic manager of the project, Carlo Rubbia, famous for changing one secretary every three weeks, and the chief technologist, Simon van der Meer, received the 1984 Nobel Prize in Physics for the discovery.

In the same way that photons are emitted by accelerated charges, W and Z bosons are emitted by accelerated weak charges. The W and the Z are observed to be elementary.
Ref. 1087 For example, the W gyromagnetic ratio is as predicted for elementary particles.

Distinguishing left from right

The next weird characteristic of the weak interaction is the nonconservation of parity P under spatial inversion. The weak interaction distinguishes between mirror systems, in contrast to everyday life, gravitation, electromagnetism, and the strong interactions. Parity non-conservation had been predicted by 1956 by Lee Tsung-Dao and Yang Chen Ning in order to explain the ability of K^0 mesons to decay either into 2 pions, which have
Ref. 1100 even parity, or into 3 pions, which have odd parity.

Lee and Yang suggested an experiment to Wu Chien-Shiung* The experiment she performed with her team is shown schematically in Figure 567. A few months after the

* Wu Chien-Shiung (1912–1997) was called 'madame Wu' by everybody. She was a bright and driven physi-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

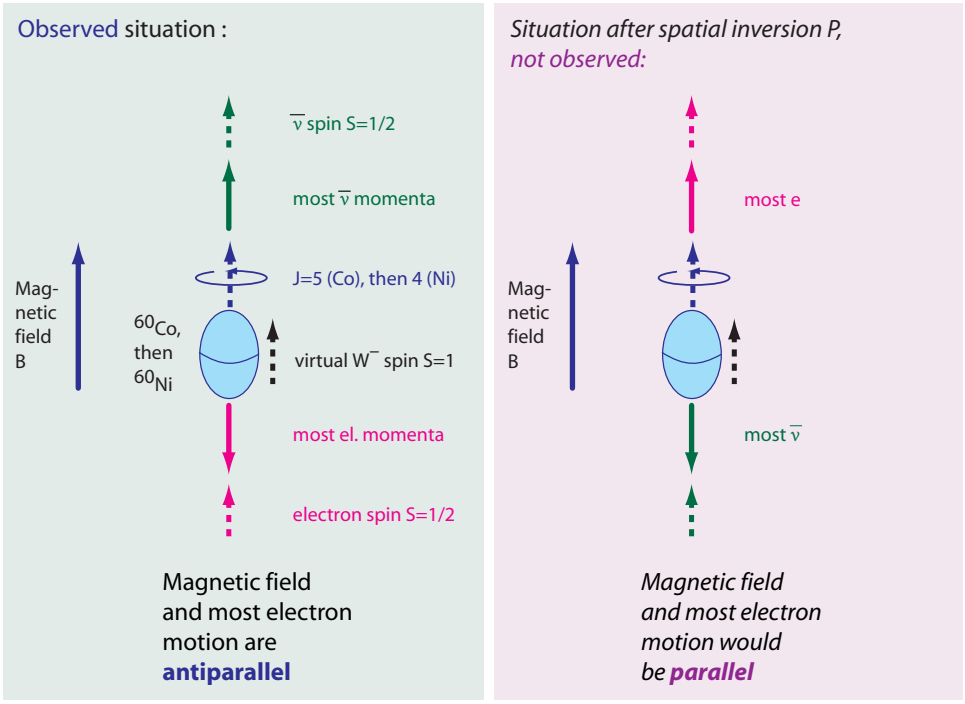

FIGURE 567 The measured behaviour of β-decay, and its imagined, but unobserved behaviour under spatial inversion P (corresponding to a mirror reflection plus subsequent rotation by π around an axis perpendicular to the mirror plane)

FIGURE 568 Wu Chien-Shiung (1912–1997)

first meetings with Lee and Yang, the Wu and her team found that in the β-decay of cobalt nuclei aligned along a magnetic field, the emitted electrons are emitted mostly *against* the spin of the nuclei. In the parity-inversed experiment, the electrons would be emitted *along* the spin direction; however, this case is not observed. Parity is violated. This earned Lee and Yang a Nobel Prize in 1957.

Parity is violated in the weak interaction. This is not only the case for β-decay. The result has been confirmed for muon decay and every other weak process studied so far.

cist born in China. She worked also on nuclear weapons; later in life she was president of the American Physical Society.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

? The weak interaction is not parity invariant. In particular, when two electrons collide, those collisions that occur through the weak interaction behave differently in a mirror experiment. The number of experiments showing this increases from year to year. In 2004, two polarized beams of electrons – one left-handed and one right-handed – were shot at a matter target and the reflected electrons were counted. The difference was 175 parts per billion – small, but measurable. The experiment also confirmed the predicted weak charge of −0.046 of the electron.

A beautiful consequence of parity violation is its influence on the *colour* of certain Ref. 1101 atoms. This prediction was made in 1974 by Bouchiat and Bouchiat. The weak interaction is triggered by the weak charge of electrons and nuclei; therefore, electrons in atoms do not exchange only virtual photons with the nucleus, but also virtual Z particles. The chance for this latter process is extremely small, around 10^{-11} times smaller than for exchange of virtual photons. But since the weak interaction is not parity conserving, this process allows electron transitions which are impossible by purely electromagnetic effects. In 1984, measurements confirmed that certain optical transitions of caesium atoms that are impossible via the electromagnetic interaction, are allowed when the weak inter- Ref. 1102 action is taken into account. Several groups have improved these results and have been able to confirm the calculations based on the weak interaction properties, including the Ref. 1103 weak charge of the nucleus, to within a few per cent.

The weak interaction thus allows one to distinguish left from right. Nature contains processes who differ from their mirror version. This is in full contrast to everyday life. In short, particle physics has shown that nature is weakly left-handed.

The handedness of nature is to be taken literally: further experiments confirmed to Challenge 1587 e central statements on the weak interaction that can be already guessed from Figure 567. First, the weak interaction only couples to left-handed particles and to right-handed antiparticles. Parity is *maximally violated* in the weak interaction. Secondly, all neutrinos observed so far are left-handed, and that all antineutrinos are right-handed. (This can only be true if their mass vanishes or is negligibly small.) These statements define several aspects of the Lagrangian of the weak interaction and of the standard model of particle physics.

Distinguishing particles and antiparticles, CP violation

In the weak interaction, the observation that only right-handed particles and left-handed antiparticles are affected has an important consequence: it implies a violation of charge Challenge 1588 e conjugation parity C. Observations of muons into electrons shows this most clearly: antimuon decay differs from muon decay. The weak interaction distinguishes particles from antiparticles. In fact, C parity, like P parity, is *maximally violated* in the weak interaction. Also this effect has been confirmed in all subsequent observations ever performed on the weak interaction.

But that is not all. The weak interaction also violates the combination of parity inversion with particle-antiparticle symmetry, the so-called CP invariance. In contrast to P violation and C violation, which are maximal, CP violation is a tiny effect. Its observation was made first in 1964 by Val Fitch and James Cronin in the decay of the neutral K mesons. This experiment earned them the Nobel Prize in 1980. CP violation has also been observed in neutral B mesons, in several different processes and reactions. The search for

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 569 The essence of the electroweak interaction Lagrangian

other manifestations of CP violation, such as in non-vanishing electric dipole moments of elementary particles, is an intense research field. The search is not simple because CP violation is a small effect in an already very weak interaction; this tends to makes experiments large and expensive.

Since the weak interaction violates CP invariance, it also violates motion (or time) reversal T. But like all gauge theories, the weak interaction is invariant under the combined CPT transformation. If CPT would be violated, the masses. lifetimes and magnetic moments of particles and antiparticles would differ. That is not observed.

Weak charge, mixings and symmetry breaking

All weak interaction processes can be described by the Feynman diagrams in Figure 569. But a few remarks are necessary. First of all, the W and Z act only on left-handed fermion and on right-handed anti-fermions. Secondly, the weak interaction conserves a *weak charge*, or *weak isospin* T_3. The three quarks u, c and t, as well as the neutrinos, have weak isospin $T_3 = 1/2$; the other three quarks and the charged leptons have weak isospin $T_3 = -1/2$. In an idealized, SU(2) world, the three vector bosons W^+, W^0, W^- would have weak isospin values 1, 0 and −1 and be massless. However, three aspects complicate the issue.

First of all, it turns out that the quarks appearing in Figure 569 are not those of the strong interaction: there is a slight difference, due to quark mixing. Secondly, also neutrinos mix. And thirdly, the vector bosons are massive and break the SU(2) symmetry of the imagined idealized world; the Lie group SU(2) is not an exact symmetry of the weak interaction, and the famous Higgs boson has mass.

1. Surprisingly, the weak interaction eigenstates of the quarks are not the same as the mass eigenstates. This is described by the so-called Cabibbo–Kobayashi–Maskawa or CKM mixing matrix. It is defined by

$$\begin{pmatrix} d' \\ s' \\ b' \end{pmatrix} = (V_{ij}) \begin{pmatrix} d \\ s \\ b \end{pmatrix} . \tag{759}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where, by convention, the states of the +2/3 quarks (u, c, t) are unmixed. In its standard parametrization, the CKM matrix reads

$$V = \begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta_{13}} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta_{13}} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta_{13}} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta_{13}} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta_{13}} & c_{23}c_{13} \end{pmatrix} \quad (760)$$

where $c_{ij} = \cos\theta_{ij}$, $s_{ij} = \sin\theta_{ij}$ and i and j label the generation ($1 \leqslant i, j \leqslant 3$). In the limit $\theta_{23} = \theta_{13} = 0$, i.e., when only two generations mix, the only remaining parameter is the angle θ_{12}, called the *Cabibbo angle*, which was introduced when only the first two generations of fermions were known. The phase δ_{13}, lying between 0 and 2π, is different from zero in nature, and expresses the fact that CP invariance is violated in the case of the weak interactions. It appears in the third column and shows that CP violation is related to the existence of (at least) three generations.

The CKM mixing matrix is predicted to be unitary in the standard model. This is confirmed by all experiments so far. The 90 % confidence upper and lower limits for the *magnitude* of the complex CKM matrix are given by

Ref. 1087

$$V = \begin{pmatrix} 0.97419(22) & 0.2257(10) & 0.00359(16) \\ 0.2256(10) & 0.97334(23) & 0.0415(11) \\ 0.00874(37) & 0.0407(10) & 0.999133(44) \end{pmatrix} \quad (761)$$

The CP violating phase δ_{13} is usually expressed with the *Jarlskog invariant*, defined as $J = \sin\theta_{12}\sin\theta_{13}\sin\theta_{23}^2\cos\theta_{12}\cos\theta_{13}\cos\theta_{23}\sin\delta_{13}$. This expression is independent of the definition of the phase angles; it was discovered by Cecilia Jarlskog, an important Swedish particle physicist. Its measured value is $J = 3.05(20)\cdot 10^{-5}$.

Ref. 1104

2. Also neutrinos mix, in the same way as the d, s and b quarks. The determination of the matrix elements is not as complete as for the quark case. This is an intense research field. Like for quarks, also for neutrinos the mass eigenstates and the flavour eigenstates differ. There is a dedicated neutrino mixing matrix, with 6 angles, and many experiments are trying to measure the parameters. Only a few are known so far, but no surprises are expected.

3. Finally, the electroweak interaction does not show a SU(2) symmetry. Electromagnetic and the weak processes lead to a single interaction, the so-called *electroweak interaction*. The electroweak interaction is described by a *coupling constant* g and by the *weak mixing angle* θ_W. The mixing angle describes the strength of the breaking of the SU(2) symmetry.

Ref. 1087

The usual electromagnetic coupling constant e is related to the electroweak coupling by

$$e = g\sin\theta_w\,, \quad (762)$$

which at low four-momentum transfers is the fine structure constant with the value 1/137.036. The electroweak coupling constant g also defines the historically defined *Fermi*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

constant G_F by

$$G_F = \frac{g^2\sqrt{2}}{8M_W^2} \,. \tag{763}$$

The broken SU(2) symmetry implies that in the *real* world, in contrast to the *ideal* SU(2) world, the intermediate vector bosons are
— the massless, neutral photon, given as $A = B\cos\theta_W + W^3\sin\theta_W$;
— the massive neutral Z boson, given as $Z = -B\sin\theta_W + W^3\cos\theta_W$;
— the massive charged W bosons, given as $W^\pm = (W^1 \mp iW^2)/\sqrt{2}$.
This implies that the electroweak interaction relates the electromagnetic coupling, the weak coupling and the intermediate boson masses by the impressive relation

$$\left(\frac{m_W}{m_Z}\right)^2 + \left(\frac{e}{g}\right)^2 = 1 \tag{764}$$

The relation is well verified by experiments.

The electroweak interaction also predicts a scalar, elementary Higgs boson. This particle is currently being searched in a large experiment at CERN.

The Lagrangian of the electroweak interaction

If we combine the observed properties of the weak interaction mentioned above, namely its observed Feynman diagrams, its particle transforming ability, P and C violation, quark mixing, neutrino mixing and symmetry breaking, we arrive at the full Lagrangian density. It is given by:

$$\begin{aligned}
\mathcal{L}_{EW} = \;& \textstyle\sum_k \overline{\psi}_k (i\,\partial\!\!\!/ - m_k - \frac{g m_k H}{2 m_W})\psi_k && \text{1. fermion mass terms}\\
& -e\textstyle\sum_k q_k \overline{\psi}_k \gamma^\mu \psi_k A_\mu && \text{2. e.m. interaction}\\
& -\frac{g}{2\sqrt{2}}\textstyle\sum_k \overline{\psi}_k \gamma^\mu (1-\gamma^5)(T^+ W_\mu^+ + T^- W_\mu^-)\psi_k && \text{3. charged weak currents}\\
& -\frac{g}{2\cos\theta_W}\textstyle\sum_k \overline{\psi}_k \gamma^\mu (g_V^k - g_A^k \gamma^5)\psi_k Z_\mu && \text{4. neutral weak currents}\\
& -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} && \text{5. electromagetic field}\\
& -\frac{1}{2}W_{\mu\nu}^+ W^{-\mu\nu} - \frac{1}{4}Z_{\mu\nu}Z^{\mu\nu} && \text{6. weak W and Z fields}\\
& +m_W^2 W^+ W^- + \frac{1}{2}m_Z^2 Z^2 && \text{7. W and Z mass terms}\\
& -gWWA - gWWZ && \text{8. cubic interaction}\\
& -\frac{g^2}{4}(W^4 + Z^4 + W^2F^2 + Z^2F^2) && \text{9. quartic interaction}\\
& +\frac{1}{2}(\partial^\mu H)(\partial_\mu H) - \frac{1}{2}m_H^2 H^2 && \text{10. Higgs boson mass}\\
& -\frac{g m_H^2}{4 m_W}H^3 - \frac{g^2 m_H^2}{32 m_W^2}H^4 && \text{11. Higgs self-interaction}\\
& +(g m_W H + \frac{g^2}{4}H^2)(W_\mu^+ W^{-\mu} + \frac{1}{2\cos^2\theta_w}Z_\mu Z^\mu) && \text{12. Higgs–W and Z int.}
\end{aligned} \tag{765}$$

The terms in the Lagrangian are easily associated to the Feynman diagrams of Figure 569:

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

1. this term describes the inertia of every object around us, yields the motion of fermions, and represents the kinetic energy of the quarks and leptons, as it appears in the usual Dirac equation, modified by the so-called *Yukawa coupling* to the Higgs field H and possibly by a Majorana term for the neutrinos (not shown);
2. the second term describes the well-known interaction of matter and electromagnetic radiation, and explains practically all material properties and colours observed in daily life;
3. the term is the so-called *charged current interaction*, due to exchange of virtual W bosons, that is responsible for the beta decay and for the fact that the Sun is shining;
4. this term is the *neutral current interaction*, the '$V - A$ theory' of George Sudarshan, that explains the elastic scattering of neutrinos in matter;
5. this term represents the kinetic energy of photons and yields the evolution of the electromagnetic field in vacuum, thus the basic Maxwell equations;
6. this term represents the kinetic energy of the weak radiation field and gives the evolution of the intermediate W and Z bosons of the weak interaction;
7. this term is the kinetic energy of the vector bosons;
8. this term represents the triple vertex of the self-interaction of the vector boson;
9. this term represents the quadruple vertex of the self-interaction of the vector boson;
10. this term is predicted to be the kinetic energy of Higgs boson;
11. this term is predicted to be the self-interaction of the Higgs;
12. the last term is predicted to represent the interaction of the vector bosons with the Higgs boson that restoring unitarity at high energies.

Let us look into the formal details. The quantities appearing in the Lagrangian are:

— The wave functions $\psi_k = (\nu'_k \;\; l^-_k)$ for leptons and $(u_k \;\; d'_k)$ for quarks are the left-handed fermion fields of the k-th fermion generation; every component is a spinor. The index $k = 1, 2, 3$ numbers the generation: the value 1 corresponds to (u d $\nu_e e^-$), the second generation is (c s $\nu_\mu \mu^-$) and the third (t b $\nu_\tau \tau^-$). The ψ_k transform as doublets under SU(2); the right handed fields are SU(2) singlets.

In the doublets, one has

$$d'_k = \sum_l V_{kl} d_l \;, \tag{766}$$

where V_{kl} is the Cabibbo–Kobayashi–Maskawa mixing matrix, d'_k are the quark flavour eigenstates and d_k are the quark mass eigenstates. A similar expression holds for the mixing of the neutrinos:

$$\nu'_k = \sum_l P_{kl} \nu_l \;, \tag{767}$$

where P_{kl} is the Pontecorvo–Maki–Nakagawa–Sakata mixing matrix, ν'_l the neutrino flavour eigenstates and ν_l the neutrino mass eigenstates.

— For radiation, A^μ and $F^{\mu\nu}$ is the field of the massless vector boson of the electromagnetic field, the *photon* γ.

$W^\pm_\mu$ are the massive charged gauge vector bosons of the weak interaction; the corresponding particles, W^+ and W^-, are each other's antiparticles.

Z_μ is the field of the massive neutral gauge vector boson of the weak interactions;

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the neutral vector boson itself is usually called Z^0.

— H is the field of the neutral scalar Higgs boson H^0, the only elementary scalar particle in the standard model. It is not yet discovered, so that all terms involving H still need final confirmation.

— Two charges appear, one for each interaction. The number q_k is the well-known *electric charge* of the particle ψ_k in units of the positron charge. The number $t_{3L}(k)$ is the *weak isospin*, or *weak charge*, of fermion k, whose value is +1/2 for u_k and ν_k and is −1/2 for d_k and l_k. These two charges together define the so-called *vector coupling*

$$g_V^k = t_{3L}(k) - 2q_k \sin^2\theta_W \tag{768}$$

and the axial coupling

$$g_A^k = t_{3L}(k)\ . \tag{769}$$

The combination $g_V^k - g_A^k$, or $V - A$ for short, expresses the maximal violation of P and C parity in the weak interaction.

— The operators T^+ and T^- are the weak isospin raising and lowering operators. Their action on a field is given e.g. by $T^+ l_k^- = \nu_k$ and $T^- u_k = d_k$.

We see that the Lagrangian indeed contains all the ideas developed above. The electroweak Lagrangian is *unique*: it could not have a different mathematical form, because both the electromagnetic terms and the weak terms are fixed by the requirements of Lorentz invariance, U(1) and broken SU(2) gauge invariance, permutation symmetry and renormalizability.

Curiosities about the weak interaction

The Lagrangian of the weak interaction has been checked by thousands of experiments. Many experiments have been design specifically to probe it to the highest precision possible. In all these cases, no contradictions between observation and calculation has ever been found. Ref. 1087

Nevertheless, the weak interaction, with its breaking of parity and its elusive neutrino, exerts a deep fascination on all those who have explored it. Let us explore this fascination a bit more. Ref. 1106

* *

The weak interaction is responsible for the burning of hydrogen to helium in the early universe. Without helium, there would be no path to make still heavier elements. Thus we owe our own existence to the weak interaction.

* *

The weak interaction is required to have an excess of matter over antimatter. Without the parity violation of the weak interactions, there would be no matter at all in the universe. Also this property of the weak interaction is necessary for our own existence.

* *

Through the emitted neutrinos, the weak interaction helps to get the energy out of a

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

supernova. If that were not the case, black holes would form in almost every supernova, heavier elements – of which we are made – would not have been spread out into space, and we would not exist.

* *

The fascination of the Higgs boson is underlined by the fact that it is the only fundamental observable field which bears the name of a physicist.

* *

The weak interaction is also responsible for the heat produced inside the Earth. This heat keeps the magma liquid. As a result, the weak interaction, despite its weakness, is responsible for most earthquakes, tsunamis and volcanic eruptions.

* *

Ref. 1105 The paper by Peter Higgs on the boson named after him is only 79 lines long, and has only five equations.

* *

Beta decay, due to the weak interaction, separates electrons and protons. Only in 2005 people have managed to propose practical ways to use this effect to build long-life batteries that could be used in satellites. Future will tell whether the method will be successful.

* *

Already in 1957, the great physicist Bruno Pontecorvo imagined that travelling neutrinos could spontaneously change into their own antiparticles. Today, it is known experimentally that travelling neutrinos can change generation, and one speaks of *neutrino oscillations*.

* *

Ref. 1107 Every second around 10^{16} neutrinos fly through our body. They have five sources:

— *Solar neutrinos* arrive on Earth at $6 \cdot 10^{14}\,/\mathrm{m}^2\mathrm{s}$, with an energy from 0 to 0.42 MeV; they are due to the p-p reaction in the sun; a tiny is due to the ^{8}B reaction and has energies up to 15 MeV.

— *Atmospheric neutrinos* are products of cosmic rays hitting the atmosphere, consist of 2/3 of muon neutrinos and one third of electron neutrinos, and have energies mainly between 100 MeV and 5 GeV.

Page 1236 — *Earth neutrinos* from the radioactivity that keeps the Earth warm form a flux of $6 \cdot 10^{10}\,/\mathrm{m}^2\mathrm{s}$.

— *Fossil neutrinos* from the big bang, with a temperature of 1.95 K are found in the universe with a density of $300\,\mathrm{cm}^{-3}$, corresponding to a flux of $10^{15}\,/\mathrm{m}^2\mathrm{s}$.

— *Man-made neutrinos* are produced in nuclear reactors (at 4 MeV) and as neutrino beams in accelerators, using pion and kaon decay. A standard nuclear plant produces $5 \cdot 10^{20}$ neutrinos per second. Neutrino beams are produced, for example, at the CERN in Geneva. They are routinely sent 700 km across the Earth to central Italy, where they are detected.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

They are mainly created in the atmosphere by cosmic radiation, but also coming directly from the background radiation and from the centre of the Sun. Nevertheless, during our whole life – around 3 thousand million seconds – we have only a 10 % chance that one of them interacts with one of the $3 \cdot 10^{27}$ atoms of our body. The reason is that the weak interaction is felt only over distances less than 10^{-17} m, about 1/100th of the diameter of a proton. The weak interaction is indeed weak.

* *

In the years 1993 and 1994 an intense marketing campaign was carried out across the United States of America by numerous particle physicists. They sought funding for the 'superconducting supercollider', a particle accelerator with a circumference of 80 km. This should have been the largest machine ever built, with a planned cost of more than twelve thousand million dollars, aiming at finding the Higgs boson before the Europeans would do so at a fraction of that cost. The central argument brought forward was the following: since the Higgs boson was the basis of mass, it was central to US science to know about it first. Apart from the issue of the relevance of the conclusion, the worst is that the premise is wrong.

Page 1269

We have seen above that 99 % of the mass of protons, and thus of the universe, is due to confinement; this part of mass appears even if the quarks are approximated as massless. The Higgs boson is *not* responsible for the origin of mass itself; it just might shed some light on the issue. In particular, discovering the Higgs boson will not allow to calculate or understand the mass of any particle. The whole campaign was a classic case of disinformation, and many people involved have shown their lack of honesty.* In the end, the project was stopped, mainly for financial reasons.

Ref. 1086

> Difficile est saturam non scribere.**
>
> Juvenal, *Saturae* 1, 30.

* *

There is no generally accepted name for the quantum field theory of the weak interaction. Expressions such as *quantum asthenodynamics* (QAD) – from the Greek word for 'weak' – have not yet been universally adopted.

* *

The weak interaction is so weak that a neutrino–antineutrino annihilation – which is only possible by producing a massive intermediate Z boson – has never been observed up to this day.

* *

* We should not be hypocrites. The supercollider lie is negligible when compared to other lies. The biggest lie in the world is probably the one that states that to ensure its survival, the USA government need to spend more on the military than all other countries in the world combined. This lie is, every single year, around 40 times as big as the once-only supercollider lie. Many other governments devote even larger percentages of their gross national product to their own version of this lie. As a result, the defence spending lie is directly responsible for most of the poverty in all the countries that use it.

** 'It is hard not to be satirical.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Only one type of particles interacts (almost) only weakly: neutrinos. Neutrinos carry no electric charge, no colour charge and almost no gravitational charge (mass). To get an impression of the weakness of the weak interaction, it is usually said that the probability of a neutrino to be absorbed by a lead screen of the thickness of one light-year is less than 50 %. The universe is thus essentially empty for neutrinos. Is there room for bound states of neutrinos circling masses? How large would such a bound state be? Can we imagine bound states, which would be called neutrinium, of neutrinos and antineutrinos circling each other? The answer depends on the mass of the neutrino. Bound states of massless particles do not exist. They could and would decay into two free massless particles.*

Challenge 1589 ny

Since neutrinos are massive, a neutrino–antineutrino bound state is possible in principle. How large would it be? Does it have excited states? Can they ever be detected? These issues are still open.

* *

Ref. 1108

Do ruminating *cows* move their jaws equally often in clockwise and anticlockwise direction? In 1927, the theoretical physicists Pascual Jordan and Ralph de Laer Kronig published a study showing that in Denmark the two directions are almost equally distributed. The rumination direction of cows is thus not related to the weak interaction.

* *

Page 1248

Challenge 1590 e

The weak interaction plays an important part in daily life. First of all, the Sun is shining. The fusion of two protons to deuterium, the first reaction of the hydrogen cycle, implies that one proton changes into a neutron. This transmutation and the normal beta decay have the same first-order Feynman diagram. The weak interaction is thus essential for the burning of the Sun. The weakness of the process is one of the guarantees that the Sun will continue burning for quite some time.

* *

Of course, the weak interaction is responsible for radioactive beta decay, and thus for part of the radiation background that leads to mutations and thus to biological evolution.

* *

What would happen if the Sun suddenly stopped shining? Obviously, temperatures would fall by several tens of degrees within a few hours. It would rain, and then all water would freeze. After four or five days, all animal life would stop. After a few weeks, the oceans would freeze; after a few months, air would liquefy.

* *

Not everything about the Sun is known. For example, the neutrino flux from the Sun oscillates with a period of 28.4 days. That is the same period with which the magnetic field of the Sun oscillates. The connections are still being studied.

* *

The energy carried away by neutrinos is important in supernovas; if neutrinos would not

* In particular, this is valid for photons bound by gravitation; this state is not possible.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

carry it away, supernovas would collapse instead of explode. That would have prevented the distribution of heavier elements into space, and thus our own existence.

* *

Even earlier on in the history of the universe, the weak interaction is important, as it prevents the symmetry between matter and antimatter, which is required to have an excess of one over the other in the universe.

* *

Due to the large toll it placed on society, research in nuclear physics, like poliomyelitis, has almost disappeared from the planet. Like poliomyelitis, nuclear research is kept alive only in a few highly guarded laboratories around the world, mostly by questionable figures, in order to build dangerous weapons. Only a small number of experiments carried on by a few researchers are able to avoid this involvement and continue to advance the topic.

* *

Interesting aspects of nuclear physics appear when powerful lasers are used. In 1999, a British team led by Ken Ledingham observed laser induced uranium fission in ^{238}U nuclei. In the meantime, this has even be achieved with table-top lasers. The latest feat, in 2003, was the transmutation of ^{129}I to ^{128}I with a laser. This was achieved by focussing a 360 J laser pulse onto a gold foil; the ensuing plasma accelerates electrons to relativistic speed, which hit the gold and produce high energy γ rays that can be used for the transmutation.

Ref. 1109

A summary of the electroweak interaction

The electroweak interaction is described by a non-abelian gauge theory based on a broken SU(2) gauge group for weak processes and an unbroken U(1) group for electrodynamic processes. This description matches the observed properties of neutrinos, of the W and Z boson, of parity violation, of β decay, of the heat production inside the Earth, of several important reactions in the Sun, and of the origin of matter in the universe. The weak interaction might be weak, but it is a bit everywhere.

Theory and experiment disagree only on the Higgs boson, which has not yet been observed, due to the large investments that were needed to do so. In all other cases, theory and experiment agree whenever comparisons have been made.

The limitatons of the theory are only conceptual. Like in all of quantum field theory, also in the case of the weak interaction the mathematical form of the Lagrangian is almost uniquely defined by requiring renormalizability, Lorentz invariance, and (broken) gauge invariance – SU(2) in this case. We say again 'almost', as we did for the case of the strong interaction, because the Lagrangian contains a few parameters that remain unexplained:

— The two coupling constants g and g' of the electroweak interaction are unexplained. (They define weak mixing angle $\theta_W = \arctan(g'/g)$.)
— The mass $M_Z = 91\,\mathrm{GeV}/c^2$ of the neutral Z boson is unexplained.
— The mass M_H of the neutral scalar Higgs boson is unknown, since the particle has not

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

been discovered yet; the present limit is $m_H > 110\,\mathrm{GeV}/c^2$.
— The number $n = 3$ of generations is unexplained.
— The masses of the six leptons and the six quarks are unexplained.
— The four parameters of the Cabibbo–Kobayashi–Maskawa quark mixing matrix and the six parameters of the neutrino mixing matrix are unexplained, including the CP violating phases.
— The properties of space-time, in particular its Lorentz invariance, its continuity and the number of its dimensions are obviously all unexplained and assumed from the outset.
— It is also not known how the weak interaction behaves in strong gravity, thus in strongly curved space-time.

Before exploring how to overcome these limitations, we summarize all results so far in the so-called *standard model of particle physics*.

Chapter 48

THE STANDARD MODEL OF ELEMENTARY PARTICLE PHYSICS – AS SEEN ON TELEVISION

The following table lists the known and predicted elementary particles. he list has not changed since the mid-1970s, mainly because of the inefficient use hat was made of the relevant research budgets across the world since then, and possibly also because the list is not far from final. The table contains *all knowledge* about matter and radiation. It is the basis for materials science, geology, chemistry, biology, medicine, the neurosciences and psychology. For this reasons, it regularly features on television.

TABLE 112 The elementary particles

Radiation	electromagnetic interaction	weak interaction	strong interaction
	γ	W^+, W^-, Z^0	g_1 ... g_8
	photon	intermediate vector bosons	gluons
	Radiation particles are bosons with spin 1. W^- is the antiparticle of W^+; all others are their own antiparticles.		
Matter	generation 1	generation 2	generation 3
Leptons	e, ν_e	μ, ν_μ	τ, ν_τ
Quarks (each in three colours)	d, u	s, c	t, b
	Matter particles are fermions with spin 1/2; all have a corresponding antiparticle.		
Hypothetical matter			
Higgs boson	H	predicted to have spin 0 and to be elementary	

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The next table lists *all* properties of the elementary particles. For reasons of space, colour and weak isospin are not mentioned explicitly. Also the decay modes of the unstable particles are not given in detail; they are found in the standard references. The table that follows is fascinating. It allows us to give a *complete* characterization of the intrinsic properties of any *composed* moving entity, be it an object or an image. The aim from the beginning of our study of motion, namely to have a complete list of the *intrinsic properties* of moving entities, is thus achieved.

Ref. 1087

Page 34

The other aim that we formulated at the same time was to have a complete list of all *state properties*. This aim is also achieved, namely by the wave function. Were it not for the possibility of space-time curvature, we would be at the end of our exploration. In short, the previous and the following table lists everything about motion in flat space-time.

TABLE 113 Elementary particle properties

Particle	Mass m [a]	Lifetime τ or energy width, [b] main decay modes	Isospin I, spin J, [c] parity P, charge parity C	Charge, isospin, strangeness, [c] charm, beauty, topness: $QISCBT$	Lepton & baryon [e] numbers LB

Hypothetical, maybe elementary (boson)					
Higgs [h] H	> 114 GeV/c^2		$J = 0$		

Notes:

a. See also the table of SI prefixes on page 910. About the eV/c^2 mass unit, see page 914.

b. The *energy width* Γ of a particle is related to its lifetime τ by the indeterminacy relation $\Gamma\tau = \hbar$. There is a difference between the *half-life* $t_{1/2}$ and the lifetime τ of a particle: they are related by $t_{1/2} = \tau \ln 2$, where $\ln 2 \approx 0.693\,147\,18$; the half-life is thus shorter than the lifetime. The unified *atomic mass unit* u is defined as 1/12 of the mass of a carbon 12 atom at rest and in its ground state. One has $1\,\mathrm{u} = \frac{1}{12} m(^{12}\mathrm{C}) = 1.660\,5402(10)$ yg.

c. To keep the table short, the header does not explicitly mention *colour*, the charge of the strong interactions. This has to be added to the list of basic object properties. Quantum numbers containing the word 'parity' are multiplicative; all others are additive. Time parity T (not to be confused with topness T), better called motion inversion parity, is equal to CP. The isospin I (or I_Z) is defined only for up and down quarks and their composites, such as the proton and the neutron. In the literature one also sees references to the so-called G-parity, defined as $G = (-1)^{IC}$.

The header also does not mention the *weak charge* of the particles. The details on weak charge g, or, more precisely, on the *weak isospin*, a quantum number assigned to all left-handed fermions (and right-handed anti-fermions), but to no right-handed fermion (and no left-handed antifermion), are given in the section on the weak interactions. Page 1277

d. 'Beauty' is now commonly called *bottomness*; similarly, 'truth' is now commonly called *topness*. The signs of the quantum numbers S, I, C, B, T can be defined in different ways. In the standard assignment shown here, the sign of each of the non-vanishing quantum numbers is given by the sign of the charge of the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

corresponding quark.
e. If supersymmetry exists, *R*-parity must be added to this column. *R*-parity is a multiplicative quantum number related to the lepton number *L*, the baryon number *B* and the spin *J* through the definition $R = (-1)^{3B+L+2J}$. All particles from the standard model are *R*-even, whereas their superpartners are *R*-odd.
Ref. 1164, Ref. 1165 *f*. The electron radius is less than 10^{-22} m. It is possible to store single electrons in traps for many months.
g. See page 1269 for the precise definition and meaning of the quark masses.
h. Currently a hypothetical particle.

To complete the standard model, apart from the above two tables, we need the Lagrangians of the electroweak and strong interaction. The combination of the Lagrangians, based on the U(1), SU(3) and broken SU(2) gauge groups, is possible only in one particular way. The resulting Lagrangian is a bit complex; since it does not contain more information than already discussed, it is not written down here. All the information on the standard model Lagrangian is contained in the Feynman diagrams of the electroweak and strong interactions, taking into account the mixing of quarks and neutrinos.

In summary, the standard model includes a minimum action, a maximum speed, electric charge quantization and conservation, colour conservation and weak charge conservation. With these basic ideas, the standard model describes *every* observation ever made in flat space-time.

Summary and open questions

The standard model of particle physics clearly distinguishes *elementary* from *composed* particles. It provides the full list of properties that characterizes a particle – and thus any moving object and image. The properties are: mass, spin, charge, colour, weak isospin, parity, charge parity, isospin, strangeness, charm, topness, beauty, lepton number and baryon number.

The standard model also describes electromagnetic and nuclear interactions as gauge theories, i.e., as exchange of virtual radiation particles. The standard model describes the three types of radiation that are observed in nature at all experimentally accessible energies. As a result, the standard model describes the structure of the atoms, their formation in the history of the universe, the properties of matter and the mechanisms of life.

In short, the standard model realizes the dream of Leucippus and Democritus, plus a bit more: we know the bricks that compose all of matter and radiation, and in addition we know precisely how they move, interact and transform.

But in addition, we also know what we still do *not* know:

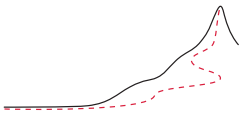
— we have not yet observed the Higgs boson;
— we do not know the origin of the coupling constants;
— we do not know the origin of the masses of the particles;
— we do not know the origin of the mixing and CP violation parameters;
— we do not know the origin of the gauge groups;
— we do not know the origin of the three generations;
— we do not know why positrons and protons have the same charge;
— we do not know whether the particle concept survives at high energy;
— we do not know what happens in curved space-time.

To study these issues, the simplest way is to explore nature at particle energies that are

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

as high as possible. There are two methods: building large experiments and exploring hypothetical models. Both are useful.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 49

DREAMS OF UNIFICATION

> Materie ist geronnenes Licht.*
>
> Albertus Magnus

Is there a common origin to the three particle interactions? We have seen in the preceding sections that the Lagrangians of the electromagnetic, the weak and the strong nuclear interactions are determined almost uniquely by two types of requirements: to possess a certain symmetry and to possess mathematical consistency. The search for *unification* of the interactions thus seems to require the identification of the one, unified symmetry of nature. (Do you agree?)

Challenge 1591 s

In the past decades, several candidate models have fuelled the hope to achieve unification through higher symmetry: grand unification, supersymmetry, conformal invariance and coupling constant duality. We start with the first, which is conceptually the simplest.

Grand unification

At all measured energies, thus below about 1 TeV, there are no contradictions between the Lagrangian of the standard model and observation. On the other hand, the Lagrangian can be seen as a low energy approximation. It should thus be possible – attention, this a belief – to find a unifying symmetry that *contains* the symmetries of the electroweak and strong interactions as subgroups and thus as different aspects of a single, unified interaction; we can then examine the physical properties that follow and compare them with observation. This approach, called *grand unification*, attempts the unified description of all types of matter. All known elementary particles are seen as fields which appear in a Lagrangian determined by a single symmetry group.

Like for each gauge theory described so far, also the grand unified Lagrangian is mainly determined by the symmetry group, the representation assignments for each particle, and the corresponding coupling constant. A general search for the symmetry group starts with all those (semisimple) Lie groups which contain $U(1) \times SU(2) \times SU(3)$. The smallest groups with these properties are SU(5), SO(10) and E(6); they are defined in Appendix B. For each of these candidate groups, the experimental consequences of the model must be studied and compared with experiment.

The data

Grand unification models make several predictions that can be matched with experiment. First of all, any grand unified model predicts relations between the quantum numbers of quarks and those of leptons. In particular, grand unification explains why the electron charge is exactly the opposite of the proton charge.

Grand unification models predict a value for the weak mixing angle θ_w; its value is not fixed by the standard model. The most frequently predicted value,

$$\sin^2 \theta_{w,th} = 0.2 \tag{770}$$

is close to the measured value of

$$\sin^2 \theta_{w,ex} = 0.231(1) \,, \tag{771}$$

which is not a good match, but might be correct.

All grand unified models predict the existence of magnetic monopoles, as was shown by Gerard 't Hooft. However, despite extensive searches, no such particles have been found yet. Monopoles are important even if there is only one of them in the whole universe: the existence of a single monopole implies that electric charge is quantized. Grand unification thus explains why electric charge appears in multiples of a smallest unit.

Ref. 1112

Grand unification predicts the existence of heavy intermediate vector bosons, called *X bosons*. Interactions involving these bosons do not conserve baryon or lepton number, but only the difference $B - L$ between baryon and lepton number. To be consistent with experiment, the X bosons must have a mass of the order of 10^{16} GeV. However, this mass is outside the range of experiments.

Most spectacularly, the X bosons of grand unification imply that the *proton decays*. This prediction was first made by Pati and Salam in 1974. If protons decay, means that neither coal nor diamond* – nor any other material – would be for ever. Depending on the precise symmetry group, grand unification predicts that protons decay into pions, electrons, kaons or other particles. Obviously, we know 'in our bones' that the proton lifetime is rather high, otherwise we would die of leukaemia; in other words, the low level of cancer already implies that the lifetime of the proton is larger than 10^{16} years.

Detailed calculations for the proton lifetime τ_p using the gauge group SU(5) yield the expression

$$\tau_p \approx \frac{1}{\alpha_G^2(M_X)} \frac{M_X^4}{M_p^5} \approx 10^{31\pm1}\,\text{a} \tag{772}$$

where the uncertainty is due to the uncertainty of the mass M_X of the gauge bosons involved and to the exact decay mechanism. Several large experiments aim to measure this lifetime. So far, the result is simple but clear. Not a single proton decay has ever been observed. The data can be summarized by

Ref. 1113

* As is well known, diamond is not stable, but metastable; thus diamonds are not for ever, but coal might be, as long as protons do not decay.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

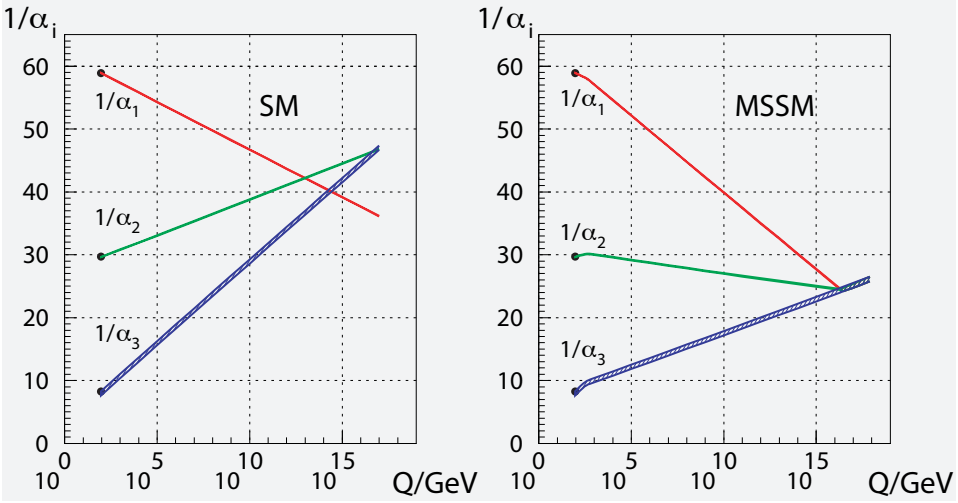

FIGURE 570 The behaviour of the three coupling constants with energy, for simple grand unification (left) and for the minimal supersymmetric model (right); the graph shows the constants $\alpha_1 = \frac{5}{3}\alpha_{em}/\cos^2\theta_W$ for the electromagnetic interaction (the factor 5/3 appears in GUTs), $\alpha_2 = \alpha_{em}/\sin^2\theta_W$ for the weak interaction and the strong coupling constant $\alpha_3 = \alpha_s$ (© Wim de Boer)

$$\begin{aligned} \tau(\mathrm{p} \to e^+ \pi^0) &> 5 \cdot 10^{33}\,\mathrm{a} \\ \tau(\mathrm{p} \to K^+ \bar{\nu}) &> 1.6 \cdot 10^{33}\,\mathrm{a} \\ \tau(\mathrm{n} \to e^+ \pi^-) &> 5 \cdot 10^{33}\,\mathrm{a} \\ \tau(\mathrm{n} \to K^0 \bar{\nu}) &> 1.7 \cdot 10^{32}\,\mathrm{a} \end{aligned} \tag{773}$$

These values are higher than the prediction by SU(5) models. For the other gauge groups the situation is not settled.

The state of grand unification

To settle the issue of grand unification definitively, one last prediction of grand unification remains to be checked: the unification of the coupling constants. Most estimates of the grand unification energy are near the Planck energy, the energy at which gravitation starts to play a role even between elementary particles. As grand unification does not take gravity into account, for a long time there was a doubt whether something was lacking in the approach. This doubt changed into certainty when the precision measurements
Ref. 1114 of the coupling constants became available. This happened in 1991, when these measurements were put into the diagram of Figure 570. It turned out that the GUT prediction of the way the constants evolve with energy imply that the three constants do *not* meet at the grand unification energy. Simple grand unification by SU(5), SU(10) or E_6 is thus ruled out by experiment.

This state of affairs is changed if *supersymmetry* is taken into account. Supersymmetry is a hypothesis on the way to take into account low-energy effects of gravitation in the particle world. Supersymmetry predicts new particles that change the curves at inter-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

mediate energies, so that they all meet at a grand unification energy of about 10^{16} GeV. (The line thicknesses in Figure 570 represent the experimental errors.) The inclusion of supersymmetry also puts the proton lifetime prediction back to a value higher (but not by much) than the present experimental bound and predicts the correct value of the mixing angle. With supersymmetry, we can thus retain the advantages of grand unification (charge quantization, one coupling constant) without being in contradiction with experiments. The predicted particles, not yet found, are in a region accessible to the LHC collider at CERN in Geneva. We will explore supersymmetry in a bit more detail below.

Pure grand unification is thus in contradiction with experiments. This is not a surprise, as its goal, to unify the description of matter, *cannot* been achieved in this way. Most of all, the symmetry group must be put in from the beginning, as grand unification cannot deduce it from a general principle. Neither does grand unification tell us what elementary particles are. In other words, grand unification only *shifts* the open questions of high energy physics to the next level, while keeping most of them unanswered. The name 'grand unification' is ridiculous.

The story of grand unification is a first hint that looking at higher energies using only low-energy concepts is not the way to solve the mystery of motion. We definitively need to continue our adventure.

Searching for higher symmetries

Since we want to reach the top of Motion Mountain, we go on. We have seen in the preceding sections that the symmetry properties are the main ingredients of the Lagrangian that describes nature. The discovery of the correct symmetry, together with mathematical consistency, usually restricts the possible choices for a Lagrangian down to a limited number (to one in the best case), and then allows to make experimental predictions.

The history of particle physics has also shown that progress was always coupled to the discovery of *larger* symmetries, in the sense that the newly discovered symmetries always included the old ones as a subgroup. Therefore, the aim soon became to find the biggest possible symmetry consistent with experiments on one hand and with gauge theories on the other hand. Since grand unification is a failure, a better approach is to search directly for a symmetry that includes gravity.

Supersymmetry

In the search for possible symmetries of a Lagrangian describing a gauge theory, one way to proceed is to find general theorems which make statements on the symmetries that a Lagrangian can possibly have.

Ref. 1115

A well-known theorem by Coleman and Mandula states that if the symmetry transformations transform fermions into fermions and bosons into bosons, no quantities other than the following can be conserved:

- the energy momentum tensor $T^{\mu\nu}$, consequence of the *external*, Poincaré space-time symmetry, and
- the internal quantum numbers, which are scalars, associated with each gauge group generator, such as electric charge, colour, etc., and are consequences of the *internal* symmetries of the Lagrangian.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

But, and here comes the way out, if transformations that *mix* fermions and bosons are considered, new conserved quantities become possible. This family of symmetries includes gravity and came to be known as *supersymmetry*. Its conserved quantities are not scalars but spinors. Therefore, *classical* supersymmetry does not exist; it is a purely quantum-mechanical symmetry. The study of supersymmetry is a research field in its own. Supersymmetry generalizes Yang-Mills gauge theory to super-Yang-Mills gauge theory. The possible super-gauge groups have been completely classified.

Supersymmetry can be extended to incorporate gravitation by changing it into a local gauge theory; in that case it is called *supergravity*. Supergravity is based on the idea that coordinates can be fermionic as well as bosonic. It thus makes specific statements on the behaviour of space-time at small distances. Supergravity predicts N additional conserved, spinorial charges. The number N lies between 1 and 8; each value leads to a different candidate Lagrangian. The simplest case is called $N = 1$ supergravity.

In short, supersymmetry is an option to unify matter and radiation at low energies. Supersymmetry, and in particular $N = 1$ supergravity, might be an approximation to reality.

Supersymmetric models make a number of predictions that can be tested by experiment.

— Supersymmetry predicts partners to the usual elementary particles. Fermions are predicted to have boson partners, and vice versa. For example, supersymmetry predicts a *photino* as fermionic partner of the photon. However, none of these particles have been observed yet; this might be due to their large mass.
— Superymmetry allows for the unification of the coupling constants in a way compatible with the data, as shown already above. Page 1297
— Supersymmetry slows down the proton decay rates predicted by grand unified theories. The slowed-down down rates are compatible with observation.
— Supersymmetry predicts electric dipole moments for the neutron (and other elementary particles). The largest predicted values, $10^{-30}\,e$ m, are in contradiction with observations; the smallest predictions have not yet been reached by experiment. In comparison, the values expected from the standard model are at most $10^{-33}\,e$ m. This is a vibrant research field.

In summary, the experimental situation of supersymmetry is weak. Is supersymmetry is an ingredient to the unified theory? The safe answer is: nobody knows yet. The optimistic answer is: supersymmetry might be discovered in upcoming experiments at CERN in Geneva. The pessimistic answer is: supersymmetry has not been confirmed by experiment, but is a belief system made up to correct the failings of grand unified theories. Time will tell which answer is correct.

Dualities – the most incredible symmetries of nature

One of the great discoveries of theoretical physics took place in 1977, when Claus Montonen and David Olive proved that the standard concept of symmetry could be expanded dramatically in a different and new way.

The standard class of symmetry transformations, which turns out to be only the first class, acts on fields. This class encompasses gauge symmetries, space-time symmetries,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

motion reversal, parities, flavour symmetries and supersymmetry.

The second, new class is quite different. If one takes all coupling constants of nature, collected in the table on page 1340, one can imagine that they are members of a continuous space of all possible coupling constants, called the *parameter space*.* Montonen and Olive showed that there are transformations in parameter space that leave nature invariant. These transformations thus form a new, second class of symmetries of nature.

In fact, we already encountered a member of this class: renormalization symmetry. But Olive and Montonen expanded the symmetry class considerably by the discovery of *electromagnetic duality*. Electromagnetic duality is a discrete symmetry exchanging

Page 718

$$e \leftrightarrow \frac{4\pi\hbar c}{e} \tag{774}$$

where the right hand turns out to be the unit of magnetic charge. Electro-magnetic duality thus relates the electric charge e and the magnetic charge m

$$Q_{\text{el}} = me \quad \text{and} \quad Q_{\text{mag}} = ng = 2\pi\hbar c/e \tag{775}$$

and puts them on equal footing. In other words, the transformation exchanges

$$\alpha \leftrightarrow \frac{1}{\alpha} \quad \text{or} \quad \frac{1}{137.04} \leftrightarrow 137.04\,, \tag{776}$$

and thus exchanges weak and strong coupling. In other words, electromagnetic duality relates a regime where particles make sense (the low coupling regime) with one where particles do not make sense (the strong coupling regime). It is the most mind-boggling symmetry ever conceived.

Dualities are among the deepest connections of physics. They contain $\hbar$ and are thus intrinsically quantum. They do not exist in classical physics and show that quantum theory is more fundamental than classical physics. More clearly stated, dualities are intrinsically non-classical symmetries. Dualities confirm that quantum theory stands on its own.

Obviously, if we want to understand the values of unexplained parameters such as coupling constants, the obvious thing to do is to study *all* possible symmetries in parameter space, thus all possible symmetries of the second class, possibly combining them with those of the first symmetry class. (Indeed, the combination of duality with supersymmetry is studied in string theory.)

Page 1514

These investigations showed that there are several types of dualities, which all are *non-perturbative* symmetries:

Ref. 1116

— S duality, the generalization of electromagnetic duality for all interactions;
— T duality, also called space-time duality, a mapping between small and large lengths and times following $l \leftrightarrow = l_{\text{Pl}}^2/l$;**

* The space of solutions for all value of the parameters is called the *moduli space*.

** Space-time duality, the transformation between large and small sizes, leads one to ask whether there is an inside and an outside to particles. (We encountered this question already in our study of gloves.) The issue has not been addressed in research yet. Sometimes one has to be patient.

Page 1052

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— infrared dualities.

So far, research into dualities has not led to experimental predictions; however, they have led to a deeper understanding of field theory. Dualities play an important role in string theory.

Page 1514

Collective aspects of quantum field theory

For many decades, mathematicians asked physicists: What is the essence of quantum field theory? Despite intensive research, this question has yet to be answered precisely.

The first half of the answer is given by the usual definition given by physicists: QFT is the most general known way to describe quantum mechanically continuous systems with a finite number of types of quanta but with an infinite number of degrees of freedom. (Of course, this definition implies that the Lagrangian must be relativistically invariant and must be described by a gauge theory.) However, this half of the answer is already sufficient to spell trouble. We will show in the next part of our ascent that neither space-time nor physical systems are continuous; we will discover that nature does not have infinite numbers of degrees of freedom. In other words, *quantum field theory is an effective theory*; this is the modern way to say that it is approximate, or more bluntly, that it is wrong.

The second, still partly unknown half of the answer would specify which (mathematical) conditions a physical system, i.e., a Lagrangian, actually needs to realize in order to become a quantum field theory. Despite the work of many mathematicians, no complete list of conditions is known yet. It is known that the list includes at least two conditions. First of all, a quantum field theory must be *renormalizable*. Secondly, a quantum field theory must be *asymptotically free*; in other words, the coupling must go to zero when the energy goes to infinity. This condition ensures that interactions are defined properly. Only a subset of renormalizable Lagrangians obey this condition.

In four dimensions, the *only* known theories with these two properties are the non-Abelian gauge theories. These Lagrangians have several general aspects which are not directly evident when we arrive at them through the usual way, i.e., by generalizing naive wave quantum mechanics. This standard approach, the historical one, emphasizes the *perturbative* aspects: we think of elementary fermions as field quanta and of interactions as exchanges of virtual bosons, to various orders of perturbation.

On the other hand, all field theory Lagrangians also show two other configurations, apart from particles, which play an important role. These mathematical solutions appear when a non-perturbative point of view is taken; they are *collective* configurations.

— Quantum field theories show solutions which are static and of finite energy, created by non-local field combinations, called *solitons*. In quantum field theories, solitons are usually magnetic monopoles and dyons; also the famous *skyrmions* are solitons. In this approach to quantum field theory, it is assumed that the actual equations of nature are nonlinear at high energy. Like in liquids, one then expects stable, localized and propagating solutions, the solitons. These solitons could be related to the observed particles.

Page 240

— Quantum field theories show self-dual or anti-self dual solutions, called *instantons*. Instantons play a role in QCD, and could also play a role in the fundamental Lagrangian of nature.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

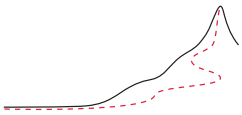
Ref. 1117 These fascinating topics have been explored in detail by mathematical physicists. Even though this has deepened the understanding of gauge theories, all the results have not helped in the path towards unification.

A summary on higher symmetries

No research program trying to unravel larger symmetries than those of the standard model has been successful so far. This includes many topics not mentioned here. For example, the topic of *quantum groups* was very popular around the year 2000. Non-commutative space-time was another fashion in elementary particle physics around the same time.

Despite hundreds of extremely smart people exploring potential higher symmetries of all kinds, their effort has not been successful for the description of nature. This leads to a question: Did researchers rely on incorrect assumptions on the structure of particles or of space-time? Or is the search for higher symmetry the wrong way to go? Before we explore these two questions, we take a break.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 50

BACTERIA, FLIES AND KNOTS

> La première et la plus belle qualité de la nature est le mouvement qui l'agite sans cesse ; mais ce mouvement n'est qu'une suite perpétuelle de crimes ; ce n'est que par des crimes qu'elle le conserve.
>
> Donatien de Sade, *Justine, ou les malheurs de la vertu*.*

Wobbly entities, in particular jellyfish or amoebas, open up a fresh vision of the world of motion, if we allow to be led by the curiosity to study them in detail. We have missed many delightful insights by leaving them aside. In particular, wobbly entities yield surprising connections between shape change and motion that will be of great use in the last part of our mountain ascent. Instead of continuing to look at the smaller and smaller, we now take a second look at everyday motion and its mathematical description.

To enjoy this chapter, we change a dear habit. So far, we always described any general example of motion as composed of the motion of *point particles*. This worked well in classical physics, in general relativity and in quantum theory; we based the approach on the silent assumption that during motion, each point of a complex system can be followed separately. We will soon discover that this assumption is *not* realized at smallest scales. Therefore the most useful description of motion of *extended* bodies uses methods that do not require that body parts be followed piece by piece. We explore these methods in this chapter; doing so is a lot of fun in its own right.

If we describe elementary particles as extended entities – as we soon will have to – a particle moving through space is similar to a dolphin swimming through water or to a bee flying through air. Let us explore how these animals do this.

Bumblebees and other miniature flying systems

If a butterfly passes by during our mountain ascent, we can stop a moment to appreciate a simple fact: a butterfly flies, and it is rather small. If we leave some cut fruit in the kitchen until it rots, we observe the even smaller fruit flies (*Drosophila melanogaster*), just around one millimetre in size. If you have ever tried to build small model aeroplanes, or if you

* 'The primary and most beautiful of nature's qualities is motion, which agitates her at all times; but this motion is simply a perpetual consequence of crimes; she conserves it by means of crimes only.' Donatien Alphonse François de Sade (1740–1814) is the intense French writer from whom the term 'sadism' was deduced.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

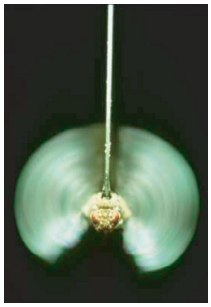


FIGURE 571 A flying fruit fly, tethered to a string

FIGURE 572 Vortices around a butterfly wing (© Robert Srygley/Adrian Thomas)

even only compare these insects to paper aeroplanes (probably the smallest man-made flying thing you ever saw) you start to get a feeling for how well evolution optimized flying insects.

Compared to paper planes, insects also have engines, flapping wings, sensors, navigation systems, gyroscopic stabilizers, landing gear and of course all the features due to life, reproduction and metabolism, built into an incredibly small volume. Evolution really is an excellent engineering team. The most incredible flyers, such as the common house fly (*Musca domestica*), can change flying direction in only 30 ms, using the stabilizers that nature has given them by reshaping the original second pair of wings. Human engineers are getting more and more interested in the technical solutions evolution has developed; many engineers trying to achieve similar miniaturization. The topic of miniature flying systems is extremely vast, so that we will pick out only a few examples.

Ref. 1125

How does a bumblebee (Bombus terrestris) fly? The lift mg generated by a *fixed* wing (as explained before) follows the empirical relation

Page 262

$$mg = f A v^2 \rho \tag{777}$$

where A is the surface of the wing, v is the speed of the wing in the fluid of density ρ. The factor f is a pure number, usually with a value between 0.2 and 0.4, that depends on the angle of the wing and its shape; here we use the average value 0.3. For a Boeing 747, the surface is 511 m^2, the top speed at sea level is 250 m/s; at an altitude of 12 km the density of air is only a quarter of that on the ground, thus only 0.31 kg/m^3. We deduce (correctly) that a Boeing 747 has a mass of about 300 ton. For bumblebees with a speed of 3 m/s and a wing surface of 1 cm^2, we get a lifted mass of about 35 mg, much less than the weight of the bee, namely about 1 g. The mismatch is even larger for fruit flies. In other words, an insect cannot fly if it keeps its wings *fixed*. It could not fly with fixed wings even if it had tiny propellers attached to them!

Ref. 1126

Page 43

Challenge 1592 e

Due to the limitations of fixed wings at small dimensions, insects and small birds must *move* their wings, in contrast to aeroplanes. They must do so not only to take off or to gain height, but also to simply remain airborne in horizontal flight. In contrast, aeroplanes generate enough lift with *fixed* wings. Indeed, if you look at flying animals,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 573 Examples of the three larger wing types in nature, all optimized for rapid flows: turkey vulture (*Cathartes aura*), ruby-throated hummingbird (*Archilochus colubris*) and a dragonfly (© S.L. Brown, Pennsylvania Game Comission/Joe Kosack and nobodythere)

such as the ones shown in Figure 573, you note that the larger they are, the less they need to move their wings (at cruising speed).

Challenge 1593 s Can you deduce from equation (777) that birds or insects can fly but people cannot? Conversely, the formula also (partly) explains why human-powered aeroplanes must be so large.*

But *how* do insects, small birds, flying fish or bats have to move their wings in order to fly? This is a tricky question and the answer has been uncovered only recently. The main point is that insect wings move in a way to produce eddies at the front edge which in turn thrust the insect upwards. Aerodynamic studies of butterflies – shown in Figure 572 – and studies of enlarged insect models moving in oil instead of in air explore the precise way insects make use of vortices. At the same time, more and more 'mechanical birds' and 'model aeroplanes' that use flapping wings for their propulsion are being built around the world. The field is literally in full swing.** Researchers are especially interested in understanding how vortices allow change of flight direction at the small dimensions typical for insects. One aim is to reduce the size of flying machines. However, none of the human-built systems is yet small enough that it actually *requires* wing motion to fly, as is the case for insects.

Ref. 1127
Ref. 1128

The expression (777) for the lift of wings also shows what is necessary for safe take-off and landing. The lift of all wings *decreases* for smaller speeds. Thus both animals and aeroplanes *increase* their wing surface in these occasions. Many birds also vigorously increase the flapping of wings in these situations. But even strongly flapping, enlarged wings often are insufficient for take-off. Many flying animals, such as swallows, therefore avoid landing completely. For flying animals which do take off from the ground, nature most commonly makes them hit the wings against each other, over their back, so that when the wings separate again, the low pressure between them provides the first lift. This method is used by insects and many birds, including pheasants. As every hunter knows, pheasants make a loud 'clap' when they take off. The clap is due to the low pressure region thus created.

* Another part of the explanation requires some aerodynamics, which we will not study here. Aerodynamics shows that the power consumption, and thus the resistance of a wing with given mass and given cruise speed, is inversely proportional to the square of the wingspan. Large wingspans with long slender wings are thus of advantage in (subsonic) flying, especially when energy is scarce.

** The website www.aniprop.de presents a typical research approach and the sites ovirc.free.fr and www.ornithopter.org give introductions into the way to build such systems for hobbyists.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Both wing use and wing construction depend on size. There are four types of wings in nature.

1. First of all, all large flying objects, such aeroplanes and large birds, fly using *fixed* wings, except during take-off and landing.
2. Second, common size birds use *flapping* wings. (Hummingbirds can have over 50 wing beats per second.) These first two types of wings have a thickness of about 10 to 15 % of the wing depth.
3. At smaller dimensions, a third wing type appears, as seen in dragonflies and other insects. At these scales, at Reynolds numbers of around 1000 and below, thin *membrane* wings are the most efficient. The *Reynolds number* measures the ratio between inertial and viscous effects in a fluid. It is defined as

$$R = \frac{l v \rho}{\eta} \tag{778}$$

   where l is a typical length of the system, v the speed, ρ the density and η the dynamic *viscosity* of the fluid.* A Reynolds number much larger than one is typical for rapid air flow and fast moving water. In fact, the Reynolds numbers specifies what is meant by a 'rapid' or 'fluid' flow on one hand, and a 'slow' or 'viscous' flow on the other. The first three wing types, shown in Figure 573, are all for rapid flows.
4. The fourth type of wings is found at the smallest possible dimensions, for insects smaller than one millimetre; their wings are not membranes at all. Typical are the cases of thrips and of parasitic wasps, which can be as small as 0.3 mm. All these small insects have wings which consist of a central *stalk* surrounded by hair. In fact, Figure 574 shows that some species of thrips have wings which look like miniature toilet brushes.

At even smaller dimensions, corresponding to Reynolds number below 10, nature does not use wings any more, though it still makes use of air transport. In principle, at the smallest Reynolds numbers gravity plays no role any more, and the process of flying merges with that of swimming. However, air currents are too strong compared with the speeds that such a tiny system could realize. No active navigation is then possible any more. At these small dimensions, which are important for the transport through air of spores and pollen, nature uses the air currents for passive transport, making use of special, but fixed shapes.

* The viscosity is the resistance to flow a fluid poses. It is defined by the force F necessary to move a layer of surface A with respect to a second, parallel one at distance d; in short, the (coefficient of) *dynamic viscosity* is defined as $\eta = d F/A v$. The unit is 1 kg/s m or 1 Pa s or 1 N s/m^2, once also called 10 P or 10 poise. In other words, given a horizontal tube, the viscosity determines how strong the pump needs to be to pump the fluid through the tube at a given speed. The viscosity of air 20 °C is 1.8×10^{-5} kg/s m or 18 μPa s and increases with temperature. In contrast, the viscosity of liquids decreases with temperature. (Why?) The viscosity of water at 0 °C is 1.8 mPa s, at 20 °C it is 1.0 mPa s (or 1 cP), and at 40 °C is 0.66 mPa s. Hydrogen has a viscosity smaller than 10 μPa s, whereas honey has 25 Pa s and pitch 30 MPa s.

Challenge 1594 ny

Physicists also use a quantity ν called the *kinematic viscosity*. It is defined with the help of the mass density of the fluid as $\nu = \eta/\rho$ and is measured in m^2/s, once called 10^4 stokes. The kinematic viscosity of water at 20 °C is 1 mm^2/s (or 1 cSt). One of the smallest values is that of acetone, with 0.3 mm^2/s; a larger one is glycerine, with 2000 mm^2/s. Gases range between 3 mm^2/s and 100 mm^2/s.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 574 The wings of a few types of insects smaller than 1 mm (thrips, *Encarsia*, *Anagrus*, *Dicomorpha*) (HortNET)

We can summarize that active flying is only possible through shape change. Only two types of shape changes are possible for active flying: that of propellers (or turbines) and that of wings. Engineers are studying with intensity how these shape changes have to take place in order to make flying most effective. Interestingly, the same challenge is posed by swimming.

Ref. 1129
Ref. 1130

Swimming

Swimming is a fascinating phenomenon. The Greeks argued that the ability of fish to swim is a proof that water is made of atoms. If atoms would not exist, a fish could not advance through it. Indeed, swimming is an activity that shows that matter cannot be continuous. Studying swimming can thus be quite enlightening. But how exactly do fish swim?

Whenever dolphins, jellyfish, submarines or humans *swim*, they take water with their fins, body, propellers, hands or feet and push it backwards. Due to momentum conservation they then move forward.* In short, people swim in the same way that fireworks or rockets fly: by throwing matter behind them. This is macroscopic swimming. Does all swimming work in this way? In particular, do *small* organisms advancing through the molecules of a liquid use the same method? No. They use a different, *microscopic* way of swimming.

Small organisms such as bacteria do *not* have the capacity to propel or accelerate water against their surroundings. Indeed, the water remains attached around a microorganism without ever moving away from it. Physically speaking, in these cases of swimming the kinetic energy of the water is negligible. In order to swim, unicellular beings thus need to use other effects. In fact, their only possibility is to change their body shape in controlled ways. From far away, the swimming of microorganisms thus resembles the motion of particles through vacuum. Like microorganisms, also particles have nothing to throw behind them.

A good way to distinguish macroscopic from microscopic swimming is provided by scallops. *Scallops* are molluscs up to a few cm in size. Scallops have a double shell connected by a hinge that they can open and close. If they close it *rapidly*, water is expelled

Page 85

* Fish could use propellers, as the arguments against wheels we collected at the beginning of our walk do not apply for swimming. But propellers with blood supply would be a weak point in the construction, and thus in the defence of a fish.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 575 A swimming scallop (here from the genus *Chlamys*) (© Dave Colwell)

and the mollusc is accelerated; the scallop then can glide for a while through the water. Then the scallop opens the shell again, this time *slowly*, and repeats the feat. When swimming, the larger scallops look like clockwork false teeth. If we reduce the size of the scallop by a thousand times to the size of single cells we get a simple result: such a tiny scallop *cannot* swim.

The origin of the lack of scalability of swimming methods is the changing ratio between inertial and dissipative effects at different scales. This ratio is measured by the Reynolds number. For the scallop the Reynolds number is about 100, which shows that when it swims, inertial effects are much more important than dissipative, viscous effects. For a bacterium the Reynolds number is much smaller than 1, so that inertial effects effectively play no role. There is no way to accelerate water *away* from a bacterial-sized scallop, and thus no way to glide. But this is not the only problem microorganism face when they want to swim.

A famous theorem states that no cell-sized being can move if the shape change is the same in the two halves of the motion (opening and closing). Such a shape change would simply make it move back and forward. There is also a mathematical theorem, the so-called *scallop theorem*, that states that no microscopic system can swim if it uses movable parts with only *one* degree of freedom. Thus it is impossible to move at cell dimensions using the method the scallop uses on centimetre scale.

Ref. 1131

In order to swim, microorganisms thus need to use a more evolved, *two-dimensional motion* of their shape. Indeed, biologists found that all microorganisms use one of the following three swimming styles:

1. Microorganisms of compact shape of diameter between 20 μm and about 20 mm, use *cilia*. Cilia are hundreds of little hairs on the surface of the organism. The organisms move the cilia in waves wandering around their surface, and these surface waves make the body advance through the fluid. All children watch with wonder *Paramecium*, the unicellular animal they find under the microscope when they explore the water in which some grass has been left for a few hours. *Paramecium*, which is between 100 μm and 300 μm in size, as well as many plankton species* use cilia for its motion. The cilia and their motion are clearly visible in the microscope. A similar swimming method is even used by some large animals; you might have seen similar waves on the borders of certain ink fish; even the motion of the manta (partially) belongs into this class. Ciliate motion is an efficient way to change the shape of a body making use of two dimensions and thus avoiding the scallop theorem.

Ref. 1132

* See the www.liv.ac.uk/ciliate website for an overview.

figure to be added

FIGURE 576 Ciliated and flagellate motion

2. Sperm and eukaryote microorganisms whose sizes are in the range between 1 µm and 50 µm swim using an (eukaryote) flagellum.* Flagella, Latin for 'small whips', work like flexible oars. Even though their motion sometimes appears to be just an oscillation, flagella get a kick only during one half of their motion, e.g. at every swing to the left. Flagella are indeed used by the cells like miniature oars. Some cells even twist their flagellum in a similar way that people rotate an arm. Some microorganisms, such as *Chlamydomonas*, even have two flagella which move in the same way as people move their legs when they perform the breast stroke. Most cells can also change the sense in which the flagellum is kicked, thus allowing them to move either forward or backward. Through their twisted oar motion, bacterial flagella avoid retracing the same path when going back and forward. As a result, the bacteria avoid the scallop theorem and manage to swim despite their small dimensions. The flexible oar motion they use is an example of a non-adiabatic mechanism; an important fraction of the energy is dissipated.

Ref. 1134 Ref. 1135

3. The smallest swimming organisms, bacteria with sizes between 0.2 µm and 5 µm, swim using *bacterial* flagella. These flagella, also called prokaryote flagella, are different from the ones just mentioned. Bacterial flagella move like turning corkscrews. They are used by the famous *Escherichia coli* bacterium and by all bacteria of the genus *Salmonella*. This type of motion is one of the prominent exceptions to the non-existence of wheels in nature; we mentioned it in the beginning of our walk. Corkscrew motion is an example of an adiabatic mechanism.

Ref. 1136 Page 85

A Coli bacterium typically has a handful of flagella, each about 30 nm thick and of corkscrew shape, with up to six turns; the turns have a 'wavelength' of 2.3 µm. Each flagellum is turned by a sophisticated rotation motor built into the cell, which the cell can control both in rotation direction and in angular velocity. For Coli bacteria, the range is between 0 and about 300 Hz.

Ref. 1137

A turning flagellum does not propel a bacterium like a propeller; as mentioned, the velocities involved are much too small, the Reynolds number being only about 10^{-4}. At these dimensions and velocities, the effect is better described by a corkscrew turning in honey or in cork: a turning corkscrew produces a motion against the material around it, in the direction of the corkscrew axis. The flagellum moves the bacterium in the same way that a corkscrew moves the turning hand with respect to the cork.

Note that still smaller bacteria do not swim at all. Indeed, each bacterium faces a minimum swimming speed requirement: is must outpace diffusion in the liquid it lives in. Slow swimming capability makes no sense; numerous microorganisms therefore do not

Ref. 1138

Ref. 1133 * The largest sperm, of 6 cm length, are produced by the 1.5 mm sized *Drosophila bifurca* fly, a relative of the famous *Drosophila melanogaster*. Even when thinking about the theory of motion, it is impossible to avoid thinking about sex.

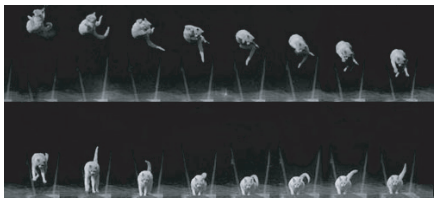

FIGURE 577 Cats can turn themselves, even with *no* initial angular momentum (photographs by Etienne-Jules Marey, 1894)

manage or do not try to swim at all. Some microorganisms are specialized to move along liquid–air interfaces. Others attach themselves to solid bodies they find in the liquid. Some of them are able to *move* along these solids. The amoeba is an example for a microorganism moving in this way. Also the smallest active motion mechanisms known, namely the motion of molecules in muscles and in cell membranes, work this way.

Page 1122

Let us summarize these observations in a different way. All known active motion, or self-propulsion, (in flat space) takes place in fluids – be it air or liquids. All active motion requires shape change. In order that shape change leads to motion, the environment, e.g. the water, must itself consist of moving components always pushing onto the swimming entity. The motion of the swimming entity can then be deduced from the particular shape change it performs. To test your intuition, you may try the following puzzle: is microscopic swimming possible in two spatial dimensions? In four?

Challenge 1595 ny

Rotation, falling cats and the theory of shape change

At small dimensions, flying and swimming takes place through phase change. In the last decades, the description of shape change has changed from a fashionable piece of research to a topic whose results are both appealing and useful. There are many studies, both experimental and theoretical, about the exact way small systems move in water and air, about the achievable and achieved efficiency, and much more. The focus is on motion through translation.

But shape change can also lead to a *rotation* of a body. In this case, the ideas are not restricted to microscopic systems, but apply at all scales. In particular, the theory of shape change is useful in explaining how falling cats manage to fall always on their feet. Cats are not born with this ability; they have to learn it. But the feat has fascinated people since centuries, as shown in the ancient photograph given in Figure 577. In fact, cats confirm in three dimensions what we already knew for two dimensions: a deformable body can change its own orientation in space without outside help. Also humans can perform the feat: simply observe the second, lateral rotation of the diver in Figure 578. Astronauts in the space station and passengers of parabolic 'zero-gravity' flights regularly do the same, as do many artificial satellites sent into space.

Page 107

In the 1980s, following the pioneering work by Michael Berry, Wilczek and Zee as well as Shapere and Wilczek made the point that all motion due to shape change is described by a gauge theory. The equivalence is shown in Table 114. A simple and beautiful example for these ideas has been given by Putterman and Raz and is shown in Figure 579. Imagine four spheres on perfect ice, all of the same mass and size, connected by four rods forming a parallelogram. Now imagine that this parallelogram can change length along one side, called a, and that it can also change the angle θ between the sides. Putterman and Raz call

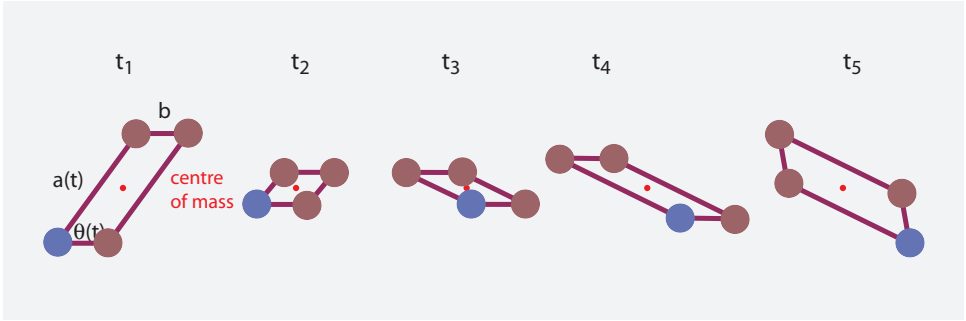

FIGURE 579 The square cat: in free space, or on perfect ice, a deformable body made of four masses that can change one body angle and one extension is able to rotate itself

this the *square cat*. The figure shows that the square cat can change its own orientation on the ice while, obviously, keeping its centre of mass at rest. The figure also shows that this only works because the two motions that the cat can perform, the stretching and the angle change, do *not* commute.

The rotation of the square cat occurs in *strokes*; large rotations are achieved by repeating strokes, similar to the situation of swimmers. If the square cat would be swimming

TABLE 114 The correspondence between shape change and gauge theory

Concept	Shape change	Gauge theory
System	deformable body	matter–field combination
Gauge freedom	freedom of description of body orientation and position	freedom to define vector potential
Gauge-dependent quantity	shape's angular orientation and position	vector potential, phase
	orientation and position change along an open path	vector potential and phase change along open path
Gauge transformation	changes angular orientation and position	changes vector potential
Gauge-independent quantities	orientation and position after full stroke	phase difference on closed path, integral of vector potential along a closed path
	deformations	field strengths
Gauge group	e.g. possible rotations SO(3) or motions E(3)	U(1), SU(2), SU(3)

in a liquid, the cat could thus rotate itself – though it could not advance.

When the cat rotates itself, each stroke results in a rotation angle that is independent of the speed of the stroke. (The same experience can be made when rotating oneself on an office chair by rotating the arm above the head: the chair rotation angle after arm turn is independent of the arm speed.) This leads to a puzzle: what is the largest angle that a cat can turn in one stroke? Challenge 1596 d

Rotation in strokes has a number of important implications. First of all, the the number of strokes is a quantity that all observers agree upon: it is observer-invariant. Secondly, the orientation change after a *complete* stroke is also observer-invariant. Thirdly, the orientation change for incomplete strokes is observer-invariant: it depends on the way that orientation is defined. For example, if orientation is defined by the direction of the body diagonal through the blue mass (see Figure 579), it changes in a certain way during a stroke. If the orientation is defined by the direction of the fixed bar attached to the blue mass, it changes in a different way during a stroke. Only when a full stroke is completed do the two values coincide. Mathematicians say that the choice of the definition and thus the value of the orientation is *gauge-dependent*, but that the value of the orientation change at a full stroke is *gauge-invariant*.

In summary, the square cat shows two interesting points. First, the orientation of a deformable body can change if the deformations it can perform are *non-commuting*. Secondly, such deformable bodies are described by *gauge theories*: certain aspects of the bodies are gauge-invariant, others are gauge-dependent. This summary leads to a question: can we use these ideas to increase our understanding of the gauge theories of the electromagnetic, weak and strong interaction? We will find out later on. In fact, shape change bears even more surprises.

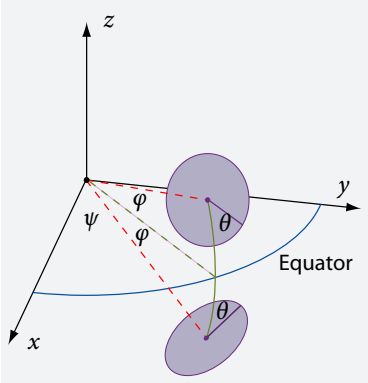

FIGURE 580 Swimming on a curved surface using two discs

Swimming in curved space

In flat space it is not possible to move through shape change. Only orientation changes are possible. Surprisingly, if space is *curved*, motion does become possible. A simple example was published in 2003 by Jack Wisdom. He found that cyclic changes in the shape of a body can lead to net translation, a rotation of the body, or both.

Ref. 1141

There is a simple system that shows the main idea. We know from Galilean physics that on a frictionless surface we cannot move, but that we can change orientation. This is true only for a flat surface. On a curved surface, we can use the ability to turn and translate it into motion.

Take to massive discs that lie on the surface of a frictionless, spherical planet, as shown in Figure 580. Consider the following four steps: 1. the disc separation φ is increased by the angle $\Delta\varphi$, 2. the discs are rotated oppositely about their centres by the angle $\Delta\theta$, 3. their separation is decreased by $-\Delta\varphi$, and 4. they are rotated back by $-\Delta\theta$. Due to to the conservation of angular momentum, the two-disc system changes its longitude $\Delta\psi$ as

Challenge 1597 ny

$$\Delta\psi = \frac{1}{2}\gamma^2 \Delta\theta\Delta\varphi \,, \tag{779}$$

where γ is the angular radius of the discs. This cycle can be repeated over and over. The cycle it allows a body, located on the surface of the Earth, to swim along the surface. Unfortunately, for a body of size of one metre, the motion for each swimming cycle is only around 10^{-27} m.

Wisdom showed that the same procedure also works in curved space, thus in the presence of gravitation. The mechanism thus allows a falling body to swim away from the path of free fall. Unfortunately, the achievable distances for everyday objects are negligibly small. Nevertheless, the effect exists.

In other words, there is a way to swim through curved space that looks similar to swimming at low Reynolds numbers, where swimming results of simple shape change. Does this tell us something about fundamental descriptions of motion? The last part of our ascent will tell.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

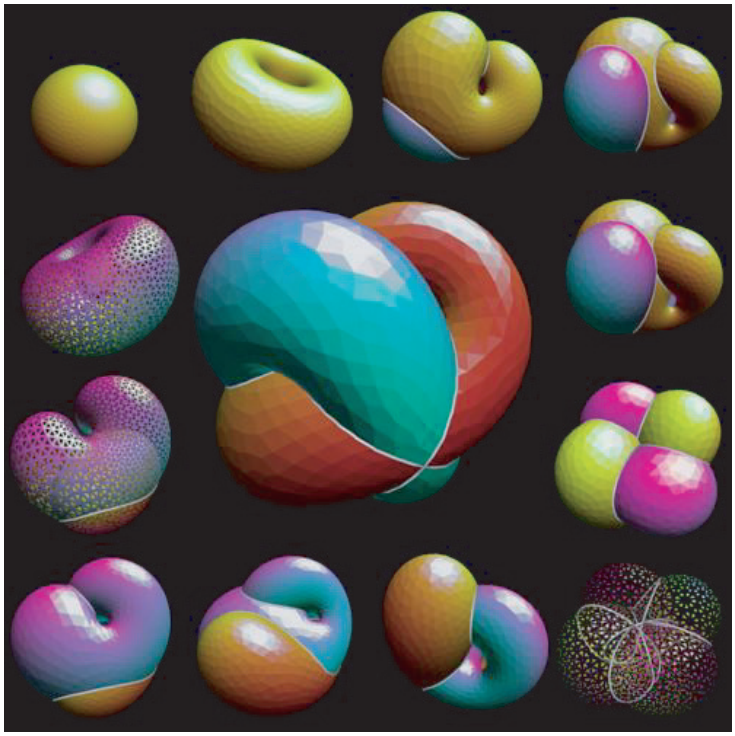

FIGURE 581 A way to turn a sphere inside out, with intermediate steps ordered clockwise (© John Sullivan)

Turning a sphere inside out

> A text should be like a lady's dress; long enough to cover the subject, yet short enough to keep it interesting.

Exploring the theme of motion of wobbly entities, a famous example cannot be avoided. In 1957, the mathematician Stephen Smale proved that a sphere can be turned inside out. Ref. 1142 The discovery brought him the Fields medal in 1966, the highest prize for discoveries in mathematics. Mathematicians call his discovery the *eversion* of the sphere.

To understand the result, we need to describe more clearly the rules of mathematical eversion. First of all, it is assumed that the sphere is made of a thin membrane which has the ability to stretch and bend without limits. Secondly, the membrane is assumed to be able to *intersect* itself. Of course, such a ghostly material does not exist in everyday life; but in mathematics, it can be imagined. A third rule requires that the moves must be performed in such a way that the membrane is not punctured, ripped nor creased; in short, everything must happen *smoothly* (or differentiably, as mathematicians like to say).

Even though Smale proved that eversion is possible, the first way to actually perform it was discovered by the blind topologist Bernard Morin in 1961, based on ideas of Arnold Shapiro. Ref. 1143, Ref. 1144 After him, several additional methods have been discovered.

Several computer videos of sphere eversions are now available.* Ref. 1145 The most famous ones

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

are Outside in, which shows an eversion due to William P. Thurston, and The Optiverse, which shows the most efficient method known so far, discovered by a team led by John Sullivan and shown in Figure 581.

Why is sphere eversion of interest to physicists? If elementary particles were extended and at the same time were of spherical shape, eversion might be a symmetry of particles. To make you think a little, we mention the effects of eversion on the whole surrounding space, not only on the sphere itself. The final effect of eversion is the transformation

$$(x, y, z) \to \frac{(x, y, -z)\, R^2}{r^2} \tag{780}$$

where R is the radius of the sphere and r is the length of the coordinate vector (x, y, z), thus $r = \sqrt{x^2 + y^2 + z^2}$. Due to the minus sign in the z-coordinate, eversion is thus different from inversion, but not by too much. As we will find out shortly, a transformation similar to eversion, space-time duality, is a fundamental symmetry of nature.

Page 1445

Clouds

Clouds are another important class of wobbly objects. The lack of a definite boundary makes them even more fascinating than amoebas, bacteria or falling cats. We can observe the varieties of clouds from an aeroplane.

Page 776

The common cumulus or cumulonimbus in the sky, like all the other types, are vapour and water droplet clouds. Galaxies are clouds of stars. Stars are clouds of plasma. The atmosphere is a gas cloud. Atoms are clouds of electrons. Nuclei are clouds of protons and neutrons, which in turn are clouds of quarks. Comparing different cloud types is illuminating and fun.

Clouds of all types can be described by a shape and a size, even though in theory they have no bound. An *effective* shape and size can be defined by that region in which the cloud density is only, say, 1 % of the maximum density; slightly different procedures can also be used. All clouds are described by *probability densities* of the components making up the cloud. All clouds show *conservation* of the number of their constituents.

Whenever we see a cloud, we can ask why it does not collapse. Every cloud is an aggregate; all aggregates are kept from collapse in only *three* ways: through rotation, through pressure, or through the Pauli principle, i.e., the quantum of action. For example, galaxies are kept from collapsing by rotation. Most stars, the atmosphere and rain clouds are kept from collapsing by gas pressure. Neutron stars, the Earth, atomic nuclei, protons or the electron clouds of atoms are kept apart by the quantum of action.

Page 202

A rain cloud is a method to keep several thousand tons of water suspended in the air. Can you explain what keeps it afloat, and what else keeps it from continuously diffusing into a thinner and thinner structure?

Challenge 1598 ny

Two rain clouds can merge. So can two atomic electron clouds. So can galaxies. But

* Summaries of the videos can be seen at the www.geom.umn.edu/docs/outreach/oi website, which also has a good pedagogical introduction. Another simple eversion and explanation is given by Erik de Neve on the www.xs4all.nl/~alife/sphere1.htm website. It is even possible to run the film software at home; see the www.cslub.uwaterloo.ca/~mjmcguff/eversion website. Figure 581 is from the new.math.uiuc.edu/optiverse website.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

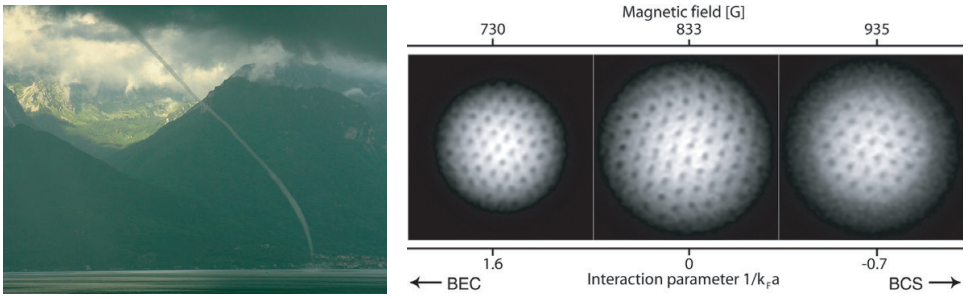

FIGURE 582 Vortices: a waterspout and a vortex lattice in cold Lithium gas (© Zé Nogueira, Andre Schirotzek)

only atomic clouds are able to *cross* each other. We remember that a normal atom can be inside a Rydberg atom and leave it again without change. In contrast, rain clouds, stars, galaxies or other macroscopic clouds cannot cross each other. When their paths cross, they can only merge or be ripped into pieces. Due to this lack of crossing ability, only microscopic clouds can be counted. In the macroscopic cases, there is no real way to define a 'single' cloud in an accurate way. If we aim for full precision, we are unable to claim that there is more than one rain cloud, as there is no clear-cut boundary between them. Electronic clouds are different. True, in a piece of solid matter we can argue that there is only a single electronic cloud throughout the object; however, when the object is divided, the cloud is divided in a way that makes the original atomic clouds reappear. We thus can speak of 'single' electronic clouds.

If one wants to be strict, galaxies, stars and rain clouds can be seen as made of localized particles. Their cloudiness is only apparent. Could the same be true for electron clouds? And what about space itself? Let us explore some aspects of these questions.

Vortices and the Schrödinger equation

Fluid dynamics is a topic with many interesting aspects. Take the *vortex* that can be observed in any deep, emptying bath tub: it is an extended, one-dimensional 'object', it is deformable, and it is observed to wriggle around. Larger vortices appear as tornadoes on Earth and on other planets, as *waterspouts*, and at the ends of wings or propellers of all kinds. Smaller vortices appear in superfluids. Some examples are shown in Figure 582.

Vortices, also called *vortex tubes* or *vortex filaments*, are thus wobbly entities. Now, a beautiful result from the 1960s states that a vortex filament in a rotating liquid is described by the one-dimensional Schrödinger equation. Let us see how this is possible.

Ref. 1146

Any deformable linear vortex, as illustrated in Figure 583, is described by a continuous set of position vectors $\boldsymbol{r}(t, s)$ that depend on time t and on a single parameter s. The parameter s specifies the relative position along the vortex. At each point on the vortex, there is a unit tangent vector $\boldsymbol{e}(t, s)$, a unit normal curvature vector $\boldsymbol{n}(t, s)$ and a unit

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

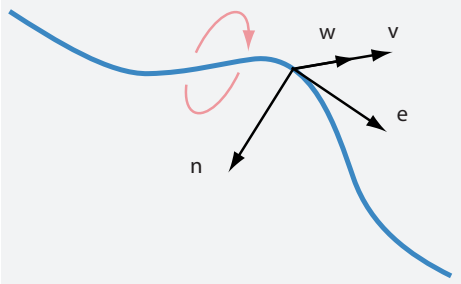

FIGURE 583 The mutually perpendicular tangent $\boldsymbol{e}$, normal $\boldsymbol{n}$, torsion $\boldsymbol{w}$ and velocity $\boldsymbol{v}$ of a vortex in a rotating fluid

torsion vector $\boldsymbol{w}(t, s)$. The three vectors, shown in Figure 583, are defined as usual as

$$\begin{aligned} \boldsymbol{e} &= \frac{\partial \boldsymbol{r}}{\partial s} \,, \\ \kappa \boldsymbol{n} &= \frac{\partial \boldsymbol{e}}{\partial s} \,, \\ \tau \boldsymbol{w} &= -\frac{\partial(\boldsymbol{e} \times \boldsymbol{n})}{\partial s} \,, \end{aligned} \tag{781}$$

where κ specifies the value of the curvature and τ specifies the value of the torsion. In general, both numbers depend on time and on the position along the line.

In the simplest possible case the rotating environment induces a local velocity $\boldsymbol{v}$ for the vortex that is proportional to the curvature κ, perpendicular to the tangent vector $\boldsymbol{e}$ and perpendicular to the normal curvature vector $\boldsymbol{n}$:

$$\boldsymbol{v} = \eta \kappa (\boldsymbol{e} \times \boldsymbol{n}) \,, \tag{782}$$

Ref. 1146 where η is the so-called *coefficient of local self-induction* that describes the coupling between the liquid and the vortex motion. This is the evolution equation of the vortex.

We now assume that the vortex is deformed only *slightly* from the straight configuration. Technically, we are thus in the *linear* regime. For such a linear vortex, directed along the x-axis, we can write

$$\boldsymbol{r} = (x, y(x, t), z(x, t)) \,. \tag{783}$$

Slight deformations imply $\partial s \approx \partial x$ and therefore

$$\begin{aligned} \boldsymbol{e} &= (1, \frac{\partial y}{\partial x}, \frac{\partial z}{\partial x}) \approx (1, 0, 0) \,, \\ \kappa \boldsymbol{n} &\approx (0, \frac{\partial^2 y}{\partial x^2}, \frac{\partial^2 z}{\partial x^2}) \,, \text{ and} \\ \boldsymbol{v} &= (0, \frac{\partial y}{\partial t}, \frac{\partial z}{\partial t}) \,. \end{aligned} \tag{784}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

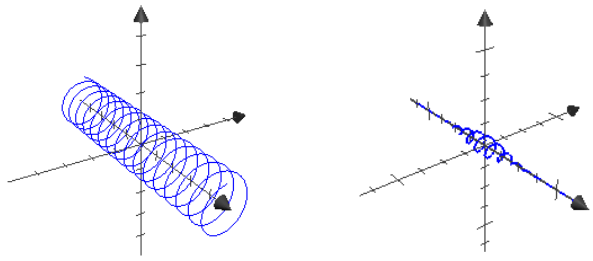

FIGURE 584 Motion of a vortex: the fundamental helical solution and a moving helical 'wave packet'

We can thus rewrite the evolution equation (782) as

$$(0, \frac{\partial y}{\partial t}, \frac{\partial z}{\partial t}) = \eta\,(0, -\frac{\partial^2 z}{\partial x^2}, \frac{\partial^2 y}{\partial x^2})\ . \tag{785}$$

This equation is well known; if we drop the first coordinate and introduce complex numbers by setting $\Phi = y + iz$, we can rewrite it as

$$\frac{\partial \Phi}{\partial t} = i\eta \frac{\partial^2 \Phi}{\partial x^2}\ . \tag{786}$$

This is the one-dimensional Schrödinger equation for the evolution of a free wave function! The complex function Φ specifies the transverse deformation of the vortex. In other words, we can say that the Schrödinger equation in one dimension describes the evolution of the deformation for an almost linear vortex in a rotating liquid. We note that there is no constant $\hbar$ in the equation, as we are exploring a *classical* system.

Ref. 1147

Schrödinger's equation is linear in Φ. Therefore the fundamental solution is

$$\Phi(x, y, z, t) = a\ \mathrm{e}^{i(\tau x - \omega t)} \quad \text{with} \quad \omega = \eta\tau^2 \quad \text{and} \quad \kappa = a\tau^2\ , \tag{787}$$

The amplitude a and the wavelength or pitch $b = 1/\tau$ can be freely chosen, as long as the approximation of small deviation is fulfilled; this condition translates as $a \ll b$.* In the present interpretation, the fundamental solution corresponds to a vortex line that is deformed into a *helix*, as shown in Figure 584. The angular speed ω is the rotation speed around the axis of the helix.

Challenge 1599 ny

A helix moves along the axis with a speed given by

* The curvature is given by $\kappa = a/b^2$, the torsion by $\tau = 1/b$. Instead of $a \ll b$ one can thus also write $\kappa \ll \tau$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$v_{\text{helix along axis}} = 2\eta\tau \,. \tag{788}$$

In other words, for extended entities following evolution equation (782), rotation and translation are coupled.* The momentum p can be defined using $\partial\Phi/\partial x$, leading to

$$p = \tau = \frac{1}{b} \,. \tag{789}$$

Momentum is thus inversely proportional to the helix wavelength or pitch, as expected. The energy E is defined using $\partial\Phi/\partial t$, leading to

$$E = \eta\tau^2 = \frac{\eta}{b^2} \,. \tag{790}$$

Energy and momentum are connected by

$$E = \frac{p^2}{2\mu} \quad \text{where} \quad \mu = \frac{1}{2\eta} \,. \tag{791}$$

In other words, a vortex with a coefficient η – describing the coupling between environment and vortex – is thus described by a number μ that behaves like an effective mass. We can also define the (real) quantity $|\Phi| = a$; it describes the *amplitude* of the deformation.

Page 1317

In the Schrödinger equation (786), the second derivative implies that the deformation 'wave packet' has tendency to spread out over space. Can you confirm that the wavelength–frequency relation for a vortex wave group leads to something like the indeterminacy relation (however, without a $\hbar$ appearing explicitly)?

Challenge 1601 ny

In summary, the complex amplitude Φ for a linear vortex in a rotating liquid behaves like the one-dimensional wave function of a non-relativistic free particle. In addition, we found a suggestion for the reason that complex numbers appear in the Schrödinger equation of quantum theory: they could be due to the intrinsic rotation of an underlying substrate. Is this suggestion correct? We will find out in the last part of our adventure.

Fluid space-time

General relativity shows that space can move and oscillate: space is a wobbly entity. Is space more similar to clouds, to fluids, or to solids?

Ref. 1148

An intriguing approach to space-time as a fluid was published in 1995 by Ted Jacobson. He explored what happens if space-time, instead of assumed to be continuous, is assumed to be the statistical average of numerous components moving in a disordered fashion.

Page 505

The standard description of general relativity describes space-time as an entity similar to a flexible mattress. Jacobson studied what happens if the mattress is assumed to be made of a fluid. A fluid is a collection of (undefined) components moving randomly and described by a temperature varying from place to place.

Page 1193

Jacobson started from the Fulling–Davies–Unruh effect and assumed that the local

Challenge 1600 ny

* A wave packet moves along the axis with a speed given by $v_{\text{packet}} = 2\eta\tau_0$, where τ_0 is the torsion of the helix of central wavelength.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

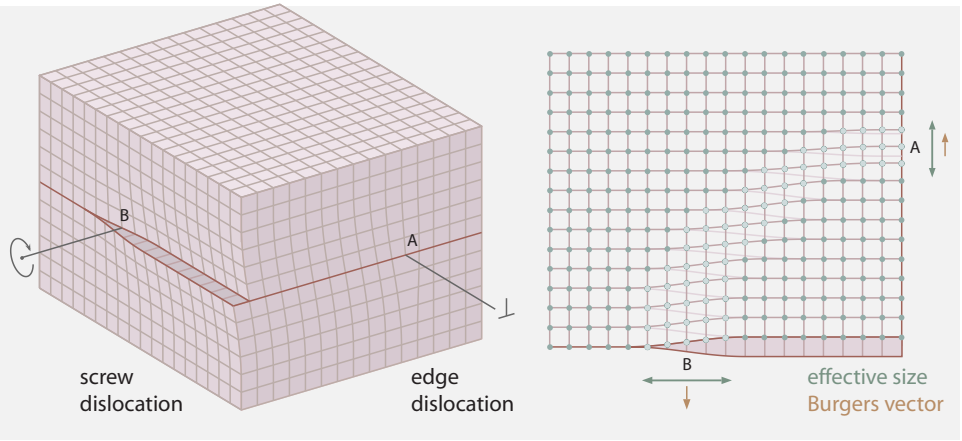

FIGURE 585 The two pure dislocation types, edge and screw dislocations, seen from the outside of a cubic crystal (left) and the mixed dislocation – a quarter of a dislocation loop – joining them in a horizontal section of the same crystal (right) (© Ulrich Kolberg)

fluid temperature is given by a multiple of the local gravitational acceleration. He also used the proportionality – correct on horizons – between area and entropy. Since the energy flowing through a horizon can be called heat, one can thus translate the expression $\delta Q = T\delta S$ into the expression $\delta E = a\delta A(c^2/4G)$, which describes the behaviour of space-time at horizons. As we have seen, this expression is fully equivalent to general relativity.

Page 1462

In other words, imagining space-time as a fluid is a powerful analogy that allows to deduce general relativity. Does this mean that space-time actually *is* similar to a fluid? So far, the analogy is not sufficient to answer the question and we have to wait for the last part of our adventure to settle it. In fact, just to confuse us a bit more, there is an old argument for the opposite statement.

Dislocations and solid space-time

General relativity tells us that space behaves like a deformable mattress; space thus behaves like a solid. There is a second argument that underlines this point and that exerts a continuing fascination. This argument is connected to a famous property of the motion of dislocations.

Dislocations are one-dimensional construction faults in crystals, as shown in Figure 585. A general dislocation is a mixture of the two pure dislocation types: *edge dislocations* and *screw dislocations*. Both are shown in Figure 585.

If one explores how the atoms involved in dislocations can rearrange themselves, one finds that edge dislocations can only move perpendicularly to the added plane. In contrast, screw dislocations can move in all directions.* An important case of general, mixed dislocations, i.e., of mixtures of edge and screw dislocations, are closed *dislocation rings*.

Challenge 1602 e

* See the uet.edu.pk/dmems/edge_dislocation.htm, uet.edu.pk/dmems/screw_dislocation.htm and uet.edu.pk/dmems/mixed_dislocation.htm web pages to watch a moving dislocation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

On such a dislocation ring, the degree of mixture changes continuously from place to place.

Any dislocation is described by its *strength* and by its effective *size*; they are shown, respectively, in red and blue in Figure 585. The strength of a dislocation is measured by the so-called *Burgers vector*; it measures the misfits of the crystal around the dislocation. More precisely, the Burgers vector specifies by how much a section of perfect crystal needs to be displaced, after it has been cut open, to produce the dislocation. Obviously, the strength of a dislocation is quantized in multiples of a minimal Burgers vector. In fact, dislocations with large Burgers vectors can be seen as composed of dislocations of minimal Burgers vector, so that one usually studies only the latter.

The size or *width* of a dislocation is measured by an *effective width* w. Also the width is a multiple of the lattice vector. The width measures the size of the deformed region of the crystal around the dislocation. Obviously, the size of the dislocation depends on the elastic properties of the crystal, can take continuous values and is direction-dependent. The width is thus related to the energy content of a dislocation.

A general dislocation can move, though only in directions which are both perpendicular to its own orientation and to its Burgers vector. Screw dislocations are simpler: they can move in any direction. Now, the motion of screw dislocations has a peculiar property. We call c the speed of sound in a pure (say, cubic) crystal. As Frenkel and Kontorowa found in 1938, when a screw dislocation moves with velocity v, its width w changes as

Ref. 1149

$$w = \frac{w_0}{\sqrt{1 - v^2/c^2}} \,. \tag{792}$$

In addition, the energy of the moving dislocation obeys

$$E = \frac{E_0}{\sqrt{1 - v^2/c^2}} \,. \tag{793}$$

A screw dislocation thus cannot move faster than the speed of sound c in a crystal and its width shows a speed-dependent contraction. (Edge dislocations have similar, but more complex behaviour.) The motion of screw dislocations in solids is thus described by the same effects and formulae that describe the motion of bodies in special relativity; the speed of sound is the limit speed for dislocations in the same way that the speed of light is the limit speed for objects.

Does this mean that elementary particles are dislocations of space or even of space-time, maybe even dislocation rings? The speculation is appealing, even though it supposes that space-time is a solid crystal, and thus contradicts the model of space or space-time as a fluid. Worse, we will soon encounter other reasons to reject modelling space-time as a lattice; maybe you can find a few arguments already by yourself. Still, expressions (792) and (793) for dislocations continue to fascinate.

Page 1410

Challenge 1603 s

At this point, we are confused. Space-time seems to be solid and liquid at the same time. Despite this contrast, the discussion somehow gives the impression that there is something waiting to be discovered. But what? We will find out in the last part of our adventure.

Polymers

Ref. 1150 The study of polymers is both economically important and theoretically fascinating. Polymers are materials built of long and flexible macromolecules that are sequences of many ('poly' in Greek) similar monomers. These macromolecules are thus wobbly entities.

Polymers form *solids*, like rubber or plexiglas, *melts*, like those used to cure teeth, and many kinds of *solutions*, like glues, paints, eggs, or people. Polymer gases are of lesser importance.

All the material properties of polymers, such as their elasticity, their viscosity, their electric conductivity or their unsharp melting point, depend on the number of monomers and the topology of their constituent molecules. In many cases, this dependence can be calculated. Let us explore an example.

If L is the contour length of a free, ideal, unbranched polymer molecule, the *average* end-to-end distance R is proportional to the square root of the length L:

$$R = \sqrt{Ll} \sim \sqrt{L} \quad \text{or} \quad R \sim \sqrt{N} \tag{794}$$

where N is the number of monomers and l is an effective monomer length describing the scale at which the polymer molecule is effectively stiff. R is usually much smaller than L; this means that free, ideal polymer molecules are usually in a *coiled* state.

Obviously, the end-to-end distance R varies from molecule to molecule, and follows a Gaussian distribution for the probability P of a end-to-end distance R:

$$P(R) \sim \mathrm{e}^{\frac{-3R^2}{2Nl^2}} \,. \tag{795}$$

The average end-to-end distance mentioned above is the root-mean-square of this distribution. Non-ideal polymers are polymers which have, like non-ideal gases, interactions with neighbouring molecules or with solvents. In practice, polymers follow the ideal behaviour quite rarely: polymers are ideal only in certain solvents and in melts.

If a polymer is *stretched*, the molecules must rearrange. This changes their entropy and produces an elastic force f that tries to inhibit the stretching. For an ideal polymer, the force is not due to molecular interactions, but is entropic in nature. Therefore the force can be deduced from the *free energy*

$$F \sim -T \ln P(R) \tag{796}$$

of the polymer: the force is then simply given as $f = \partial F(R)/\partial R$. For an ideal polymer, using its probability distribution, the force turns out to be proportional to the stretched
Challenge 1604 e length. Thus the spring constant k can be introduced, given by

$$k = \frac{f}{R} = \frac{3T}{Ll} \,. \tag{797}$$

We thus deduced a material property, the spring constant k, from the simple idea that polymers are made of long, flexible molecules. The proportionality to temperature T is a result of the entropic nature of the force; the dependence on L shows that longer

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

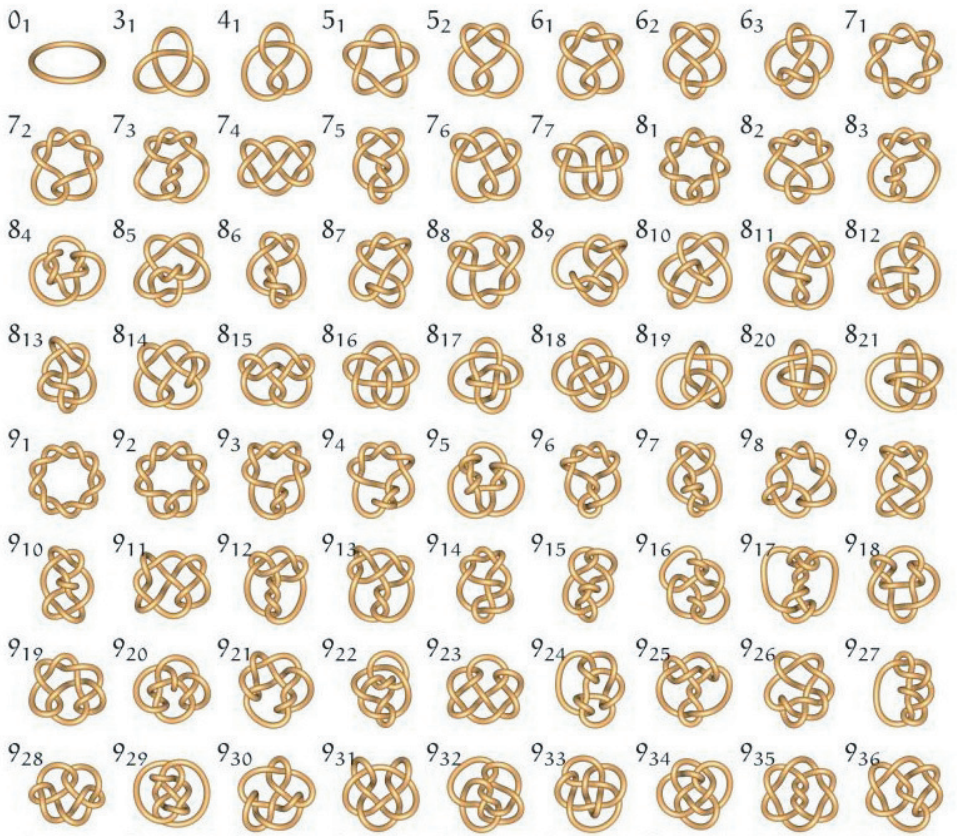

FIGURE 586 The knot diagrams for the simplest prime knots (© Robert Scharein)

molecules are more easy to stretch. For a real, non-ideal polymer, the calculation is more complex, but the procedure is the same. Indeed, this is the mechanism at the basis of the elasticity of rubber.

Using the free energy of polymer conformations, we can calculate the material properties of macromolecules in many other situations, such as their reaction to compression, their volume change in the melt, their interactions in solutions, the effect of branched molecules, etc. This is a vast field of knowledge on its own, which we do not pursue here. Modern research topics include the study of knotted polymers and the study of polymer mixtures. Extensive computer calculations and experiments are regularly compared.

Knots and links

> Don't touch this, or I shall tie your fingers into knots!
>
> (Surprisingly efficient child education technique.)

Knots and their generalization are central to the study of wobbly object motion. A *(mathematical) knot* is a closed piece of rubber string, i.e., a string whose ends have been glued together, which cannot be deformed into a circle or a simple loop. The simple loop is also called the *trivial knot*.

Knots are of importance in the context of this chapter as they visualize the limitations of the motion of wobbly entities. In addition, we will discover other reasons to study knots later on. In this section, we just have a bit of fun.* Ref. 1151

In 1949, Schubert proved that every knot can be decomposed in a unique way as sum of prime knots. Knots thus behave similarly to integers. Ref. 1152

If prime knots are ordered by their crossing numbers, as shown in Figure 586, the trivial knot (0_1) is followed by the trefoil knot (3_1) and by the figure-eight knot (4_1). The figure only shows *prime knots*, i.e., knots that cannot be decomposed into two knots that are connected by two parallel strands. In addition, the figure only shows one of the often possible two mirror versions.

Together with the search for invariants, the tabulation of knots is a modern mathematical sport. Flat knot diagrams are usually ordered by the minimal number of crossings as done in Figure 586. There is 1 knot with zero, 1 with three and 1 with four crossings (not counting mirror knots); there are 2 knots with five and 3 with six crossings, 7 knots with seven, 21 knots with eight, 41 with nine, 165 with ten, 552 with eleven, 2176 with twelve, 9988 with thirteen, 46 972 with fourteen, 253 293 with fifteen and 1 388 705 knots with sixteen crossings. Ref. 1152

The mirror image of a knot usually, but not always, is different from the original. If you want a challenge, try to show that the trefoil knot, the knot with three crossings, is different from its mirror image. The first mathematical proof was by Max Dehn in 1914.

Antiknots do not exist. An *antiknot* would be a knot on a rope that cancels out the corresponding knot when the two are made to meet along the rope. It is easy to prove that this is impossible. We take an infinite sequence of knots and antiknots on a string, $K - K + K - K + K - K \ldots$. On one hand, we could make them disappear in this way $K-K+K-K+K-K\ldots = (K-K)+(K-K)+(K-K)\ldots = 0$. On the other hand, we could do the same thing using $K-K+K-K+K-K\ldots = K(-K+K)+(-K+K)+(-K+K)\ldots = K$. The only knot K with an antiknot is thus the unknot $K = 0$.** Ref. 1154

How do we describe such a knot through the telephone? Mathematicians have spent a lot of time to figure out smart ways to achieve it. The obvious way is to flatten the knot onto a plane and to list the position and the type (below or above) of the crossings. But what is the *simplest* way to describe knots by the telephone? The task is not completely finished, but the end is in sight. Mathematicians do not talk about 'telephone messages',

* Beautiful illustrations and detailed information about knots can be found on the Knot Atlas website at katlas.math.toronto.edu and at the KnotPlot website at www.knotplot.com.

** This proof does *not* work when performed with numbers; we would be able to deduce $1 = 0$ by setting K=1. Why is this proof valid with knots but not with numbers? Challenge 1605 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

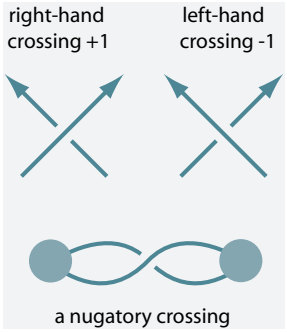

FIGURE 587 Crossing types in knots

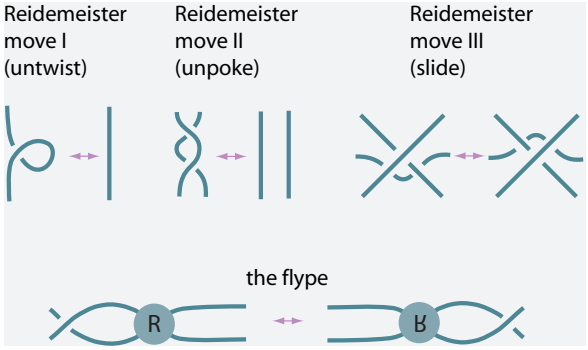

FIGURE 588 The Reidemeister moves and the flype

they talk about *knot invariants*, i.e., about quantities that do not depend on the precise shape of the knot. At present, the best description of knots use polynomial invariants. Most of them are based on a discovery by Vaughan Jones in 1984. However, though the Jones polynomial allows to uniquely describe most simple knots, it fails to do so for more complex ones. But the Jones polynomial finally allowed to prove that a diagram which is alternating and eliminates nugatory crossings (i.e. if it is 'reduced') is indeed one which has minimal number of crossings. The polynomial also allows to show that any two reduced alternating diagrams are related by a sequence of flypes.

– CS – More on knot polynomials and moves will be included here – CS –

In short, the simplest way to describe a knot through the telephone is to give its Kauffman polynomial, together with a few other polynomials.

Since knots are stable in time, a knotted line in three dimensions is equivalent to a knotted surface in space-time. When thinking in higher dimensions, we need to be careful. Every knot (or knotted line) can be untied in four or more dimensions. However, there is no surface *embedded* in four dimensions which has as $t = 0$ slice a knot, and as $t = 1$ slice the circle. Such a surface embedding needs at least five dimensions.

In higher dimensions, knots are thus possible *only* if n-spheres are tied instead of circles; for example, as just said, 2-spheres can be tied into knots in 4 dimensions, 3-spheres in 5 dimensions and so forth.

The hardest open problems that you can tell your grandmother

Even though mathematicians have achieved good progress in the classification of knots, surprisingly, they know next to nothing about the *shapes* of knots. Here are a few problems that are still open today:

— Take a piece of rope, and tie a knot into it. Pull the rope as tight as possible. By how many diameters did the ends of the rope come closer? Mathematicians call this the *ropelength* of an open knot (or of a long knot). Of course, there are computer approxi-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

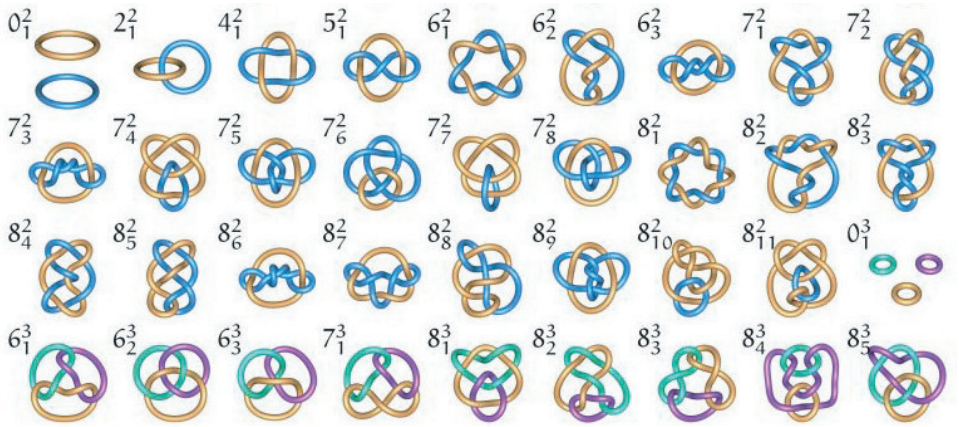

FIGURE 589 The diagrams for the simplest links with two and three components (© Robert Scharein)

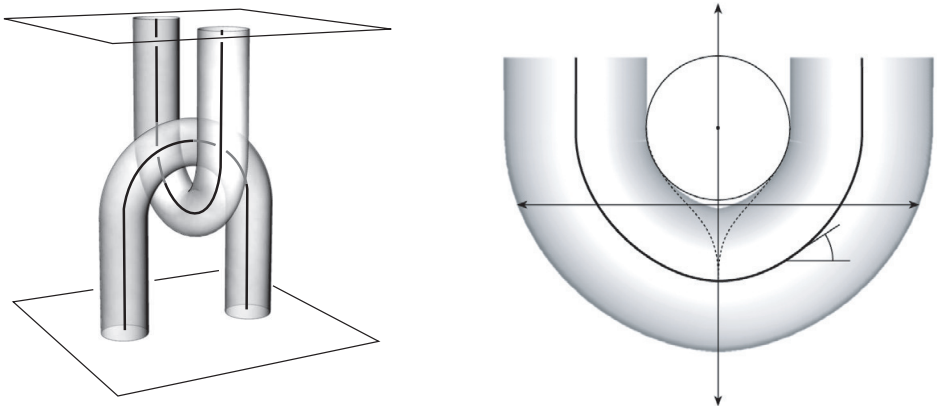

FIGURE 590 The ropelength problem for the simple clasp, and the candidate configuration that probably minimizes ropelenth, leaving a gap between the two ropes (© Jason Cantarella)

Ref. 1155, Ref. 1156

mations for the value – though only a few. The ropelength for the open granny/trefoil knot is about 10.1 diameters, and for the open figure-eight knot it is around 13.7 diameters. But there *no* formula giving these numbers is known.

— For mathematical knots, i.e., *closed* knots, the problem is equally unsolved. For example: the ropelength of the tight trefoil knot is known to be around 16.37 diameters, and that of the figure-eight knot about 21.04 diameters. For beautiful visualizations of the tightening process, see the animations on the website www.jasoncantarella.com/movs. But what is the formula giving the ropelength values? Nobody knows, because the precise shape of the trefoil knot – or of any other knot – is unknown. Lou Kauffman has a simple comment for the situation: 'It is a scandal of mathematics!'

Ref. 1156

— Mathematicians also study more general structures than knots. *Links* are the generalization of knots to several closed strands. *Braids* and *long links* are the generalization of links to *open* strands. Now comes the next surprise, illustrated in Figure 590.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Even for two ropes that form a simple *clasp*, i.e., two linked letters 'U', the ropelength problem is unsolved – and there is not even a knot involved! In fact, in 2004, Jason Cantarella and his colleagues have presented a candidate for the shape that minimizes ropelength. Astonishingly, the candidate configuration leaves a small gap between the two ropes, as shown in Figure 590.

Ref. 1157

In short, the shape of knots is a research topic that has barely taken off. Therefore we have to leave these questions for a future occasion.

Curiosities and fun challenges on knots and wobbly entities

> Any pair of shoes proves that we live on the inside of a sphere. Their soles are worn out at the ends, and hardly at all in between.
>
> Anonymous

Proteins, the molecules that make up many cell structures, are chains of aminoacids. It seems that very few proteins are knotted, and that most of these form trefoil knots. However, a figure-eight knotted protein has been discovered in 2000 by William Taylor.

Ref. 1158

* *

Knots form also in other polymers. They seem to play a role in the formation of radicals in carbohydrates. Research on knots in polymers is presently in full swing.

* *

This is the simplest unsolved knot problem: Imagine an ideally wobbly rope, that is, a rope that has the same radius everywhere, but whose curvature can be changed as one prefers. Tie a trefoil knot into the rope. By how much do the ends of the rope get nearer? In 2006, there are only numerical estimates for the answer: about 10.1 radiuses. There is no formula yielding the number 10.1. Alternatively, solve the following problem: what is the rope length of a closed trefoil knot? Also in this case, only numerical values are known – about 16.33 radiuses – but no exact formula. The same is valid for any other knot, of course.

Challenge 1606 r

* *

A famous type of eel, the *knot fish Myxine glutinosa*, also called hagfish or slime eel, is able to make a knot in his body and move this knot from head to tail. It uses this motion to cover its body with a slime that prevents predators from grabbing it; it also uses this motion to escape the grip of predators, to get rid of the slime after the danger is over, and to push against a prey it is biting in order to extract a piece of meat. All studied knot fish form only left handed trefoil knots, by the way; this is another example of chirality in nature.

Ref. 1159

* *

One of the most incredible discoveries of recent years is related to knots in DNA molecules. The *DNA molecules* inside cell nuclei can be hundreds of millions of base pairs long; they regularly need to be packed and unpacked. When this is done, often the same

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 591 A hagfish tied into a knot (© Christine Ortlepp)

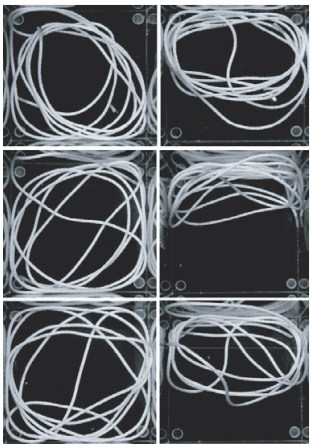

FIGURE 592 How apparent order for long rope coils (left) changes over time when shaking the container (right) (© 2007 PNAS)

happens as when a long piece of rope or a long cable is taken out of a closet.

It is well known that you can roll up a rope and put it into a closet in such a way that it looks orderly stored, but when it is pulled out at one end, a large number of knots is suddenly found. In 2007, this effects was finally explored in detail. Strings of a few metres in length were put into square boxes and shaken, in order to speed up the effect. The result, shown partly in Figure 592, was astonishing: almost every imaginable knot – up to a certain complexity that depends on the length and flexibility of the string – was formed in this way.

Ref. 1160

To make a long story short, this also happens to nature when it unpacks DNA in cell nuclei. Life requires that DNA molecules move inside the cell nucleus without hindrance. So what does nature do? Nature takes a simpler approach: when there are unwanted crossings, it cuts the DNA, moves it over and puts the ends together again. In cell nuclei, there are special enzymes, the so-called topoisomerases, which perform this process. The details of this fascinating process are still object of modern research.

* *

The great mathematician Carl-Friedrich Gauß was the first person to ask what would happen when an electrical current I flows along a wire A linked with a wire B. He discovered a beautiful result by calculating the effect of the magnetic field of one wire onto the other. Gauss found the expression

Ref. 1161

$$\frac{1}{4\pi I}\int_A \mathrm{d}\boldsymbol{x}_A \cdot \boldsymbol{B}_B = \frac{1}{4\pi}\int_A \mathrm{d}\boldsymbol{x}_A \cdot \int_B \mathrm{d}\boldsymbol{x}_B \times \frac{(\boldsymbol{x}_A - \boldsymbol{x}_B)}{|\boldsymbol{x}_A - \boldsymbol{x}_B|^3} = n\,, \tag{798}$$

where the integrals are performed along the wires. Gauss found that the number n does

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

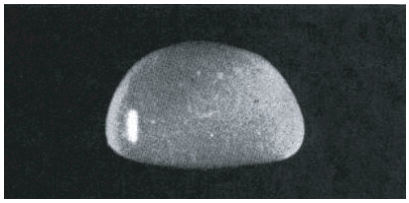

FIGURE 593 A large raindrop falling downwards

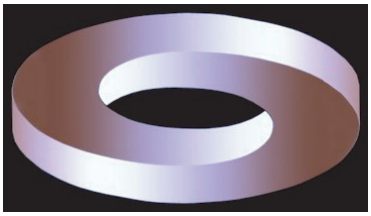

FIGURE 594 Is this possible?

not depend on the precise shape of the wires, but only on the way they are linked. Deforming the wires does not change it. Mathematicians call such a number a *topological invariant*. In short, Gauss discovered a physical method to calculate a mathematical invariant for links; the research race to do the same for other invariants, also for knots and braids, is still going on today.

In the 1980s, Edward Witten was able to generalize this approach to include the nuclear interactions, and to define more elaborate knot invariants, a discovery that brought him the Fields medal.

* *

Knots are also of importance at Planck scales, the smallest dimensions possible in nature. We will soon explore how knots and the structure of elementary particles are related.

* *

Challenge 1607 r

Knots appear rarely in nature. For example, tree roots do not seem to grow many knots during the lifetime of a plant. How do plants avoid this? In other words, why are there no knotted bananas in nature?

* *

Challenge 1608 ny

If we move along the knot and count the crossings where we stay above and subtract the number of crossings where we pass below, we get a number called the *writhe* of the knot. It is not an invariant, but usually a tool in building them. The writhe is not necessarily invariant under one of the three Reidemeister moves. Can you see which one? However, the writhe is invariant under flypes.

* *

Challenge 1609 s

Ref. 1162

What is the shape of raindrops? Try to picture it. However, use your reason, not your prejudice! By the way, it turns out that there is a maximum size for raindrops, with a value of about 4 mm. The shape of such a large raindrop is shown in Figure 593. Can you imagine where the limit comes from?

Page 740

Page 752

For comparison, the drops in clouds, fog or mist are in the range of 1 to 100 μm, with a peak at 10 to 15 μm. In situations where all droplets are of similar size and where light is scattered only once by the droplets, one can observe coronae, glories or fogbows.

* *

* *

Challenge 1611 d Can you find a way to classify tie knots?

* *

Challenge 1612 s Are you able to find a way to classify the way shoe laces can be threaded?

* *

A striking example of how wobbly entities can behave is given in Figure 595. There is indeed a family of snakes that like to jump off a tree and sail through the air to a neighbouring tree. Both the jump and the sailing technique have been studied in recent years. The website www.flyingsnake.org by Jake Socha provides additional films. His fascinating publications tell more about these intriguing reptiles. Ref. 1163

* *

When a plane moves at supersonic speed through humid air, sometimes a conical cloud forms and moves with the plane. How does this cloud differ from the ones studied above? Page 247 Challenge 1613 e

* *

Challenge 1614 ny One of the biggest challenges about clouds: is it possible to make rain on demand? So far, there are almost no positive results. Inventing a method, possibly based on hygroscopic salt injection, will be a great help to mankind.

Summary on wobbly objects

We can sum up the possible motions of extended systems in a few key themes. In earlier chapters we studied the first: waves, solitons and interpenetration. In this chapter we explored the way to move through shape change, explored eversion and duality, studied Page 240

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

polymers, knots and their rearrangement, and looked at the relation between clouds and extension. As an interesting application, we explored some possible analogies for the Schrödinger equation and for space-time.

The motion of wobbly objects is often a neglected topic in textbooks on motion. Research is progressing at full speed; it is expected that many beautiful analogies will be discovered in the near future. For example, in this chapter we have not explored any possible analogy for the motion of light; similarly, including quantum theory into the description of wobbly bodies' motion remains a fascinating issue for anybody aiming to publish in a new field.

Chapter 51

QUANTUM PHYSICS IN A NUTSHELL

Compared to classical physics, quantum theory is remarkably more complex. The basic idea however, is simple: in nature there is a minimum change, or a minimum action, or again, a minimum angular momentum $\hbar/2$. The minimum action leads to all the strange observations made in the microscopic domain, such as wave behaviour of matter, tunnelling, indeterminacy relations, randomness in measurements, quantization of angular momentum, pair creation, decay, indistinguishability and particle reactions.

The essence of quantum theory is thus the lack of the infinitely small. The mathematics of quantum theory is often disturbingly involved. Was this part of our walk worth the effort? It was; the accuracy is excellent and the results profound. We give an overview of both and then turn to the list of questions that are still left open.

Achievements in precision

Quantum theory improved the accuracy of predictions from the few – if any – digits common in classical mechanics to the full number of digits – sometimes thirteen – that can be measured today. The limited precision is usually *not* given by the inaccuracy of theory, it is given by the measurement accuracy. In other words, the agreement is only limited by the amount of money the experimenter is willing to spend. Table 115 shows this in more detail.

TABLE 115 Selected comparisons between classical physics, quantum theory and experiment

Observable	Classical prediction	Prediction of quantum theory[a]	Measurement	Cost[b] estimate
Superconductivity (high T)	none	*none yet*	exists	100 k€

a. All these predictions are calculated from the quantities of Table 116, and no other input. Their most precise experimental values are given in Appendix C.

b. Sometimes the cost for the calculation of the prediction is higher than that of the experimental observation. (Can you spot the examples?) The sum of the two is given.

We notice that the predicted values are not noticeably different from the measured ones. If we remember that classical physics does not allow to calculate any of the predicted values we get an idea of the progress quantum physics has allowed. But despite this impressive agreement, there still are *unexplained* observations. In fact, these unexplained observations provide the input for the calculations just cited; we list them in detail below, in Table 116.

In summary, in the microscopic domain we are left with the impression that quantum theory is in *perfect* correspondence with nature; despite prospects of fame and riches, despite the largest number of researchers ever, no contradiction with observation has been found yet.

Physical results of quantum theory

> Deorum offensae diis curae.
> Voltaire, *Traité sur la tolérance.*

All of quantum theory can be resumed in two sentences.

▷ *In nature, actions smaller than* $\hbar/2 = 0.53 \cdot 10^{-34}$ Js *are not observed.*

▷ *All intrinsic properties in nature – with the exception of mass – such as electric charge, spin, parities, etc., appear as integer numbers; in composed systems they either add or multiply.*

In fact, the second statement results from the first. The existence of a smallest action in nature directly leads to the main lesson we learned about motion in the quantum part of our adventure:

▷ *If it moves, it is made of quantons, or quantum particles.*

This statement applies to everything, thus to all objects and to all images, i.e., to matter and to radiation. Moving stuff is made of *quantons*. Stones, water waves, light, sound waves, earthquakes, gelatine and everything else we can interact with is made of quantum particles. We started the quantum part of our mountain ascent with the title question: what is matter and what are interactions? Now we know: they are composites of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

elementary particles.

To be clear, an *elementary particle* is a countable entity, smaller than its own Compton wavelength, described by energy, momentum, and the following *complete* list of intrinsic properties: mass, spin, electric charge, colour, weak isospin, parity, charge parity, isospin, strangeness, charm, topness, beauty, lepton number and baryon number. Experiments so far failed to detect a non-vanishing size for any elementary particle.

Page 1290

Moving entities are made of quantum particles. To see how deep this result is, you can apply it to all those moving entities for which it is usually forgotten, such as ghosts, spirits, angels, nymphs, daemons, devils, gods, goddesses and souls. You can check yourself what happens when their particle nature is taken into account.

Challenge 1617 e

Quantons, or quantum particles, differ from everyday particles: quantum particles interfere: they behave like a mixture of particles and waves. This property, follows from the existence of $\hbar$, the smallest action in nature. From the existence of a minimum action, quantum theory deduces all its statements about quantum particle motion. We summarize the main ones.

There is *no rest* for microscopic particles. All objects obey the indeterminacy principle, which states that the indeterminacies in position x and momentum p follow

$$\Delta x \Delta p \geqslant \hbar/2 \quad \text{with} \quad \hbar = 1.1 \cdot 10^{-34}\,\text{Js} \tag{799}$$

and making rest an impossibility. The state of particles is defined by the same observables as in classical physics, with the difference that observables do not commute. Classical physics appears in the limit that the Planck constant $\hbar$ can effectively be set to zero.

Quantum theory introduces a *probabilistic element* into motion. It results from the minimum action value through the interactions with the baths in the environment of any system.

Large number of identical particles with the same momentum behave like *waves*. The so-called de Broglie wavelength λ is given by the momentum p of a single particle through

$$\lambda = \frac{h}{p} = \frac{2\pi\hbar}{p} \tag{800}$$

both in the case of matter and of radiation. This relation is the origin of the wave behaviour of light. The light particles are called photons; their observation is now standard practice. All waves interfere, refract and diffract. This applies to electrons, atoms, photons and molecules. All waves being made of particles, all waves can be seen, touched and moved. Light for example, can be 'seen' in photon-photon scattering, can be 'touched' using the Compton effect and it can be 'moved' by gravitational bending. Matter particles, such as molecules or atoms, can be seen, e.g. in electron microscopes, as well as touched and moved, e.g. with atomic force microscopes. The interference and diffraction of wave particles is observed daily in the electron microscope.

Particles cannot be enclosed. Even though matter is impenetrable, quantum theory shows that tight boxes or insurmountable obstacles do not exist. Waiting long enough always allows to overcome boundaries, since there is a finite probability to overcome any obstacle. This process is called *tunnelling* when seen from the spatial point of view and is called *decay* when seen from the temporal point of view. Tunnelling explains the working

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of television tubes as well as radioactive decay.

Particles possess an intrinsic angular momentum called *spin*, specifying their behaviour under rotations. Bosons have integer spin, fermions have half integer spin. An even number of bound fermions or any number of bound bosons yield a composite boson; an odd number of bound fermions or an infinite number of interacting bosons yield a low-energy fermion. Solids are impenetrable because of the fermion character of its electrons in the atoms.

Identical particles are *indistinguishable*. Radiation is made of indistinguishable particles called bosons, matter of fermions. Under exchange, fermions commute at space-like separations, whereas bosons anticommute. All other properties of quantum particles are the same as for classical particles, namely countability, interaction, mass, charge, angular momentum, energy, momentum, position, as well as impenetrability for matter and penetrability for radiation.

In collisions, particles *interact locally*, through the exchange of other particles. When matter particles collide, they interact through the exchange of virtual bosons, i.e., off-shell bosons. Motion change is thus due to particle exchange. Exchange bosons of even spin mediate only attractive interactions. Exchange bosons of odd spin mediate repulsive interactions as well.

Quantum theory defines *elementary* particles as particles smaller than their own Compton wavelength. Experiments so far failed to detect a non-vanishing size or a inner structure for any elementary particle.

The properties of collisions imply the existence of *antiparticles*, as regularly observed in experiments. Elementary fermions, in contrast to many elementary bosons, differ from their antiparticles; they can be created and annihilated only in pairs. Apart from neutrinos, elementary fermions have non-vanishing mass and move slower than light.

Images, made of radiation, are described by the same properties as matter. Images can only be localized with a precision of the wavelength λ of the radiation producing it.

The appearance of Planck's constant $\hbar$ implies that *length scales* and *time scales* exist in nature. Quantum theory introduces a fundamental jitter in every example of motion. Thus the infinitely small is eliminated. In this way, lower limits to structural dimensions and to many other measurable quantities appear. In particular, quantum theory shows that it is impossible that on the electrons in an atom small creatures live in the same way that humans live on the Earth circling the Sun. Quantum theory shows the impossibility of Lilliput.

Clocks and metre bars have *finite precision*, due to the existence of a smallest action and due to their interactions with baths. On the other hand, all measurement apparatuses must contain baths, since otherwise they would not be able to record results.

Ref. 1118 Quantum physics leaves no room for cold fusion, astrology, teleportation, telekinesis, supernatural phenomena, multiple universes, or faster than light phenomena – the EPR paradox notwithstanding.

Results of quantum field theory

Quantum field theory is that part of quantum theory that includes the process of transformation of particles into each other. The possibility of transformation results from the

Page 988 existence of a minimum action and of a maximum speed. Particle transformations have

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

important consequences.

Radioactivity, the working of the sun, the history of the composite matter we are made of is due to particle transformations.

Objects are composed of quantum particles. Quantum field theory provides a complete list of the intrinsic properties which make up what is called an 'object' in everyday life, namely the same which characterize particles. All other properties of objects, such as shape, temperature, (everyday) colour, elasticity, density, magnetism, etc., are merely combinations of the properties from the particle properties. In particular, quantum theory specifies an object, like every system, as a part of nature interacting weakly and incoherently with its environment.

Page 1291

Composite matter is separable because of the finite interaction energies of the constituents. Atoms are made of a nucleus made of quarks surrounded by electrons. Their interactions provide an effective minimal length scale to all everyday matter.

Elementary particles have the same properties as either objects or images, except divisibility. The elementary fermions (objects) are: the six leptons electron, muon, tau, each with its corresponding neutrino, and the six quarks. The elementary bosons (images) are the photon, the eight gluons and the two weak interaction bosons.

Page 1290

Quantum electrodynamics is the quantum field description of electromagnetism. Like all the other interactions, its Lagrangian is determined by the gauge group, the requirements of space-time (Poincaré) symmetry, permutation symmetry and renormalizability. The latter requirement follows from the continuity of space-time. Through the effects of virtual particles, QED describes decay, pair creation, vacuum energy, Unruh radiation for accelerating observers, the Casimir effect, i.e., the attraction of neutral conducting bodies, and the limit for the localization of particles. In fact, an object of mass m can be localized only within intervals of the Compton wavelength

$$\lambda_C = \frac{h}{mc} = \frac{2\pi\hbar}{mc} \,, \tag{801}$$

where c is the speed of light. At the latest at these distances we must abandon the classical description and use quantum field theory. Quantum field theory introduces corrections to classical electrodynamics; among others, the nonlinearities thus appearing produce small departures from the superposition principle for electromagnetic fields, resulting in photon-photon scattering.

Quantum chromodynamics, the field theory of the strong interactions, explains the masses of mesons and baryons through its descriptions as bound quark states. At fundamental scales, the strong interaction is mediated by eight elementary gluons. At femtometre scales, the strong interaction effectively acts through the exchange of spin 0 pions, is strongly attractive, and leads to the formation of atomic nuclei.

Page 1248

The theory of electroweak interactions describes electromagnetism and the weak interactions. It includes the Higgs mechanism, massive Vector bosons, quark mixings and neutrino mixings.

Quantum theory explains the origin of material properties and the origin of the properties of life. Quantum theory, especially the study of the electroweak and the strong forces, has allowed to give a common basis of concepts and descriptions to materials science, nuclear physics, chemistry, biology, medicine and to most of astronomy.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

For example, the same concepts allow to answer questions such as why water is liquid at room temperature, why copper is red, why the rainbow is coloured, why the Sun and the stars continue to shine, why there are about 110 elements, where a tree takes the material to make its wood and why we are able to move our right hand at our own will.

Matter objects are permanent because, in contrast to radiation, matter particles can only disappear when their antiparticles are present. It turns out that in our environment antimatter is almost completely absent, except for the cases of radioactivity and cosmic rays, where it appears in tiny amounts.

The particle description of nature, e.g. particle number conservation, follows from the possibility to describe interactions perturbatively. This is possible only at low and medium energies. At extremely high energies the situation changes and non-perturbative effects come into play.

Is quantum theory magic?

Studying nature is like experiencing magic. Nature often looks different from what it is. During magic we are fooled – but only if we forget our own limitations. Once we start to see ourselves as part of the game, we start to understand the tricks. That is the fun of it. The same happens in physics.

* *

The world looks irreversible, even though it isn't. We never remember the future. We are fooled because we are macroscopic.

* *

The world looks decoherent, even though it isn't. We are fooled again because we are macroscopic.

* *

There are no clocks possible in nature. We are fooled because we are surrounded by a huge number of particles.

* *

Motion seems to disappear, even though it is eternal. We are fooled again, because our senses cannot experience the microscopic domain.

* *

The world seems dependent on the choice of the frame of reference, even though it is not. We are fooled because we are used to live on the surface of the Earth.

* *

Objects seem distinguishable, even though the statistical properties of their components show that they are not. We are fooled because we live at low energies.

* *

Matter looks continuous, even though it isn't. We are fooled because of the limitations of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

our senses.

In short, our human condition permanently fools us. The answer to the title question is affirmative: quantum theory is magic. That is its main attraction.

The dangers of buying a can of beans

Another summary of our walk so far is given by the ultimate product warning, which according to certain well-informed lawyers should be printed on every cans of beans and on every product package. It shows in detail how deeply our human condition fools us.

Ref. 1119

Warning: care should be taken when **looking** at this product:

- It emits heat radiation.
- Bright light has the effect to compress this product.

Warning: care should be taken when **touching** this product:

- Part of it could heat up while another part cools down, causing severe burns.

Warning: care should be taken when **handling** this product:

- This product consists of at least 99.999 999 999 999 % empty space.
- This product contains particles moving with speeds higher than one million kilometres per hour.
- Every kilogram of this product contains the same amount of energy as liberated by about one hundred nuclear bombs.*
- In case this product is brought in contact with antimatter, a catastrophic explosion will occur.
- In case this product is rotated, it will emit gravitational radiation.

Warning: care should be taken when **transporting** this product:

- The force needed depends on its velocity, as does its weight.
- This product will emit additional radiation when accelerated.
- This product attracts, with a force that increases with decreasing distance, every other object around, including its purchaser's kids.

Warning: care should be taken when **storing** this product:

- It is impossible to keep this product in a specific place and at rest at the same time.
- Except when stored underground at a depth of several kilometres, over time cosmic radiation will render this product radioactive.
- This product may disintegrate in the next 10^{35} years.
- It could cool down and lift itself into the air.

* A standard nuclear warhead has an explosive yield of about 0.2 megatons (implied is the standard explosive trinitrotoluene or TNT), about thirteen times the yield of the Hiroshima bomb, which was 15 kilotonne. A megatonne is defined as 1 Pcal=4.2 PJ, even though TNT delivers about 5 % slightly less energy than this value. In other words, a megaton is the energy content of about 47 g of matter. That is less than a handful for most solids or liquids.

Ref. 1120

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

- Parts of this product are hidden in other dimensions.
- This product warps space and time in its vicinity, including the storage container.
- Even if stored in a closed container, this product is influenced and influences all other objects in the universe, including your parents in law.
- This product can disappear from its present location and reappear at any random place in the universe, including your neighbour's garage.

Warning: care should be taken when **travelling away from** this product:

- It will arrive at the expiration date before the purchaser does so.

Warning: care should be taken when **using** this product:

- Any use whatsoever will increase the entropy of the universe.
- The constituents of this product are exactly the same as those of any other object in the universe, including those of rotten fish.
- The use could be disturbed by the (possibly) forthcoming collapse of the universe.

The impression of a certain paranoid side to physics is purely coincidental.

The essence of quantum theory

We can summarize quantum physics with a simple statement: *quantum physics is the description of matter and radiation* without *the concept of infinitely small*. Matter and radiation are described by finite quantities.

We had already eliminated the infinitely large in our exploration of relativity. Quantum theory eliminates the infinitely small from the description of matter and radiation. However, some types of infinities remain. We had to retain the infinitely small in the description of space or time, and in topics related to them, such as renormalization. Therefore, we did not manage to eliminate all infinities yet; we are not yet at the end of our quest. Surprisingly, we shall soon find out that a completely finite description of all of nature is equally impossible. Let us have a look at the path that still remains to be followed.

What is unexplained by quantum theory and general relativity?

The material gathered in this quantum part of our mountain ascent, together with the earlier summary of general relativity, allows us to describe all observed phenomena connected to motion. Therefore, we are also able to provide a complete list of the *unexplained* properties of nature. Whenever we ask 'why?' about an observation and continue doing so after each answer, we arrive at one of the points listed in Table 116.

TABLE 116 *Everything* quantum field theory and general relativity do *not* explain; in other words, a list of *the only* experimental data and criteria available for tests of the unified description of motion

Observable	Property unexplained so far
Local quantities, from quantum theory	
α_{em}	the low energy value of the electromagnetic coupling constant
α_{w}	the low energy value of the weak coupling constant
α_{s}	the value of the strong coupling constant at one specific energy value

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Observable	Property unexplained so far
m_q	the values of the 6 quark masses
m_l	the values of 6 lepton masses
m_W	the value of the mass of the W vector boson
m_H	the value of the mass of the scalar Higgs boson
θ_w	the value of the weak mixing angle
$\theta_{12}, \theta_{13}, \theta_{23}$	the value of the three quark mixing angles
δ	the value of the CP violating phase for quarks
$\theta^\nu_{12}, \theta^\nu_{13}, \theta^\nu_{23}$	the value of the three neutrino mixing angles
$\delta^\nu, \alpha_1, \alpha_2$	the value of the three CP violating phases for neutrinos
3	the number of particle generations
$3+1$	the number of space and time dimensions
Global quantities, from general relativity	
$1.2(1) \cdot 10^{26}$ m (?)	the distance of the horizon, i.e., the 'size' of the universe (if it makes sense)
10^{82} (?)	the number of baryons in the universe (if it makes sense), i.e., the average matter density in the universe
10^{92} (?)	the initial conditions for more than 10^{92} particle fields in the universe (if or as long as they make sense), including those at the origin of galaxies or stars
$\rho_{de} = 0.5\,\mathrm{nJ/m^3}$	the value and nature of the observed vacuum energy density, dark energy or cosmological constant
ρ_{dm}	the nature of dark matter
Local structures, from quantum theory	
$S(n)$	the origin of particle identity, i.e., of permutation symmetry
Ren. group	the renormalization properties, i.e., the existence of point particles
SO(3,1)	the origin of Lorentz (or Poincaré) symmetry (i.e., of spin, position, energy, momentum)
C^*	the origin of the algebra of observables
Gauge group	the origin of gauge symmetry, in particular:
U(1)	the origin of the electromagnetic gauge group (i.e., of the quantization of electric charge, as well as the vanishing of magnetic charge)
SU(2)	the origin of weak interaction gauge group
SU(3)	the origin of strong interaction gauge group
Global structures, from general relativity	
maybe $\mathrm{R} \times \mathrm{S}^3$ (?)	the unknown topology of the universe (if it makes sense)

The table has several notable aspects.* First of all, neither quantum mechanics nor gen-

* Every now and then, researchers provide other lists of open questions. However, they all fall into the list above. The elucidation of dark matter and of dark energy, the details of the big bang, the modifications of general relativity by quantum theory, the mass of neutrinos, the quest for unknown elementary particles such as the inflaton field, magnetic monopoles or others, the functioning of cosmic high-energy particle accelerators, the stability or decay of protons, the origins of the heavy chemical elements, other interactions

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

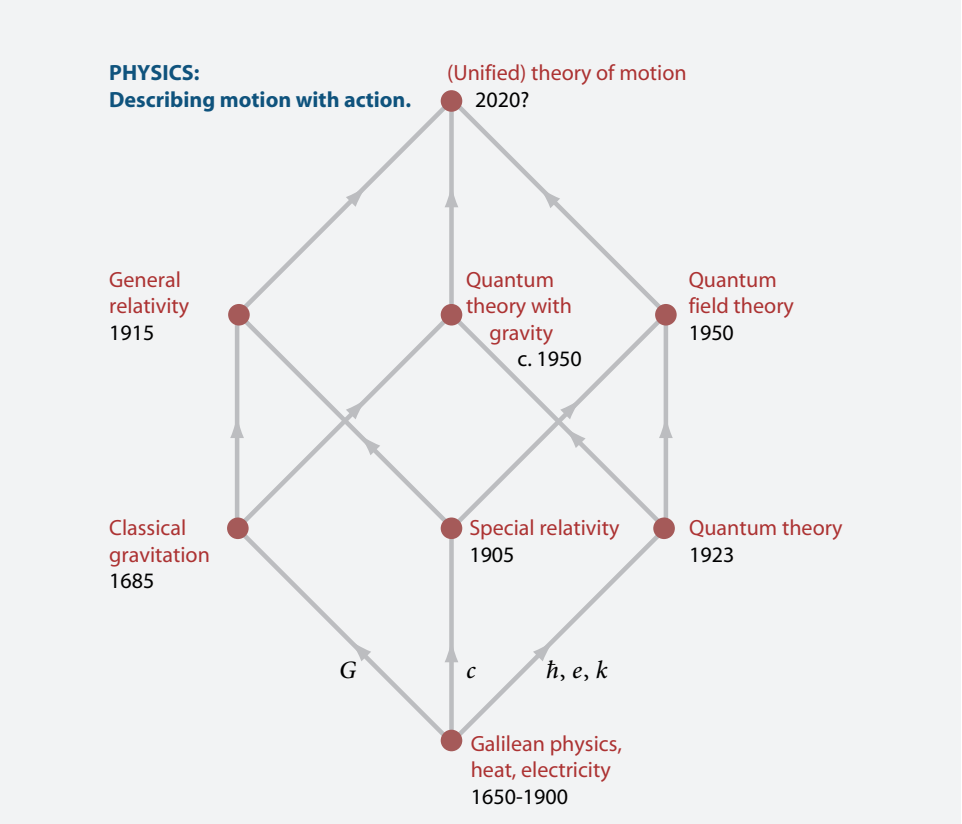

FIGURE 596 A simplified history of the description of motion in physics, by giving the limits to motion included in each description

eral relativity explain any property unexplained in the other field. The two theories do not help each other; the unexplained parts of both fields simply add up. Secondly, both in quantum theory and in general relativity, motion still remains the change of position with time. In short, in the first two parts of this walk we did not achieve our goal: we still do not understand motion. Our basic questions remain: What is time and space? What is mass? What is charge and what are the other properties of objects? What are fields? Why are all the electrons the same?

We also note that Table 116 lists extremely *different* concepts. That means that at this point of our walk there is *a lot* we do not understand. Finding the answers will not be easy, but will require effort.

On the other hand, the list of unexplained properties of nature is also *short*. The description of nature our adventure has produced so far is concise and precise. No discrepancies from experiments are known. In other words, we have a good description of motion *in practice*. Going further is unnecessary if we only want to improve measurement

between matter and radiation or the possibility of higher spatial dimensions are questions that all fall into the table above.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

precision. Simplifying the above list is mainly important from the *conceptual* point of view. For this reason, the study of physics at university often stops at this point. However, as Table 116 shows, even though we have *no* known discrepancies with experiments, we are *not* at the top of Motion Mountain.

Another summary of the progress and open issues of physics, already given in the introduction, is shown in Figure 596. From the lowest corner of a cube, representing Galilean physics and related topics, three edges – labelled c, G and $\hbar$, e, k – lead to classical gravity, special relativity and quantum theory. Each constant implies a limit to motion; in the corresponding theory, this limit is taken into account. From these first level theories, corresponding parallel edges lead to general relativity, quantum field theory and quantum theory in gravity, which take into account two of the limits.* From the second level theories, all edges lead to the last missing corner: the theory of motion. The theory of motion takes into account all limits found so far. Only this theory is a complete or unified description of motion. The important point is that we already know all limits to motion. To arrive at the last point, no new experiments are necessary. No new knowledge is required. We only have to advance in the right direction, with careful thinking. Reaching the final theory of motion is the topic of the last part of our adventure.

How to delude oneself that one has reached the top of Motion Mountain

Nowadays it is deemed chic to pretend that the adventure is over at the stage we have just reached.** The reasoning is as follows. If we change the values of the unexplained constants from Table 116 only ever so slightly, nature would look completely different from what it does. The consequences have been studied in great detail; Table 117 gives an overview of the results. Ref. 1122

TABLE 117 A selection of the consequences of changing the properties of nature

Observable	Change	Result
Local quantities, from quantum theory		
α_{em}	smaller:	only short lived, smaller and hotter stars; no Sun
	larger:	darker Sun, animals die of electromagnetic radiation, too much proton decay, no planets, no stellar explosions, no star formation, no galaxy formation
	+60%:	quarks decay into leptons

* Of course, Figure 596 gives a simplified view of the history of physics. A more precise diagram would use three different arrows for $\hbar$, e and k, making the figure a five-dimensional cube. However, not all of its corners would have dedicated theories (can you confirm this?), and moreover, the diagram would be much less appealing. Challenge 1618 e

** Actually this attitude is not new. Only the arguments have changed. Maybe the greatest physicist ever, James Clerk Maxwell, already fought against this attitude over a hundred years ago: 'The opinion seems to have got abroad that, in a few years, all great physical constants will have been approximately estimated, and that the only occupation which will be left to men of science will be to carry these measurements to another place of decimals. ... The history of science shows that even during that phase of her progress in which she devotes herself to improving the accuracy of the numerical measurement of quantities with which she has long been familiar, she is preparing the materials for the subjugation of new regions, which would have remained unknown if she had been contented with the rough methods of her early pioneers.' Ref. 1121

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Observable	Change	Result
	+200%:	proton-proton repulsion makes nuclei impossible
α_w	−50%:	carbon nucleus unstable
	very weak:	no hydrogen, no p-p cycle in stars, no C-N-O cycle
	+2%:	no protons from quarks
	$G_F m_e^2 \not\ll \sqrt{G m_e^2}$:	either no or only helium in the universe
	much larger:	no stellar explosions, faster stellar burning
α_s	−9%:	no deuteron, stars much less bright
	−1%:	no C resonance, no life
	+3.4%:	diproton stable, faster star burning
	much larger:	carbon unstable, heavy nuclei unstable, widespread leukaemia
n-p mass difference	larger:	neutron decays in proton inside nuclei; no elements
	smaller:	free neutron not unstable, all protons into neutrons during big bang; no elements
	smaller than m_e:	protons would capture electrons, no hydrogen atoms, star life much shorter
m_l changes:		
e-p mass ratio	much different:	no molecules
	much smaller:	no solids
3 generations	6-8:	only helium in nature
	>8:	no asymptotic freedom and confinement
Global quantities, from general relativity		
horizon size	much smaller:	no people
baryon number	very different:	no smoothness
	much higher:	no solar system
Initial condition changes:		
Moon mass	smaller:	small Earth magnetic field; too much cosmic radiation; widespread child skin cancer
Moon mass	larger:	large Earth magnetic field; too little cosmic radiation; no evolution into humans
Sun's mass	smaller:	too cold for the evolution of life
Sun's mass	larger:	Sun too short lived for the evolution of life
Jupiter mass	smaller:	too many comet impacts on Earth; extinction of animal life
Jupiter mass	larger:	too little comet impacts on Earth; no Moon; no dinosaur extinction
Oort cloud object number	smaller:	no comets; no irregular asteroids; no Moon; still dinosaurs

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Observable	Change	Result
galaxy centre distance	smaller:	irregular planet motion; supernova dangers
initial cosmic speed	+0.1%:	1000 times faster universe expansion
	−0.0001%:	universe recollapses after 10 000 years
vacuum energy density	change by 10^{-55}:	no flatness
3 + 1 dimensions	different:	no atoms, no planetary systems
Local structures, from quantum theory		
permutation symmetry	none:	no matter
Lorentz symmetry	none:	no communication possible
U(1)	different:	no Huygens principle, no way to *see* anything
SU(2)	different:	no radioactivity, no Sun, no life
SU(3)	different:	no stable quarks and nuclei
Global structures, from general relativity		
topology	other:	unknown; possibly correlated gamma ray bursts or star images at the antipodes

Some even speculate that the table can be condensed into a single sentence: if any parameter in nature is changed, the universe would either have too many or too few black holes. However, the proof of this condensed summary is not complete yet.

Ref. 1123

Challenge 1619 r

In fact, Table 117, on the effects of changing nature, is overwhelming. Obviously, even the tiniest changes in the properties of nature are incompatible with our existence. What does this mean? Answering this question too rapidly is dangerous. Many fall into a common trap, namely to refuse admitting that the unexplained numbers and other properties need to be explained, i.e., deduced from more general principles. It is easier to throw in some irrational belief. The three most fashionable beliefs are that the universe is *created* or *designed*, that the universe is *designed for people*, or that the values are random, as our universe happens to be *one of many others*.

All these beliefs have in common that they have no factual basis, that they discourage further search and that they sell many books. Physicists call the issue of the first belief *fine tuning*, and usually, but not always, steer clear from the logical errors contained in the so common belief in 'creation' discussed earlier on. However, many physicists subscribe to the second belief, namely that the universe is designed for people, calling it the *anthropic principle*, even though we saw that it is indistinguishable both from the simian principle or from the simple request that statements be based on observations. In 2004, this belief has even become fashionable among older string theorists. The third belief, namely *multiple universes*, is a minority view, but also sells well.

Page 862

Page 868

Stopping our mountain ascent with a belief at the present point is not different from doing so directly at the beginning. Doing so used to be the case in societies which lacked the passion for rational investigation, and still is the case in circles which discourage the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

use of reason among their members. Looking for beliefs instead of looking for answers means to give up the ascent of Motion Mountain while pretending to have reached the top.

That is a pity. In our adventure, accepting the powerful message of Table 117 is one of the most awe-inspiring, touching and motivating moments. There is only one possible implication based on facts: the evidence implies that we are only a *tiny part* of the universe, but *linked* with all other aspects of it. Due to our small size and to all the connections with our environment, any imagined tiny change would make us disappear, like a water droplet is swept away by large wave. Our walk has repeatedly reminded us of this smallness and dependence, and overwhelmingly does so again at this point.

Having faced this powerful experience, everybody has to make up his own mind on whether to proceed with the adventure or not. Of course, there is no obligation to do so. Challenge 1620 s

What awaits us?

The shortness of the list of unexplained aspects of nature means that *no additional experimental data* are available as check of the final description of nature. Everything we need to arrive at the final description of motion will probably be deduced from the experimental data given in this list, and from nothing else. In other words, future experiments will *not* help us – except if they change something in the list, as supersymmetry might do with the gauge groups or astronomical experiments with the topology issue.

This lack of new experimental data means that to continue the walk is a *conceptual* adventure only. We have to walk into storms raging near the top of Motion Mountain, keeping our eyes open, without any other guidance except our reason: this is not an adventure of action, but an adventure of the mind. And it is an incredible one, as we shall soon find out. To provide a feeling of what awaits us, we rephrase the remaining issues in five simple challenges.

1 – What determines *colours*? In other words, what relations of nature fix the famous fine structure constant? Like the hero of Douglas Adams' books, physicists know the answer to the greatest of questions: it is 137.036. But they do not know the question.

2 – What fixes the contents of a *teapot*? It is given by its size to the third power. But why are there only three dimensions? Why is the tea content limited in this way?

3 – Was Democritus *right*? Our adventure has confirmed his statement up to this point; nature is indeed well described by the concepts of particles and of vacuum. At large scales, relativity has added a horizon, and at small scales, quantum theory added vacuum energy and pair creation. Nevertheless, both theories *assume* the existence of particles and the existence of space-time, and neither *predicts* them. Even worse, both theories completely fail to predict the existence of *any* of the properties either of space-time – such as its dimensionality – or of particles – such as their masses and other quantum numbers. A lot is missing.

4 – Was Democritus *wrong*? It is often said that the standard model has only about twenty unknown parameters; this common mistake negates about 10^{93} initial conditions! To get an idea of the problem, we simply estimate the number N of possible states of all particles in the universe by

$$N = n\, v\, d\, p\, f \tag{802}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where n is the number of particles, v is the number of variables (position, momentum, spin), d is the number of different values each of them can take (limited by the maximum of 61 decimal digits), p is the number of visible space-time points (about 10^{183}) and f is a factor expressing how many of all these initial conditions are actually independent of each other. We thus have the following number of possibilities

$$N = 10^{92} \cdot 8 \cdot 10^{61} \cdot 10^{183} \cdot f = 10^{336} \cdot f \tag{803}$$

from which the 10^{93} actual initial conditions have to be explained. There is a small problem that we know nothing whatsoever about f. Its value could be 0, if all data were interdependent, or 1, if none were. Worse, above we noted that initial conditions cannot be defined for the universe at all; thus f should be undefined and not be a number at all! Whatever the case, we need to understand how all the visible particles get their 10^{93} states assigned from this range of options.

Page 1097

Page 317

5 – Were our efforts up to this point *in vain*? Quite at the beginning of our walk we noted that in classical physics, space and time are defined using matter, whereas matter is defined using space-time. Hundred years of general relativity and of quantum theory, including dozens of geniuses, have not solved this oldest paradox of all. The issue is still open at this point of our walk, as you might want to check by yourself.

Challenge 1621 e

The answers to these five questions define the top of Motion Mountain. Answering them means to know *everything* about motion. In summary, our quest for the unravelling of the essence of motion gets really interesting only from this point onwards!

> That is why Leucippus and Democritus, who say that the atoms move always in the void and the unlimited, must say what movement is, and in what their natural motion consists.
>
> Aristotle, *Treaty of the Heaven*

Appendix E

COMPOSITE PARTICLE PROPERTIES

The following table lists the most important composite particles. The list has not changed much recently, mainly because of the vast progress that was achieved in the middle of the twentieth century. In principle, using the standard model of particle physics, together with the fundamental constants, *all* properties of composite matter and radiation can be deduced. In particular, all properties of objects encountered in everyday life follow. (Can you explain how the size of an apple follows from the standard model?) The most important examples of composites are grouped in the following table.

Page 1290
Page 921
Challenge 1622 s

TABLE 118 Properties of selected composites

Composite	Mass m, quantum numbers	Lifetime τ, main decay modes	Size (diam.)
mesons (hadrons, bosons) (selected from over 130 known types)			
pion $\pi^0(u\bar{u} - d\bar{d})/\sqrt{2}$	134.976 4(6) MeV/c^2 $I^G(J^{PC}) = 1^-(0^{-+})$, $S = C = B = 0$	84(6) as, 2γ 98.798(32)%	~ 1 fm
pion $\pi^+(u\bar{d})$	139.569 95(35) MeV/c^2 $I^G(J^P) = 1^-(0^-)$, $S = C = B = 0$	26.030(5) ns, $\mu^+\nu_\mu$ 99.987 7(4)%	~ 1 fm
kaon K^0_S	$m_{K^0_S}$	89.27(9) ps	~ 1 fm
kaon K^0_L	$m_{K^0_S} + 3.491(9)\,\mu\text{eV}/c^2$	51.7(4) ns	~ 1 fm
kaon $K^\pm$ ($us\bar{}$, $\bar{u}s$)	493.677(16) MeV/c^2	12.386(24) ns, $\mu^+\nu_\mu$ 63.51(18)% $\pi^+\pi^0$ 21.16(14)%	~ 1 fm
kaon K^0 (d$\bar{s}$) (50 % K_S, 50 % K_L) all kaons $K^\pm, K^0, K^0_S, K^0_L$	497.672(31) MeV/c^2 $I(J^P) = \frac{1}{2}(0^-)$, $S = \pm 1$, $B = C = 0$	n.a.	~ 1 fm
baryons (hadrons, fermions) (selected from over 100 known types)			
proton p or N^+ (uud)	1.672 621 58(13) yg = 1.007 276 466 88(13) u = 938.271 998(38) MeV/c^2 $I(J^P) = \frac{1}{2}(\frac{1}{2}^+)$, $S = 0$ gyromagnetic ratio $\mu_p/\mu_N = 2.792\,847\,337(29)$	$\tau_{\text{total}} > 1.6 \cdot 10^{25}$ a, $\tau(p \to e^+\pi^0) > 5.5 \cdot 10^{32}$ a	0.89(1) fm Ref. 1166

Composite	Mass m, quantum numbers	Lifetime τ, main decay modes	Size (diam.)
blue whale nerve cell	~ 1 kg	~ 50 a	20 m
cell (red blood)	0.1 ng	7 plus 120 days	~ 10 µm
cell (sperm)	10 pg	not fecundated: ~ 5 d	length 60 µm, head 3 µm×5 µm
cell (ovule)	1 µg	fecundated: over 4000 million years	~ 120 µm
cell (*E. coli*)	1 pg	4000 million years	body: 2 µm
adult human	35 kg < m < 350 kg	$\tau \approx 2.5 \cdot 10^9$ s Ref. 1170 ≈ 600 million breaths ≈ 2 500 million heartbeats < 122 a, 60 % H_2O and 40 % dust	~ 1.7 m
heaviest living thing: colony of aspen trees	$6.6 \cdot 10^6$ kg	> 130 a	> 4 km
larger composites	See the table on page 204.		

Page 1292 Notes (see also those of the previous table):

- G-parity is defined only for mesons and given by $G = (-1)^{L+S+I} = (-1)^I C$.
- Neutrons bound in nuclei have a lifetime of at least 10^{20} years.
- The $f_0(1500)$ resonance is a candidate for the glueball ground state and thus for a *radiation composite*.
- The $Y(3940)$ resonance is a candidate for a hybrid meson, a composite of a gluon and a quark–antiquark pair. This prediction of 1980 seems to have been confirmed in 2005.

Ref. 1171
- In 2002, the first evidence for the existence of tetra-neutrons was published by a French group. However, more recent investigations seem to have refuted the claim.
- The number of existing molecules is several orders of magnitude larger than the number of molecules that have been analysed and named.
- Some nuclei have not yet been observed; in 2006 the known nuclei ranged from 1 to 116, but 113 and 115 were still missing.
- The first *anti-atoms*, made of antielectrons and antiprotons, were made in January 1996 at CERN

Ref. 1172 in Geneva. All properties of antimatter checked so far are consistent with theoretical predictions.

- The charge parity C is defined only for certain neutral particles, namely those that are different from their antiparticles. For neutral mesons, the charge parity is given by $C = (-1)^{L+S}$, where L is the orbital angular momentum.
- P is the parity under space inversion $\boldsymbol{r} \to -\boldsymbol{r}$. For mesons, it is related to the orbital angular momentum L through $P = (-1)^{L+1}$.
- The electric polarizability, defined on page 704, is predicted to vanish for all elementary particles.

The most important matter composites are the *atoms*. Their size, structure and interactions determine the properties and colour of everyday objects. Atom types, also called *ele-*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ments in chemistry, are most usefully set out in the so-called *periodic table*, which groups together atoms with similar properties in rows and columns. It is given in Table 119 and results from the various ways in which protons, neutrons and electrons can combine to form aggregates.

Comparable to the periodic table of the atoms, there are tables for the mesons (made of two quarks) and the baryons (made of three quarks). Neither the meson nor the baryon table is included here; they can both be found in the *Review of Particle Physics* at pdg.web.cern.ch. In fact, the baryon table still has a number of vacant spots. However, the missing particles are extremely heavy and short-lived (which means expensive to make and detect), and their discovery is not expected to yield deep new insights.

TABLE 119 The periodic table of the elements known in 2006, with their atomic numbers

Group	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18

The atomic number gives the number of protons (and electrons) found in an atom of a given element. This number determines the chemical behaviour of an element. Most

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

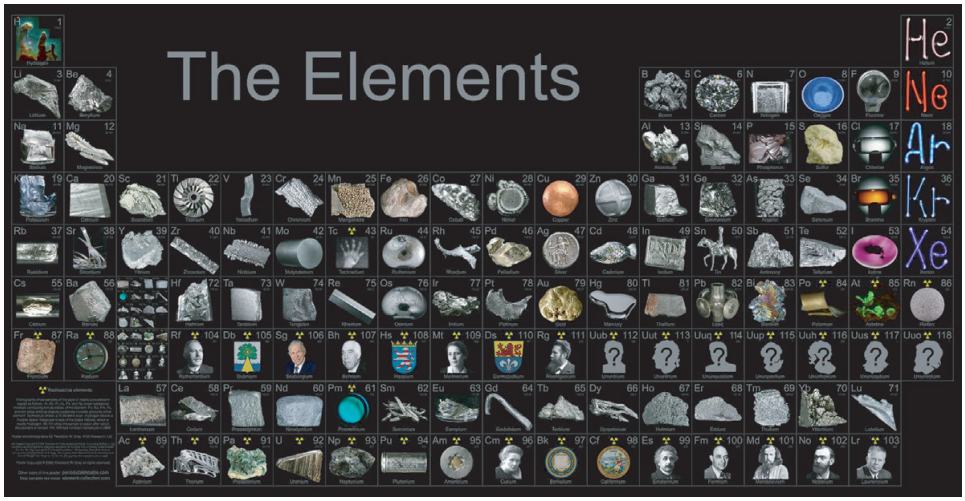

FIGURE 597 A modern table of the elements (© Theodore Gray, for sale at www.theodoregray.com)

– but not all – elements up to 92 are found on Earth; the others can be produced in laboratories. The highest element discovered is element 116. (In a famous case of research fraud, a scientist in the 1990s tricked two whole research groups into claiming to have made and observed elements 116 and 118. Element 116 was independently made and observed by another group later on.) Nowadays, extensive physical and chemical data are available for every element. Photographs of the pure elements are shown in Figure 597.

Ref. 1174

Elements in the same *group* behave similarly in chemical reactions. The *periods* define the repetition of these similarities. More elaborate periodic tables can be found on the chemlab.pc.maricopa.edu/periodic website. The most beautiful of them all can be found on page 1148 of this text.

Group 1 are the alkali metals (though hydrogen is a gas), group 2 the Earth-alkali metals. Actinoids, lanthanoids and groups 3 to 13 are metals; in particular, groups 3 to 12 are transition or heavy metals. The elements of group 16 are called *chalkogens*, i.e., ore-formers; group 17 are the *halogens*, i.e., the salt-formers, and group 18 are the inert *noble gases*, which form (almost) no chemical compounds. The groups 13, 14 and 15 contain metals, semimetals, a liquid and gases; they have no special name. Groups 1 and 13 to 17 are central for the chemistry of life; in fact, 96 % of living matter is made of C, O, N, H;* almost 4 % of P, S, Ca, K, Na, Cl; trace elements such as Mg, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Pb, Sn, Li, Mo, Se, Si, I, F, As, B form the rest. Over 30 elements are known to be essential for animal life. The full list is not yet known; candidate elements to extend this list are Al, Br, Ge and W.

Many elements exist in versions with different numbers of neutrons in their nucleus, and thus with different mass; these various *isotopes* – so called because they are found at the *same place* in the periodic table – behave identically in chemical reactions. There are over 2000 of them.

Ref. 1167, Ref. 1173

* The 'average formula' of life is approximately $C_5H_{40}O_{18}N$.

TABLE 120 The elements, with their atomic number, average mass, atomic radius and main properties

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Actinium[b]	Ac	89	(227.0277(1)) 21.77(2) a	(188)	highly radioactive metallic rare Earth (Greek *aktis* ray) 1899, used as alpha-emitting source
Aluminium	Al	13	26.981 538 (8) stable	118c, 143m	light metal (Latin *alumen* alum) 1827, used in machine construction and living beings
Americium[b]	Am	95	(243.0614(1)) 7.37(2) ka	(184)	radioactive metal (Italian *America* from Amerigo) 1945, used in smoke detectors
Antimony	Sb	51	121.760(1)[f] stable	137c, 159m, 205v	toxic semimetal (via Arabic from Latin *stibium*, itself from Greek, Egyptian for one of its minerals) antiquity, colours rubber, used in medicines, constituent of enzymes
Argon	Ar	18	39.948(1)[f] stable	(71n)	noble gas (Greek *argos* inactive, from *anergos* without energy) 1894, third component of air, used for welding and in lasers
Arsenic	As	33	74.921 60(2) stable	120c, 185v	poisonous semimetal (Greek *arsenikon* tamer of males) antiquity, for poisoning pigeons and doping semiconductors
Astatine[b]	At	85	(209.9871(1)) 8.1(4) h	(140)	radioactive halogen (Greek *astatos* unstable) 1940, no use
Barium	Ba	56	137.327(7) stable	224m	Earth-alkali metal (Greek *bary* heavy) 1808, used in vacuum tubes, paint, oil industry, pyrotechnics and X-ray diagnosis
Berkelium[b]	Bk	97	(247.0703(1)) 1.4(3) ka	n.a.	made in lab, probably metallic (Berkeley, US town) 1949, no use because rare
Beryllium	Be	4	9.012 182(3) stable	106c, 113m	toxic Earth-alkali metal (Greek *beryllos*, a mineral) 1797, used in light alloys, in nuclear industry as moderator
Bismuth	Bi	83	208.980 40(1) stable	170m, 215v	diamagnetic metal (Latin via German *weisse Masse* white mass) 1753, used in magnets, alloys, fire safety, cosmetics, as catalyst, nuclear industry
Bohrium[b]	Bh	107	(264.12(1)) 0.44 s[g]	n.a.	made in lab, probably metallic (after Niels Bohr) 1981, found in nuclear reactions, no use
Boron	B	5	10.811(7)[f] stable	83c	semimetal, semiconductor (Latin *borax*, from Arabic and Persian for brilliant) 1808, used in glass, bleach, pyrotechnics, rocket fuel, medicine

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Bromine	Br	35	79.904(1) stable	120c, 185v	red-brown liquid (Greek *bromos* strong odour) 1826, fumigants, photography, water purification, dyes, medicines
Cadmium	Cd	48	112.411(8)[f] stable	157m	heavy metal, cuttable and screaming (Greek *kadmeia*, a zinc carbonate mineral where it was discovered) 1817, electroplating, solder, batteries, TV phosphors, dyes
Caesium	Cs	55	132.905 4519(2) stable	273m	alkali metal (Latin *caesius* sky blue) 1860, getter in vacuum tubes, photoelectric cells, ion propulsion, atomic clocks
Calcium	Ca	20	40.078(4)[f] stable	197m	Earth-alkali metal (Latin *calcis* chalk) antiquity, pure in 1880, found in stones and bones, reducing agent, alloying
Californium[b]	Cf	98	(251.0796(1)) 0.90(5) ka	n.a.	made in lab, probably metallic, strong neutron emitter (Latin *calor* heat and *fornicare* have sex, the land of hot sex :-) 1950, used as neutron source, for well logging
Carbon	C	6	12.0107(8)[f] stable	77c	makes up coal and diamond (Latin *carbo* coal) antiquity, used to build most life forms
Cerium	Ce	58	140.116(1)[f] stable	183m	rare Earth metal (after asteroid Ceres, Roman goddess) 1803, cigarette lighters, incandescent gas mantles, glass manufacturing, self-cleaning ovens, carbon-arc lighting in the motion picture industry, catalyst, metallurgy
Chlorine	Cl	17	35.453(2)[f] stable	102c, 175v	green gas (Greek *chloros* yellow-green) 1774, drinking water, polymers, paper, dyes, textiles, medicines, insecticides, solvents, paints, rubber
Chromium	Cr	24	51.9961(6) stable	128m	transition metal (Greek *chromos* colour) 1797, hardens steel, makes steel stainless, alloys, electroplating, green glass dye, catalyst
Cobalt	Co	27	58.933 195(5) stable	125m	ferromagnetic transition metal (German *Kobold* goblin) 1694, part of vitamin B_{12}, magnetic alloys, heavy-duty alloys, enamel dyes, ink, animal nutrition

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

NAME	SYMBOL	AT. N.	AVER. MASS[a] IN U (ERROR), LONGEST LIFETIME	ATOMIC[e] RADIUS IN PM	MAIN PROPERTIES, (NAMING)[h] DISCOVERY DATE AND USE
Copper	Cu	29	63.546(3)[f] stable	128m	red metal (Latin *cuprum* from Cyprus island) antiquity, part of many enzymes, electrical conductors, bronze, brass and other alloys, algicides, etc.
Curium[b]	Cm	96	(247.0704(1)) 15.6(5) Ma	n.a.	highly radioactive, silver-coloured (after Pierre and Marie Curie) 1944, used as radioactivity source
Darmstadtium[b]	Ds	110	(271) 1.6 min[g]	n.a.	(after the German city) 1994, no use
Dubnium[b]	Db	105	(262.1141(1)) 34(5) s	n.a.	made in lab in small quantities, radioactive (Dubna, Russian city) 1967, no use (once known as hahnium)
Dysprosium	Dy	66	162.500(1)[f] stable	177m	rare Earth metal (Greek *dysprositos* difficult to obtain) 1886, used in laser materials, as infrared source material, and in nuclear industry
Einsteinium[b]	Es	99	(252.0830(1)) 472(2) d	n.a.	made in lab, radioactive (after Albert Einstein) 1952, no use
Erbium	Er	68	167.259(3)[f] stable	176m	rare Earth metal (Ytterby, Swedish town) 1843, used in metallurgy and optical fibres
Europium	Eu	63	151.964(1)[f] stable	204m	rare Earth metal (named after the continent) 1901, used in red screen phosphor for TV tubes
Fermium[b]	Fm	100	(257.0901(1)) 100.5(2) d	n.a.	(after Enrico Fermi) 1952, no use
Fluorine	F	9	18.998 4032(5) stable	62c, 147v	gaseous halogen (from fluorine, a mineral, from Greek *fluo* flow) 1886, used in polymers and toothpaste
Francium[b]	Fr	87	(223.0197(1)) 22.0(1) min	(278)	radioactive metal (from France) 1939, no use
Gadolinium	Gd	64	157.25(3)[f] stable	180m	(after Johan Gadolin) 1880, used in lasers and phosphors
Gallium	Ga	31	69.723(1) stable	125c, 141m	almost liquid metal (Latin for both the discoverer's name and his nation, France) 1875, used in optoelectronics
Germanium	Ge	32	72.64(1) stable	122c, 195v	semiconductor (from Germania, as opposed to gallium) 1886, used in electronics
Gold	Au	79	196.966 569(4) stable	144m	heavy noble metal (Sanskrit *jval* to shine, Latin aurum) antiquity, electronics, jewels

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Hafnium	Hf	72	178.49(2)[c] stable	158m	metal (Latin for Copenhagen) 1923, alloys, incandescent wire
Hassium[b]	Hs	108	(277) 16.5 min[g]	n.a.	radioactive element (Latin form of German state Hessen) 1984, no use
Helium	He	2	4.002 602(2)[f] stable	(31n)	noble gas (Greek *helios* Sun) where it was discovered 1895, used in balloons, stars, diver's gas and cryogenics
Holmium	Ho	67	164.930 32(2) stable	177m	metal (Stockholm, Swedish capital) 1878, alloys
Hydrogen	H	1	1.007 94(7)[f] stable	30c	reactive gas (Greek for water-former) 1766, used in building stars and universe
Indium	In	49	114.818(3) stable	141c, 166m	soft metal (Greek *indikon* indigo) 1863, used in solders and photocells
Iodine	I	53	126.904 47(3) stable	140c, 198v	blue-black solid (Greek *iodes* violet) 1811, used in photography
Iridium	Ir	77	192.217(3) stable	136m	precious metal (Greek *iris* rainbow) 1804, electrical contact layers
Iron	Fe	26	55.845(2) stable	127m	metal (Indo-European *ayos* metal, Latin ferrum) antiquity, used in metallurgy
Krypton	Kr	36	83.798(2)[f] stable	(88n)	noble gas (Greek *kryptos* hidden) 1898, used in lasers
Lanthanum	La	57	138.905 47(7)[c,f] stable	188m	reactive rare Earth metal (Greek *lanthanein* to be hidden) 1839, used in lamps and in special glasses
Lawrencium[b]	Lr	103	(262.110 97(1)) 3.6(3) h	n.a.	appears in reactions (after Ernest Lawrence) 1961, no use
Lead	Pb	82	207.2(1)[c,f] stable	175m	poisonous, malleable heavy metal (Latin *plumbum*) antiquity, used in car batteries, radioactivity shields, paints
Lithium	Li	3	6.941(2)[f] stable	156m	light alkali metal with high specific heat (Greek *lithos* stone) 1817, used in batteries, anti-depressants, alloys and many chemicals
Lutetium	Lu	71	174.967(1)[f] stable	173m	rare Earth metal (Latin *Lutetia* for Paris) 1907, used as catalyst
Magnesium	Mg	12	24.3050(6) stable	160m	light common alkaline Earth metal (from Magnesia, a Greek district in Thessalia) 1755, used in alloys, pyrotechnics, chemical synthesis and medicine, found in chlorophyll

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Manganese	Mn	25	54.938 045(5) stable	126m	brittle metal (Italian *manganese*, a mineral) 1774, used in alloys, colours amethyst and permanganate
Meitnerium[b]	Mt	109	(268.1388(1)) 0.070 s[g]	n.a.	appears in nuclear reactions (after Lise Meitner) 1982, no use
Mendelevium[b]	Md	101	(258.0984(1)) 51.5(3) d	n.a.	appears in nuclear reactions (after Дмитрии Иванович Менделеев Dmitriy Ivanovich Mendeleyev) 1955, no use
Mercury	Hg	80	200.59(2) stable	157m	liquid heavy metal (Latin god Mercurius, Greek *hydrargyrum* liquid silver) antiquity, used in switches, batteries, lamps, amalgam alloys
Molybdenum	Mo	42	95.94(2)[f] stable	140m	metal (Greek *molybdos* lead) 1788, used in alloys, as catalyst, in enzymes and lubricants
Neodymium	Nd	60	144.242(3)[c,f] stable	182m	(Greek *neos* and *didymos* new twin) 1885
Neon	Ne	10	20.1797(6)[f] stable	(36n)	noble gas (Greek *neos* new) 1898, used in lamps, lasers and cryogenics
Neptunium[b]	Np	93	(237.0482(1)) 2.14(1) Ma	n.a.	radioactive metal (planet Neptune, after Uranus in the solar system) 1940, appears in nuclear reactors, used in neutron detection and by the military
Nickel	Ni	28	58.6934(2) stable	125m	metal (German *Nickel* goblin) 1751, used in coins, stainless steels, batteries, as catalyst
Niobium	Nb	41	92.906 38(2) stable	147m	ductile metal (Greek Niobe, mythical daughter of Tantalos) 1801, used in arc welding, alloys, jewellery, superconductors
Nitrogen	N	7	14.0067(2)[f] stable	70c, 155v	diatomic gas (Greek for nitre-former) 1772, found in air, in living organisms, Viagra, fertilizers, explosives
Nobelium[b]	No	102	(259.1010(1)) 58(5) min	n.a.	(after Alfred Nobel) 1958, no use
Osmium	Os	76	190.23(3)[f] stable	135m	heavy metal (from Greek *osme* odour) 1804, used for fingerprint detection and in very hard alloys

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Oxygen	O	8	15.9994(3)[f] stable	66c, 152v	transparent, diatomic gas (formed from Greek to mean 'acid former') 1774, used for combustion, blood regeneration, to make most rocks and stones, in countless compounds, colours auroras red
Palladium	Pd	46	106.42(1)[f] stable	138m	heavy metal (from asteroid Pallas, after the Greek goddess) 1802, used in alloys, white gold, catalysts, for hydride storage
Phosphorus	P	15	30.973 762(2) stable	109c, 180v	poisonous, waxy, white solid (Greek *phosphoros* light bearer) 1669, fertilizers, glasses, porcelain, steels and alloys, living organisms, bones
Platinum	Pt	78	195.084(9) stable	139m	silvery-white, ductile, noble heavy metal (Spanish *platina* little silver) pre-Columbian, again in 1735, used in corrosion-resistant alloys, magnets, furnaces, catalysts, fuel cells, cathodic protection systems for large ships and pipelines; being a catalyst, a fine platinum wire glows red hot when placed in vapour of methyl alcohol, an effect used in hand warmers
Plutonium	Pu	94	(244.0642(1)) 80.0(9) Ma	n.a.	extremely toxic alpha-emitting metal (after the planet) synthesized 1940, found in nature 1971, used as nuclear explosive, and to power space equipment, such as satellites and the measurement equipment brought to the Moon by the Apollo missions
Polonium	Po	84	(208.9824(1)) 102(5) a	(140)	alpha-emitting, volatile metal (from Poland) 1898, used as thermoelectric power source in space satellites, as neutron source when mixed with beryllium; used in the past to eliminate static charges in factories, and on brushes for removing dust from photographic films
Potassium	K	19	39.0983(1) stable	238m	reactive, cuttable light metal (German *Pottasche*, Latin *kalium* from Arabic *quilyi*, a plant used to produce potash) 1807, part of many salts and rocks, essential for life, used in fertilizers, essential to chemical industry

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

NAME	SYMBOL	AT. N.	AVER. MASS[a] IN U (ERROR), LONGEST LIFETIME	ATOMIC[e] RADIUS IN PM	MAIN PROPERTIES, (NAMING)[h] DISCOVERY DATE AND USE
Praeseodymium	Pr	59	140.907 65(2) stable	183m	white, malleable rare Earth metal (Greek *praesos didymos* green twin) 1885, used in cigarette lighters, material for carbon arcs used by the motion picture industry for studio lighting and projection, glass and enamel dye, darkens welder's goggles
Promethium[b]	Pm	61	(144.9127(1)) 17.7(4) a	181m	radioactive rare Earth metal (from the Greek mythical figure of Prometheus) 1945, used as beta source and to excite phosphors
Protactinium	Pa	91	(231.035 88(2)) 32.5(1) ka	n.a.	radioactive metal (Greek *protos* first, as it decays into actinium) 1917, found in nature, no use
Radium	Ra	88	(226.0254(1)) 1599(4) a	(223)	highly radioactive metal (Latin *radius* ray) 1898, no use any more; once used in luminous paints and as radioactive source and in medicine
Radon	Rn	86	(222.0176(1)) 3.823(4) d	(130n)	radioactive noble gas (from its old name 'radium emanation') 1900, no use (any more), found in soil, produces lung cancer
Rhenium	Re	75	186.207(1)[c] stable	138m	(Latin *rhenus* for Rhine river) 1925, used in filaments for mass spectrographs and ion gauges, superconductors, thermocouples, flash lamps, and as catalyst
Rhodium	Rh	45	102.905 50(2) stable	135m	white metal (Greek *rhodon* rose) 1803, used to harden platinum and palladium alloys, for electroplating, and as catalyst
Roentgenium[b]	Rg	111	(272.1535(1)) 1.5 ms[g]	n.a.	1994, no use
Rubidium	Rb	37	85.4678(3)[f] stable	255m	silvery-white, reactive alkali metal (Latin *rubidus* red) 1861, used in photocells, optical glasses, solid electrolytes
Ruthenium	Ru	44	101.107(2)[f] stable	134m	white metal (Latin *Rhuthenia* for Russia) 1844, used in platinum and palladium alloys, superconductors, as catalyst; the tetroxide is toxic and explosive
Rutherfordium[b]	Rf	104	(261.1088(1)) 1.3 min[g]	n.a.	radioactive transactinide (after Ernest Rutherford) 1964, no use

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Samarium	Sm	62	150.36(2)[c,f] stable	180m	silver-white rare Earth metal (from the mineral samarskite, after Wassily Samarski) 1879, used in magnets, optical glasses, as laser dopant, in phosphors, in high-power light sources
Scandium	Sc	21	44.955 912(6) stable	164m	silver-white metal (from Latin *Scansia* Sweden) 1879, the oxide is used in high-intensity mercury vapour lamps, a radioactive isotope is used as tracer
Seaborgium[b]	Sg	106	266.1219(1) 21 s[g]	n.a.	radioactive transurane (after Glenn Seaborg) 1974, no use
Selenium	Se	34	78.96(3)[f] stable	120c, 190v	red or black or grey semiconductor (Greek *selene* Moon) 1818, used in xerography, glass production, photographic toners, as enamel dye
Silicon	Si	14	28.0855(3)[f] stable	105c, 210v	grey, shiny semiconductor (Latin *silex* pebble) 1823, Earth's crust, electronics, sand, concrete, bricks, glass, polymers, solar cells, essential for life
Silver	Ag	47	107.8682(2)[f] stable	145m	white metal with highest thermal and electrical conductivity (Latin *argentum*, Greek *argyros*) antiquity, used in photography, alloys, to make rain
Sodium	Na	11	22.989 769 28(2) stable	191m	light, reactive metal (Arabic *souwad* soda, Egyptian and Arabic *natrium*) component of many salts, soap, paper, soda, salpeter, borax, and essential for life
Strontium	Sr	38	87.62(1)[f] stable	215m	silvery, spontaneously igniting light metal (Strontian, Scottish town) 1790, used in TV tube glass, in magnets, and in optical materials
Sulphur	S	16	32.065(5)[f] stable	105c, 180v	yellow solid (Latin) antiquity, used in gunpowder, in sulphuric acid, rubber vulcanization, as fungicide in wine production, and is essential for life; some bacteria use sulphur instead of oxygen in their chemistry
Tantalum	Ta	73	180.947 88(2) stable	147m	heavy metal (Greek Tantalos, a mythical figure) 1802, used for alloys, surgical instruments, capacitors, vacuum furnaces, glasses

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Technetium[b]	Tc	43	(97.9072(1)) 6.6(10) Ma	136m	radioactive (Greek *technetos* artificial) 1939, used as radioactive tracer and in nuclear technology
Tellurium	Te	52	127.60(3)[f] stable	139c, 206v	brittle, garlic-smelling semiconductor (Latin *tellus* Earth) 1783, used in alloys and as glass component
Terbium	Tb	65	158.925 35(2) stable	178m	malleable rare Earth metal (Ytterby, Swedish town) 1843, used as dopant in optical material
Thallium	Tl	81	204.3833(2) stable	172m	soft, poisonous heavy metal (Greek *thallos* branch) 1861, used as poison and for infrared detection
Thorium	Th	90	232.038 06(2)[d,f] 14.0(1) Ga	180m	radioactive (Nordic god Thor, as in 'Thursday') 1828, found in nature, heats Earth, used as oxide, in alloys and as coating
Thulium	Tm	69	168.934 21(2) stable	175m	rare Earth metal (Thule, mythical name for Scandinavia) 1879, found in monazite
Tin	Sn	50	118.710(7)[f] stable	139c, 210v, 162m	grey metal that, when bent, allows one to hear the 'tin cry' (Latin *stannum*) antiquity, used in paint, bronze and superconductors
Titanium	Ti	22	47.867(1) stable	146m	metal (Greek hero Titanos) 1791, alloys, fake diamonds
Tungsten	W	74	183.84(1) stable	141m	heavy, highest-melting metal (Swedish *tung sten* heavy stone, German name *Wolfram*) 1783, lightbulbs
Ununbium[b]	Uub	112	(285) 15.4 min[g]	n.a.	1996, no use
Ununtrium	Uut	113		n.a.	2004, no use
Ununquadium[b]	Uuq	114	(289) 30.4 s[g]	n.a.	1999, no use
Ununpentium	Uup	115		n.a.	2004, no use
Ununhexium[b]	Uuh	116	(289) 0.6 ms[g]	n.a.	2000 (earlier claim was false), no use
Ununseptium	Uus	117		n.a.	not yet observed
Ununoctium	Uuo	118		n.a.	not yet observed, but false claim in 1999
Uranium	U	92	238.028 91(3)[d,f] $4.468(3) \cdot 10^9$ a	156m	radioactive and of high density (planet Uranus, after the Greek sky god) 1789, found in pechblende and other minerals, used for nuclear energy
Vanadium	V	23	50.9415(1) stable	135m	metal (Vanadis, scandinavian goddess of beauty) 1830, used in steel

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Name	Symbol	At. n.	Aver. mass[a] in u (error), longest lifetime	Atomic[e] radius in pm	Main properties, (naming)[h] discovery date and use
Xenon	Xe	54	131.293(6)[f] stable	(103n) 200v	noble gas (Greek *xenos* foreign) 1898, used in lamps and lasers
Ytterbium	Yb	70	173.04(3)[f] stable	174m	malleable heavy metal (Ytterby, Swedish town) 1878, used in superconductors
Yttrium	Y	39	88.905 85(2) stable	180m	malleable light metal (Ytterby, Swedish town) 1794, used in lasers
Zinc	Zn	30	65.409(4) stable	139m	heavy metal (German *Zinke* protuberance) antiquity, iron rust protection
Zirconium	Zr	40	91.224(2)[f] stable	160m	heavy metal (from the mineral zircon, after Arabic *zargum* golden colour) 1789, chemical and surgical instruments, nuclear industry

a. The atomic mass unit is defined as $1\,\mathrm{u} = \frac{1}{12}m(^{12}\mathrm{C})$, making $1\,\mathrm{u} = 1.660\,5402(10)\,\mathrm{yg}$. For elements found on Earth, the *average* atomic mass for the naturally occurring isotope mixture is given, with the error in the last digit in brackets. For elements not found on Earth, the mass of the *longest living* isotope is given; as it is not an average, it is written in brackets, as is customary in this domain. Ref. 1173

b. The element is not found on Earth because of its short lifetime.

c. The element has at least one radioactive isotope.

d. The element has no stable isotopes.

e. Strictly speaking, the *atomic radius* does not exist. Because atoms are clouds, they have no boundary. Several approximate definitions of the 'size' of atoms are possible. Usually, the radius is defined in such a way as to be useful for the estimation of distances between atoms. This distance is different for different bond types. In the table, radii for metallic bonds are labelled m, radii for (single) covalent bonds with carbon c, and Van der Waals radii v. Noble gas radii are labelled n. Note that values found in the literature vary by about 10 %; values in brackets lack literature references. Ref. 1175 Ref. 1175

The covalent radius can be up to 0.1 nm smaller than the metallic radius for elements on the (lower) left of the periodic table; on the (whole) right side it is essentially equal to the metallic radius. In between, the difference between the two decreases towards the right. Can you explain why? By the way, ionic radii differ considerably from atomic ones, and depend both on the ionic charge and the element itself. Challenge 1623 s

All these values are for atoms in their ground state. Excited atoms can be hundreds of times larger than atoms in the ground state; however, excited atoms do not form solids or chemical compounds.

f. The isotopic composition, and thus the average atomic mass, of the element varies depending on the place where it was mined or on subsequent human treatment, and can lie outside the values given. For example, the atomic mass of commercial lithium ranges between 6.939 and 6.996 u. The masses of isotopes are known in atomic mass units to nine or more significant digits, and usually with one or two fewer digits in kilograms. The errors in the atomic mass are thus mainly due to the variations in isotopic composition. Ref. 1167 Ref. 1173

g. The lifetime errors are asymmetric or not well known.

h. Extensive details on element names can be found on elements.vanderkrogt.net.

The best experts are those who help others to overcome traumas. Peter A. Levine & Ann Frederick, *Waking the Tiger – Healing Trauma – The Innate Capacity to Transform Overwhelming Experiences*, North Atlantic Books, 1997. Geoff Graham, *How to Become the Parent You Never Had - a Treatment for Extremes of Fear, Anger and Guilt*, Real Options Press, 1986.

A good complement to these texts is the systemic approach, as presented by Bert Hellinger, *Zweierlei Glück*, Carl Auer Verlag, 1997. Some of his books are also available in English. The author explains how to achieve a life of contentness, living with the highest possible responsibility of one's actions, by reducing entaglements with one's past and with other people. He presents a simple and efficient technique for realising this disentanglement.

The next step, namely full mastery in the enjoyment of life, can be found in any book written by somebody who has achieved mastery in any one topic. The topic itself is not important, only the passion is.

de la Garanderie, *Le dialogue pédagogique avec l'élève*, Centurion, 1984, A. de la Garanderie/ *Pour une pédagogie de l'intelligence*, Centurion, 1990, A. de la Garanderie/ *Réussir ça s'apprend*, Bayard, 1994. De la Garanderie explains how the results of teaching and learning depend in particular on the importance of evocation, imagination and motivation.

Plato, *Phaedrus*, Athens, 380 bce.

Françoise Dolto, *La cause des enfants*, Laffont, 1985, and her other books. Dolto (1908–1988), a child psychiatrist, is one of the world experts on the growth of the child; her main theme was that growth is only possible by giving the highest possible responsibility to every child during its development.

In the domain of art, many had the passion to achieve full pleasure. A good piece of music, a beautiful painting, an expressive statue or a good film can show it. On a smaller scale, the art to typeset beautiful books, so different from what many computer programs do by default, the best introduction are the works by Jan Tschichold (1902–1974), the undisputed master of the field. Among the many books he designed are the beautiful Penguin books of the late 1940s; he also was a type designer, e.g. of the *Sabon* typeface. A beautiful summary of his views is the short but condensed text Jan Tschichold, *Ausgewählte Aufsätze über Fragen der Gestalt des Buches und der Typographie*, Birkhäuser Verlag, Basel, 1993. An extensive and beautiful textbook on the topic is Hans Peter Willberg & Friedrich Forssman, Lesetypographie, Verlag Hermann Schmidt, Mainz, 1997. See also Robert Bringhurst, *The Elements of Typographic Style*, Hartley & Marks, 2004.

Many scientists passionately enjoyed their occupation. Any biography of Charles Darwin will purvey his fascination for biology, of Friedrich Bessel for astronomy, of Albert Einstein for physics and of Linus Pauling for chemistry.

942 The group of John Wearden in Manchester has shown by experiments with humans that the accuracy of a few per cent is possible for any action with a duration between a tenth of a second and a minute. See J. McCrone, When a second lasts forever, *New Scientist* pp. 53–56, 1 November 1997. Cited on page 1134.

943 E. J. Zimmerman, The macroscopic nature of space-time, *American Journal of Physics* **30**, pp. 97–105, 1962. Cited on page 1137.

944 The possibilities for precision timing using single-ion clocks are explained in ... Cited on page 1137.

945 See P.D. Pešić, The smallest clock, *European Journal of Physics* **14**, pp. 90–92, 1993. Cited on page 1137.

1084 H. Fritsch, M. Gell-Mann & H. Leutwyler, Advantages of the color octet picture, *Physics Letters B* **47**, pp. 365–368, 1973. Cited on page 1260.

1085 Quantum chromodynamics can be explored in books of several levels. The first, the popular one, is described most clearly by one of its founders, in the longseller Harald Fritzsch, *Quarks – Urstoff unserer Welt*, Piper Verlag, 2006, or, in English language, *Quarks: the stuff of matter*, Penguin Books, 1983. In the second level, the field can be explored in texts on high energy physics, as those of Ref. 1082. The third level contains books

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

like Kerson Huang, Quarks, Leptons and Gauge Fields, World Scientific, 1992, or Felix J. Ynduráin, The Theory of Quark and Gluon Interactions, Springer Verlag, 1992, or Walter Greiner & Andreas Schäfer, Quantum Chromodynamics, Springer Verlag, 1995, or the modern and detailed text by Stephan Narison, *QCD as a Theory of Hadrons*, Cambridge University Press, 2004. As always, a student has to discover by himself or herself which text he or she likes most. Cited on pages 1260, 1266, and 1268.

1086 The approximation of QCD with zero mass quarks is described by F. Wilczek, Getting its from bits, *Nature* **397**, pp. 303–306, 1999. It is also explained in F. Wilczek, Asymptotic freedom, *Nobel lecture* 2004. The proton's mass is set by the energy scale at which the strong coupling, coming from its value at Planck energy, becomes of order unity. Cited on pages 1270 and 1286.

1087 The official reference for all particle data, worth a look for every physicist, is the massive collection of information compiled by the Particle Data Group, with the website pdg.web.cern.ch containing the most recent information. A printed review is published about every two years in one of the major journals on elementary particle physics. See for example C. Amsler & al., The Review of Particle Physics, *Physics Letters B* **667**, p. 1, 2008. For some measured properties of these particles, the official reference is the set of so-called CODATA values, found at physics.nist.gov/cuu/Constants/. The most recent list was published on paper as P. J. Mohr, B. N. Taylor & D. B. Newell, CODATA recommended values of the fundamental physical constants: 2006, *Reviews of Modern Physics* **80**, pp. 633–730, 2008. It is available also on the NIST site. Cited on pages 1259, 1268, 1270, 1271, 1277, 1281, 1284, and 1291.

1088 For a pedagogical introduction to lattice QCD calculations, see R. Gupta, Introduction to Lattice QCD, preprint at arxiv.org/abs/hep-lat/9807028, or the clear introduction by Michael Creutz, *Quarks, Gluons and Lattices*, Cambridge University Press, 1983. Cited on page 1267.

1089 S. Bethke, Experimental tests of asymptotic freedom, *Progress in Particle and Nuclear Physics* **58**, pp. 351–368, 2007, preprint at arxiv.org/abs/hep-ex/0606035. Cited on page 1268.

1090 A. J. Buchmann & E. M. Henley, Intrinsic quadrupole moment of the nucleon, *Physical Review C* **63**, p. 015202, 2000. Alfons Buchmann also predicts that the quadrupole moment of the other, strange $J = 1/2$ octet baryons is positive, and predicts a prolate structure for all of them (private communication). For the decuplet baryons, with $J = 3/2$, the quadrupole moment can often be measured spectroscopically, and is always negative. The four Δ baryons are thus predicted to have a negative intrinsic quadrupole moment and thus an oblate shape. This explained in A. J. Buchmann & E. M. Henley, Quadrupole moments of baryons, *Physical Review D* **65**, p. 073017, 2002. For recent updates, see A. J. Buchmann, Charge form factors and nucleon shape, pp. 110–125, in the Shape of Hadrons Workshop Conference, Athens Greece, 27-29 April 2006, AIP Conference Proceedings 904, Eds. C.N. Papanicolas, Aron Bernstein. For updates on other baryons, see A. J. Buchmann, Structure of strange baryons, Hyp 2006, International Conference on Hypernuclear and Strange Particle Physics, Oct.10-14, Mainz, Germany, to be published in European Physics Journal A 2007. The topic is an active field of research; for example, results on magnetic octupole moments are expected soon. Cited on page 1270.

1091 S. Strauch & al., Polarization transfer in the ^{4}He (e,e'p) ^{3}H reaction up to $Q^2 = 2.6(\mathrm{GeV/c})^2$, *Physical Review Letters* **91**, p. 052301, 2003. Cited on page 1270.

CHALLENGE HINTS AND SOLUTIONS

Challenge 1462, page 1119: A virus is an example. It has no own metabolism. (By the way, the ability of some viruses to form crystals is not a proof that they are not living beings, in contrast to what is often said.)

Challenge 1463, page 1120: The navigation systems used by flies are an example.

Challenge 1464, page 1122: The thermal energy kT is about 4 zJ and a typical relaxation time is 0.1 ps.

Challenge 1465, page 1126: The argument is correct.

Challenge 1466, page 1127: This is not possible at present. If you know a way, publish it. It would help a sad single mother who has to live without financial help from the father, despite a lawsuit, as it was yet impossible to decide which of the two candidates is the right one.

Challenge 1467, page 1127: Also identical twins count as different persons and have different fates. Imprinting in the womb is different, so that their temperament will be different. The birth experience will be different; this is the most intense experience of every human, strongly determining his fears and thus his character. A person with an old father is also quite different from that with a young father. If the womb is not that of his biological mother, a further distinction of the earliest and most intensive experiences is given.

Challenge 1468, page 1127: Be sure to publish your results.

Challenge 1469, page 1127: Life's chemicals are synthesized inside the body; the asymmetry has been inherited along the generations. The common asymmetry thus shows that all life has a common origin.

Challenge 1470, page 1127: Well, men are more similar to chimpanzees than to women. More seriously, the above data, even though often quoted, are wrong. Newer measurements by Roy Britten in 2002 have shown that the difference in genome between humans and chimpanzees is about 5 % (See R. J. Britten, Divergence between samples of chimpanzee and human DNA sequences is 5 %, counting indels, *Proceedings of the National Academy of Sciences* **99**, pp. 13633–13635, 15th of October, 2002.) In addition, though the difference between man and woman is smaller than one whole chromosome, the large size of the X chromosome, compared with the small size of the Y chromosome, implies that men have about 3 % less genetic material than women. However, all men have an X chromosome as well. That explains that still other measurements suggest that all humans share a pool of at least 99.9 % of common genes.

Challenge 1473, page 1130: Chemical processes, including diffusion and reaction rates, are strongly temperature dependent. They affect the speed of motion of the individual and thus its chance of survival. Keeping temperature in the correct range is thus important for evolved life forms.

Challenge 1474, page 1130: The first steps are not known at all.

Challenge 1475, page 1130: Since all the atoms we are made of originate from outer space, the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

answer is yes. But if one means that biological cells came to Earth from space, the answer is no, as most cells do not like vacuum. The same is true for DNA.

In fact, life and reproduction are properties of complex systems. In other words, asking whether life comes from outer space is like asking: 'Could car insurance have originated in outer space?'

Challenge 1476, page 1133: Haven't you tried yet? Physics is an experimental science.

Challenge 1486, page 1142: Radioactive dating methods can be said to be based on the nuclear interactions, even though the detection is again electromagnetic.

Challenge 1487, page 1143: All detectors of light can be called relativistic, as light moves with maximal speed. Touch sensors are not relativistic following the usual sense of the word, as the speeds involved are too small. The energies are small compared to the rest energies; this is the case even if the signal energies are attributed to electrons only.

Challenge 1488, page 1143: The noise is due to the photoacoustic effect; the periodic light periodically heats the air in the jam glass at the blackened surface and thus produces sound. See M. EULER, Kann man Licht hören?, *Physik in unserer Zeit* **32**, pp. 180–182, 2001.

Challenge 1494, page 1151: It implies that neither resurrection nor reincarnation nor eternal life are possible.

Challenge 1495, page 1152: You get an intense yellow colour due to the formation of lead iodide (PbI_2).

Challenge 1497, page 1160: With a combination of the methods of Table 98 it is possible; but whether there will ever be an organization willing to pay for this to happen is another question.

Challenge 1498, page 1170: If you find one, please send the author a mail.

Challenge 1500, page 1171: For example, a heavy mountain will push down the Earth's crust into the mantle, makes it melt on the bottom side, and thus lowers the position of the top.

Challenge 1501, page 1171: These developments are just starting; the results are still far from the original one is trying to copy, as they have to fulfil a second condition, in addition to being a 'copy' of original feathers or of latex: the copy has to be cheaper than the original. That is often a much tougher request than the first.

Challenge 1503, page 1171: Since the height of the potential is always finite, walls can always be overcome by tunnelling.

Challenge 1504, page 1171: The lid of a box can never be at rest, as is required for a tight closure, but is always in motion, due to the quantum of action.

Challenge 1507, page 1173: The concentrations and can be measured from polar ice caps, by measuring how the isotope concentration changes over depth. Both in evaporation and in condensation of water, the isotope ratio depends on the temperature. The measurements in Antarctica and in Greenland coincide, which is a good sign of their trustworthiness.

Challenge 1511, page 1184: The one somebody else has thrown away. Energy costs about 10 cents/kWh. For new lamps, the fluorescence lamp is the best for the environment, even though it is the least friendly to the eye and the brain, due to its flickering.

Challenge 1512, page 1187: This old dream depends on the precise conditions. How flexible does the display have to be? What lifetime should it have? The newspaper like display is many years away and maybe not even possible.

Challenge 1513, page 1187: The challenge here is to find a cheap way to deflect laser beams in a controlled way. Cheap lasers are already available.

Challenge 1514, page 1187: There is only speculation on the answer; the tendency of most researchers is to say no.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1515, page 1187: No, as it is impossible because of momentum conservation, because of the no-cloning theorem.

Challenge 1516, page 1188: There are companies trying to do sell systems based on quantum cryptology; but despite the technical interest, the commercial success is questionable.

Challenge 1517, page 1188: The author predicts that mass-produced goods using this technology (at least 1 million pieces sold) will not be available before 2025.

Challenge 1518, page 1188: Maybe, but for extremely high prices.

Challenge 1519, page 1191: For example, you could change gravity between two mirrors.

Challenge 1520, page 1191: As usual in such statements, either group or phase velocity is cited, but not the corresponding energy velocity, which is always below c.

Challenge 1521, page 1192: Echoes do not work once the speed of sound is reached and do not work well when it is approached. Both the speed of light and that of sound have a finite value. Moving with a mirror still gives a mirror image. This means that the speed of light cannot be reached. If it cannot be reached, it must be the same for all observers.

Challenge 1522, page 1193: Mirrors do not usually work for matter; in addition, if they did, matter would require much higher acceleration values.

Challenge 1525, page 1195: The overhang can have any value whatsoever. There is no limit. Taking the indeterminacy principle into account introduces a limit as the last brick or card must not allow the centre of gravity, through its indeterminacy, to be over the edge of the table.

Challenge 1526, page 1195: A larger charge would lead to a field that spontaneously generates electron positron pairs, the electron would fall into the nucleus and reduce its charge by one unit.

Challenge 1529, page 1196: The Hall effect results from the deviation of electrons in a metal due to an applied magnetic field. Therefore it depends on their speed. One gets values around 1 mm. Inside atoms, one can use Bohr's atomic model as approximation.

Challenge 1530, page 1197: The usual way to pack oranges on a table is the densest way to pack spheres.

Challenge 1531, page 1198: Just use a paper drawing. Draw a polygon and draw it again at latter times, taking into account how the sides grow over time. You will see by yourself how the faster growing sides disappear over time.

Challenge 1532, page 1199: The steps are due to the particle nature of electricity and all other moving entities.

Challenge 1533, page 1199: If we could apply the Banach–Tarksi paradox to vacuum, it seems
Page 60 that we could split, without any problem, one ball of vacuum into *two* balls of vacuum, each with the same volume as the original. In other words, one ball with vacuum energy E could not be distinguished from two balls of vacuum energy $2E$.

We used the Banach–Tarski paradox in this way to show that chocolate (or any other matter)
Page 250 possesses an intrinsic length. But it is *not* clear that we can now deduce that the vacuum has an intrinsic length. Indeed, the paradox cannot be applied to vacuum for *two* reasons. First, there indeed is a maximum energy and minimum length in nature. Secondly, there is no place in nature without vacuum energy; so there is no place were we could put the second ball. We thus do not know why the Banach–Tarski paradox for vacuum cannot be applied, and thus cannot use it to deduce the existence of a minimum length in vacuum.

It is better to argue in the following way for a minimum length in vacuum. If there were no intrinsic length cut-off, the vacuum energy would be infinite. Experiments however, show that it is finite.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1534, page 1199: Mud is a suspension of sand; sand is not transparent, even if made of clear quartz, because of the scattering of light at the irregular surface of its grains. A suspension cannot be transparent if the index of refraction of the liquid and the suspended particles is different. It is never transparent if the particles, as in most sand types, are themselves not transparent.

Challenge 1536, page 1199: No. Bound states of massless particles are always unstable.

Challenge 1537, page 1199: The first answer is probably no, as composed systems cannot be smaller than their own compton wavelength; only elementary systems can. However, the universe is not a system, as it has no environment. As such, its length is not a precisely defined concept, as an environment is needed to measure and to define it. (In addition, gravity must be taken into account in those domains.) Thus the answer is: in those domains, the question makes no sense.

Challenge 1538, page 1200: Methods to move on perfect ice from mechanics:

— if the ice is perfectly flat, rest is possible only in one point – otherwise you oscillate around that point, as shown in challenge 24;
— do nothing, just wait that the higher centrifugal acceleration at body height pulls you away;
— to rotate yourself, just rotate your arm above your head;
— throw a shoe or any other object away;
— breathe in vertically, breathing out (or talking) horizontally (or vice versa);
— wait to be moved by the centrifugal acceleration due to the rotation of the Earth (and its oblateness);
— jump vertically repeatedly: the Coriolis acceleration will lead to horizontal motion;
— wait to be moved by the Sun or the Moon, like the tides are;
— 'swim' in the air using hands and feet;
— wait to be hit by a bird, a flying wasp, inclined rain, wind, lava, earthquake, plate tectonics, or any other macroscopic object (all objects pushing count only as one solution);
— wait to be moved by the change in gravity due to convection in Earth's mantle;
— wait to be moved by the gravitation of some comet passing by;
— counts only for kids: spit, sneeze, cough, fart, pee; or move your ears and use them as wings.

Note that gluing your tongue is not possible on perfect ice.

Challenge 1539, page 1200: Methods to move on perfect ice using thermodynamics and electrodynamics:

— use the radio/TV stations nearby to push you around;
— use your portable phone and a mirror;
— switch on a pocket lam, letting the light push you;
— wait to be pushed around by Brownian motion in air;
— heat up one side of your body: black body radiation will push you;
— heat up one side of your body, e.g. by muscle work: the changing airflow or the evaporation will push you;
— wait for one part of the body to be cooler than the other and for the corresponding black body radiation effects;
— wait for the magnetic field of the Earth to pull on some ferromagnetic or paramagnetic metal piece in your clothing or in your body;
— wait to be pushed by the light pressure, i.e. by the photons, from the Sun or from the stars, maybe using a pocket mirror to increase the efficiency;
— rub some polymer object to charge it electrically and then move it in circles, thus creating a magnetic field that interacts with the one of the Earth.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Note that perfect frictionless surfaces do not melt.

Challenge 1540, page 1200: Methods to move on perfect ice using quantum effects:

— wait for your wave function to spread out and collapse at the end of the ice surface;
— wait for the pieces of metal in the clothing to attract to the metal in the surrounding through the Casimir effect;
— wait to be pushed around by radioactive decays in your body.

Challenge 1541, page 1200: Methods to move on perfect ice using general relativity:

— move an arm to emit gravitational radiation;
— deviate the cosmic background radiation with a pocket mirror;
— wait to be pushed by gravitational radiation from star collapses;
— wait for the universe to contract.

Challenge 1542, page 1200: Methods to move on perfect ice using materials science, geophysics, astrophysics:

— be pushed by the radio waves emitted by thunderstorms and absorbed in painful human joints;
— wait to be pushed around by cosmic rays;
— wait to be pushed around by the solar wind;
— wait to be pushed around by solar neutrinos;
— wait to be pushed by the transformation of the Sun into a red giant;
— wait to be hit by a meteorite.

Challenge 1543, page 1200: A method to move on perfect ice using self-organization, chaos theory, and biophysics:

— wait that the currents in the brain interact with the magnetic field of the Earth by controlling your thoughts.

Challenge 1544, page 1200: Methods to move on perfect ice using quantum gravity, supersymmetry, and string theory:

— accelerate your pocket mirror with your hand;
— deviate the Unruh radiation of the Earth with a pocket mirror;
— wait for proton decay to push you through the recoil.

Challenge 1549, page 1207: This is easy only if the black hole size is inserted into the entropy bound by Bekenstein. A simple deduction of the black hole entropy that includes the factor 1/4 is not yet at hand.

Challenge 1550, page 1207: An entropy limit implies an information limit; only a given information can be present in a given region of nature. This results in a memory limit.

Challenge 1551, page 1207: In natural units, the expression for entropy is $S = A/4 = 0.25A$. If each Planck area carried one bit (degree of freedom), the entropy would be $S = \ln W = \ln(2^A) = A \ln 2 = 0.693A$. This quite near the exact value.

Challenge 1555, page 1212: The universe has about 10^{22} stars; the Sun has a luminosity of about 10^{26} W; the total luminosity of the visible matter in the universe is thus about 10^{48} W. A gamma ray burster emits up to $3 \cdot 10^{47}$ W.

Challenge 1561, page 1214: They are carried away by the gravitational radiation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1567, page 1218: No system is known in nature which emits or absorbs only one graviton at a time. This is another point speaking against the existence of gravitons.

Challenge 1571, page 1226: Two stacked foils show the same effect as one foil of the same total thickness. Thus the surface plays no role.

Challenge 1573, page 1228: The electron is held back by the positive charge of the nucleus, if the number of protons in the nucleus is sufficient, as is the case for those nuclei we are made of.

Challenge 1575, page 1236: The number is small compared with the number of cells. However, it is possible that the decays are related to human ageing.

Challenge 1576, page 1236: There is way to conserve both energy and momentum in such a decay.

Challenge 1578, page 1237: The radioactivity necessary to keep the Earth warm is low; lava is only slightly more radioactive than usual soil.

Challenge 1580, page 1245: By counting decays and counting atoms to sufficient precision.

Challenge 1581, page 1250: The nuclei of nitrogen and carbon have a high electric charge which strongly repels the protons.

Challenge 1583, page 1258: Touching something requires getting near it; getting near means a small time and position indeterminacy; this implies a small wavelength of the probe that is used for touching; this implies a large energy.

Challenge 1585, page 1264: The processes are electromagnetic in nature, thus electric charges give the frequency with which they occur.

Challenge 1586, page 1273: Designing a nuclear weapon is not difficult. University students can do it, and even have done so a few times. The first students who did so were two physics graduates in 1964, as told on http://www.guardian.co.uk/world/2003/jun/24/usa.science. It is not hard to conceive a design and even to build it. By far the hardest problem is getting or making the nuclear material. That requires either an extensive criminal activity or a vast technical effort, with numerous large factories, extensive development, and coordination of many technological activities. Most importantly, such a project requires a large financial investment, which poor countries cannot afford without great sacrifices for all the population. The problems are thus not technical, but financial.

Challenge 1582, page 1256: See the paper by C. J. Hogan, Why the universe is just so, *Reviews of Modern Physics* 72, pp. 1149–1161, 2000.

Challenge 1591, page 1295: In 2008 an estimated 98% of all physicists agreed. Time will tell whether they are right.

Challenge 1593, page 1305: A mass of 100 kg and a speed of 8 m/s require 43 m^2 of wing surface.

Challenge 1596, page 1312: The largest rotation angle $\Delta\varphi$ that can be achieved in one stroke C is found by maximizing the integral

$$\Delta\varphi = -\int_C \frac{a^2}{a^2+b^2}\mathrm{d}\theta \tag{804}$$

Since the path C in shape space is closed, we can use Stokes' theorem to transform the line integral to a surface integral over the surface S enclosed by C in shape space:

$$\Delta\varphi = \int_S \frac{2ab^2}{(a^2+b^2)^2}\mathrm{d}a\,\mathrm{d}\theta\ . \tag{805}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The maximum angle is found by noting that θ can vary at most between 0 and π, and that a can vary at most between 0 and ∞. This yields

$$\Delta\varphi_{\max} = \int_{\theta=0}^{\pi} \int_{a=0}^{\infty} \frac{2ab^2}{(a^2+b^2)^2} \mathrm{d}a \, \mathrm{d}\theta = \pi \,. \tag{806}$$

Challenge 1605, page 1324: The infinite sum is not defined for numbers; however, it is defined for a knotted string.

Challenge 1607, page 1329: This is a simple but hard question. Find out.

Challenge 1603, page 1321: Lattices are not isotropic, lattices are not Lorentz invariant.

Challenge 1609, page 1329: Large raindrops are pancakes with a massive border bulge. When the size increases, e.g. when a large drop falls through vapour, the drop splits, as the central membrane is then torn apart.

Challenge 1610, page 1330: It is a drawing; if it is interpreted as an image of a three-dimensional object, it either does not exist, or is not closed, or is an optical illusion of a torus.

Challenge 1611, page 1330: See T. Fink & Y. Mao, *The 85 Ways to Tie a Tie*, Broadway Books, 2000.

Challenge 1612, page 1330: See T. Clarke, Laces high, *Nature Science Update* 5th of December, 2002, or http://www.nature.com/nsu/021202/021202-4.html.

Challenge 1616, page 1334: Most macroscopic matter properties fall in this class, such as the change of water density with temperature.

Challenge 1619, page 1345: Before the speculation can be fully tested, the relation between particles and black holes has to be clarified first.

Challenge 1620, page 1346: Never expect a correct solution for personal choices. Do what you yourself think and feel is correct.

Challenge 1622, page 1348: The gauge coupling constants, via the Planck length, determine the size of atoms, the strength of chemical bonds and thus the size of all things.

Challenge 1623, page 1362: Covalent bonds tend to produce full shells; this is a smaller change on the right side of the periodic table.

Sixth Part

Motion Without Motion: What Are Space, Time and Particles?

Where through the combination of
quantum mechanics and general relativity,
the top of Motion Mountain is reached,
and it is discovered
that vacuum is indistinguishable from matter,
that space, time and mass are easily confused,
that there is no difference between the very large and the very small,
and that a complete description of motion is possible.
(Well, wait a few more years for the last line.)

Contents

1396 52 General relativity versus quantum theory

The contradictions 1396

1398 **Does matter differ from vacuum?**

Planck scales 1399 • Farewell to instants of time 1401 • Farewell to points in space 1403 • Farewell to the space-time manifold 1405 • Farewell to observables and measurements 1408 • Can space-time be a lattice? – A glimpse of quantum geometry 1409 • Farewell to particles 1410 • Farewell to mass 1413 • Curiosities and fun challenges on Planck scales 1416 • Farewell to the big bang 1419 • The baggage left behind 1420

1420 **Some experimental predictions**

Additional predictions 1421

1425 53 Nature at large scales – Is the universe something or nothing?

Cosmological scales 1425 • Maximum time 1426 • Does the universe have a definite age? 1427 • How precise can age measurements be? 1427 • Does time exist? 1429 • What is the error in the measurement of the age of the universe? 1429 • Maximum length 1433 • Is the universe really a big place? 1433 • The boundary of space-time – is the sky a surface? 1435 • Does the universe have initial conditions? 1435 • Does the universe contain particles and stars? 1436 • Does the universe contain masses and objects? 1437 • Do symmetries exist in nature? 1438 • Does the universe have a boundary? 1439 • Is the universe a set? – Again 1440 • Curiosities and fun challenges about the universe 1441 • Hilbert's sixth problem settled 1442 • Does the universe make sense? 1443 • Abandoning sets and discreteness eliminates contradictions 1444 • Extremal scales and open questions in physics 1445 • Is extremal identity a principle of nature? 1445

1447 54 The physics of love – a summary of the first five-and-a-half parts

Summary on love and physics 1457

1458 55 Maximum force and minimum distance – physics in limit statements

1458 **Fundamental limits to all observables**

Special relativity in one statement 1459 • Quantum theory in one statement 1460 • General relativity in one statement 1461 • Deducing general relativity 1462 • Deducing universal gravitation 1465 • The size of physical systems in general relativity 1465 • A mechanical analogy for the maximum force 1466

1466 **Units and limit values for all physical observables**

Limits to space and time 1468 • Mass and energy limits 1469 • Virtual particles – a new definition 1469 • Limits in thermodynamics 1470 • Electromagnetic limits and units 1470 • Vacuum and mass–energy – two sides of the same coin 1471 • Curiosities and fun challenges about Planck limits 1472

1475 **Upper and lower limits to observables**

Size and energy dependence 1475 • Angular momentum, action and speed 1475 • Force, power and luminosity 1477 • Acceleration 1477 • Momentum 1478 • Lifetime, distance and curvature 1478 • Mass change 1478 • Mass and density 1479 • The strange charm of the entropy bound 1479 • Temperature 1481 • Electromagnetic observables 1481 • Curiosities and fun challenges about limits to observ-

Chapter 52

GENERAL RELATIVITY VERSUS QUANTUM THEORY

> Man muß die Denkgewohnheiten durch Denknotwendigkeiten ersetzen.*
>
> Albert Einstein

The two stories told in the two parts of the path we have followed up to now, namely hat of general relativity and that of quantum field theory, are both beautiful and horoughly successful. Both are confirmed by experiments to the precision that is possible at present. We have thus reached a considerable height in our mountain ascent. The precision we have achieved in the description of nature is impressive, and we are now able to describe all known examples of motion. So far we have encountered no exceptions.

On the other hand, the most important aspects of any type of motion, the masses of the particles involved and the strength of their coupling, are still unexplained. Furthermore, the origin of all the particles in the universe,** their initial conditions, and the dimensionality of space-time remain hidden from us. Obviously, our adventure is not yet complete.***

This last part of our hike will be the most demanding. In the ascent of any high mountain, the head gets dizzy because of the lack of oxygen. The finite amount of energy at our disposal requires that we leave behind all unnecessary baggage and everything that slows us down. In order to determine what is unnecessary, we need to focus on what we want to achieve. Our aim is the precise description of motion. But even though general relativity and quantum theory are extremely precise, we carry a burden: the two theories and their concepts *contradict* each other. We first list these contradictions.

The contradictions

In classical physics and in general relativity, the vacuum, or empty space-time, is a region with no mass, no energy and no momentum. If matter or gravitational fields are present, space-time is curved. The best way to measure the mass or energy content of space-time is to measure the average curvature of the universe. Cosmology tells us how we can do this. Cosmological measurements reveal an average energy density of the 'vacuum' of

Ref. 1176
Page 587

* 'One needs to replace habits of thought by necessities of thought.'

** The photograph on page 1393 shows an extremely distant, thus extremely young, part of the universe, with its large number of galaxies (NASA).

*** Nevertheless, nothing of what follows if of interest for biology, chemistry, medicine, geology, or engineering, neither for their work nor for their examinations.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$E/V \approx 1\,\mathrm{nJ/m^3}\ . \tag{807}$$

Ref. 1177 However, quantum field theory tells a different story. A vacuum is a region with zero-point fluctuations. The energy content of a vacuum is the sum of the zero-point energies Page 1189 of all the fields it contains. Indeed, the Casimir effect 'proves' the reality of these zero-Page 1192 point energies. Their energy density is given, within one order of magnitude, by

$$\frac{E}{V} = \frac{4\pi h}{c^3}\int_0^{\nu_{\max}} \nu^3 \mathrm{d}\nu = \frac{\pi\, h}{c^3}\nu_{\max}^4\ . \tag{808}$$

The approximation is valid for the case in which the cut-off frequency $\nu_{\max}$ is much larger than the rest mass m of the particles corresponding to the field under consideration. Particle physicists argue that the cut-off energy has to be at least the energy of grand unification, about 10^{16} GeV= 1.6 MJ. That would give a vacuum energy density of

$$\frac{E}{V} \approx 10^{99}\,\mathrm{J/m^3}\ , \tag{809}$$

which is about 10^{108} times higher than the experimental limit deduced from spatial curvature using general relativity estimates. In other words, something is slightly wrong here.

General relativity and quantum theory contradict each other in other ways. Gravity Ref. 1178 is curved space-time. Extensive research has shown that quantum field theory, which describes electrodynamics and nuclear forces, fails for situations with strongly curved space-times. In these cases the concept of 'particle' is not precisely defined. Quantum field theory cannot be extended to include gravity consistently, and thus to include general relativity. Without the concept of the particle as a discrete entity, we also lose the ability to perform perturbation calculations – and these are the only calculations possible in quantum field theory. In short, quantum theory only works because it assumes that gravity does not exist. Indeed, the gravitational constant does not appear in any consistent quantum field theory.

On the other hand, general relativity neglects the commutation rules between physical quantities discovered in experiments on a microscopic scale. General relativity assumes that the classical notions of position and momentum of material objects are meaningful. It thus ignores Planck's constant $\hbar$, and only works by neglecting quantum effects.

Measurements also lead to problems. In general relativity, as in classical physics, it is assumed that arbitrary precision of measurement is possible – for example, by using Page 831 finer and finer ruler marks. In quantum mechanics, on the other hand, the precision of measurement is limited. The indeterminacy principle yields limits that result from the Page 1136 mass M of the apparatus.

The contradictions are most evident in relation to *time*. According to relativity, time is what is read from clocks. But quantum theory says that precise clocks do not exist, especially if gravitation is taken into account. What does 'waiting 10 minutes' mean, if the clock goes into a quantum-mechanical superposition as a result of its coupling to space-time geometry?

In addition, quantum theory associates mass with an inverse length via the Compton wavelength; general relativity associates mass with length via the Schwarzschild radius.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Similarly, general relativity implies that space and time cannot be distinguished, whereas quantum theory implies that matter does make a distinction between them. Quantum theory is a theory of – admittedly weird – local observables. In general relativity, there are no local observables, as Einstein's hole argument shows.

Page 622

The contradiction between the two theories is shown most dramatically by the failure of general relativity to describe the pair creation of particles with spin 1/2, a typical and essential quantum process. John Wheeler and others have shown that, in such a case, the topology of space necessarily has to *change*; in general relativity, however, the topology of space is fixed. In short, quantum theory says that matter is made of *fermions*, which cannot be incorporated into general relativity.

Ref. 1179, Ref. 1180 Ref. 1181, Ref. 1182

No description of nature that contains contradictions can lead to a unified description or to a completely correct description. In order to proceed, let us take the shortest and fastest path: let us investigate the contradictions in more detail.

DOES MATTER DIFFER FROM VACUUM?

There is a simple way to state the origin of *all* contradictions between general relativity and quantum mechanics.* Both theories describe motion in terms of objects, made up of particles, and space-time, made up of events. Let us see how these two concepts are defined.

Ref. 1183

A *particle* – and in general any object – is defined as a conserved entity which has a position and which can move. (The etymology of the word *object* is connected to the latter property.) In other words, a particle is a small entity with conserved mass, charge and so on, whose position can vary with time.

In every physics text, *time* is defined with the help of moving objects, usually called 'clocks', or moving particles, such as those emitted by light sources. Similarly, *length* is defined in terms of objects, either with an old-fashioned ruler or in terms of the motion of light, which is itself motion of particles.

Ref. 1184

Modern physics has sharpened our definitions of particles and space-time. Quantum mechanics assumes that space-time is given (as a symmetry of the Hamiltonian), and studies the properties of particles and their motion, both for matter and for radiation. General relativity, and especially cosmology, takes the opposite approach: it assumes that the properties of matter and radiation are given (for example, via their equations of state), and describes in detail the space-time that follows from them, in particular its curvature.

However, one fact remains unchanged throughout all these advances in physics: these two concepts, of particles and of space-time, are *each defined with the help of the other*. To eliminate the contradiction between quantum mechanics and general relativity, and to create a more complete theory, we must eliminate this circular definition. As we will discover below, this necessitates a radical change in our description of nature, and in particular of the continuity of space-time.

For a long time, the contradictions between these two descriptions of nature were ac-

* The main results of this section are standard knowledge among specialists of unification; they are given here using simple arguments. For another derivation, see the summary section on limit statements in nature, on page 1458.

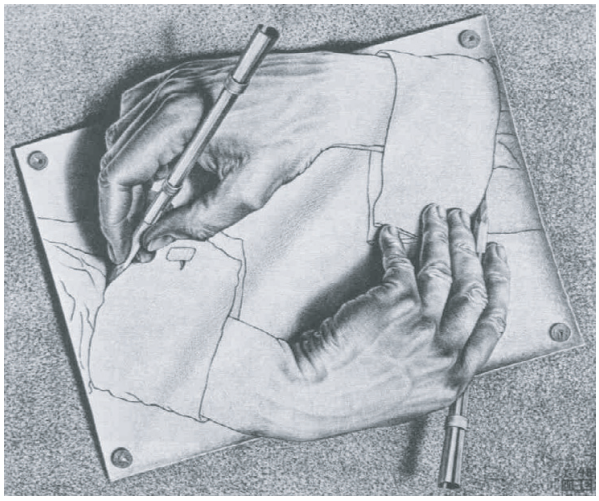

FIGURE 598 'Tekenen' by Maurits Escher, 1948 – a metaphor for the way in which 'particles' and 'space-time' are usually defined: each with the help of the other (© M.C. Escher Heirs)

commodated by keeping the two theories separate. One often hears the statement that quantum mechanics is valid at small scales and general relativity is valid at large scales. But this separation is artificial; worse, it prevents us from solving the problem. The situation resembles the well-known drawing (Figure 598) by Maurits Escher (1898–1972) in which two hands, each holding a pencil, seem to be drawing each other. If one hand is taken as a symbol of space-time and the other as a symbol of particles, with the act of drawing taken as the act of defining, the picture gives a description of standard twentieth-century physics. The apparent contradiction is solved by recognizing that the two concepts (the two hands) both originate from a third, hidden concept. In the picture, this third entity is the hand of the artist.

Ref. 1185, Ref. 1186 Ref. 1187, Ref. 1188

In the case of space-time and matter, the search for the underlying common concept is making renewed progress. The conceptual changes required for this are so striking that they should interest anybody who has an interest in physics. The most effective way to deduce the new concepts is to focus on that domain where the contradiction between the two standard theories is most dramatic, and where both theories are necessary at the same time.

Planck scales

Both general relativity and quantum mechanics are successful theories for the description of nature. Each provides a criterion for determining when classical Galilean physics is no longer applicable. (In the following, we use the terms 'vacuum' and 'empty space-time' interchangeably.)

General relativity shows that it is necessary to take into account the curvature of space-time whenever we approach an object of mass m to within a distance of the order of the Schwarzschild radius r_S, given by

$$r_S = 2Gm/c^2 \,. \tag{810}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The gravitational constant G and the speed of light c act as conversion constants. Indeed, as the Schwarzschild radius of an object is approached, the difference between general relativity and the classical $1/r^2$ description of gravity becomes larger and larger. For example, the barely measurable gravitational deflection of light by the Sun is due to the light approaching the Sun to within $2.4 \cdot 10^5$ times its Schwarzschild radius. Usually, we are forced to stay away from objects at a distance that is an even larger multiple of the Schwarzschild radius, as shown in Table 121. For this reason, general relativity is unnecessary in everyday life. (An object smaller than its own Schwarzschild radius is called a *black hole*, because according to general relativity, no signals from inside the Schwarzschild radius can reach the outside world.)

Ref. 1179, Ref. 1189

Ref. 1190

Similarly, quantum mechanics shows that Galilean physics must be abandoned and quantum effects must be taken into account whenever an object is approached to within distances of the order of the (reduced) Compton wavelength λ_C, given by

$$\lambda_C = \frac{\hbar}{m\,c} \,. \tag{811}$$

In this case, Planck's constant $\hbar$ and the speed of light c act as conversion factors to transform the mass m into a length scale. Of course, this length is only relevant if the object is smaller than its own Compton wavelength. At these scales we get relativistic quantum effects, such as particle–antiparticle creation or annihilation. Table 121 shows that the approach distance is near to or smaller than the Compton wavelength only in the microscopic world, so that such effects are not observed in everyday life. We do not therefore need quantum field theory to describe common observations.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The *combined* concepts of quantum field theory and general relativity are required in situations where both conditions are satisfied simultaneously. The necessary approach distance for such situations is calculated by setting $r_S = 2\lambda_C$ (the factor 2 is introduced for simplicity). We find that this is the case when lengths or times are (of the order of)

$$\begin{aligned} l_{Pl} = \sqrt{\hbar G/c^3} &= 1.6 \cdot 10^{-35}\,\text{m, the } \textit{Planck length}, \\ t_{Pl} = \sqrt{\hbar G/c^5} &= 5.4 \cdot 10^{-44}\,\text{s , the } \textit{Planck time}. \end{aligned} \tag{812}$$

Whenever we approach objects at these scales, both general relativity and quantum mechanics play a role, and effects of *quantum gravity* appear. Because the values of the Planck dimensions are extremely small, this level of sophistication is unnecessary in everyday life, in astronomy and even in particle physics.

However, to answer the questions posed at the beginning of the book – why do we live in three dimensions, and why is the proton 1836.15 times heavier than the electron? – we require a precise and complete description of nature. The contradictions between quantum mechanics and general relativity appear to make the search for answers impossible. However, although the unified theory of quantum gravity is not yet complete, we can already get a few glimpses of its implications.

Challenge 1624 s
Ref. 1191

Note that the Planck scales specify one of only two domains of nature where quantum mechanics and general relativity apply simultaneously. (What is the other?) As Planck scales are the easier of the two to study, they provide the best starting point for the following discussion. When Max Planck discovered the existence of those scales, he was interested in them mainly as *natural units of measurement*. However, their importance in nature is much greater. As we will discover, they determine what is called *quantum geometry*.

Farewell to instants of time

> Time is composed of time atoms ... which in fact are indivisible.
>
> Moses Maimonides, twelfth century

The appearance of the quantum of action in the description of motion leads to quantum limits to all measurements. These limits have important consequences at Planck scales. Measurement limits appear most clearly when we investigate the properties of clocks and metre rules. Is it possible to construct a clock that is able to measure time intervals shorter than the Planck time? Surprisingly, the answer is no, even though the time–energy indeterminacy relation $\Delta E \Delta t \geqslant \hbar$ seems to indicate that by making ΔE large enough, we can make Δt arbitrary small.

Ref. 1192, Ref. 1193

Every clock is a device with some moving parts. Parts can be mechanical wheels, particles of matter in motion, changing electrodynamic fields (i.e., photons), or decaying radioactive particles. For each moving component of a clock the indeterminacy principle applies. As explained most clearly by Michael Raymer, the indeterminacy relation for two non-commuting variables describes two different, but related, situations: it makes a statement about standard *deviations* of *separate* measurements on *many* identical systems; and it describes the measurement *precision* for a *joint* measurement on a *single*

Ref. 1194, Ref. 1195
Ref. 1196

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

system. In what follows, we will consider only the second situation.

For a clock to be useful, we need to know both the time and the energy of each hand. Otherwise it would not be a recording device. More generally, a clock must be a classical system. We need the combined knowledge of the non-commuting variables for each moving component of the clock. Let us focus on the component with the largest time indeterminacy Δt. It is evident that the smallest time interval δt that can be measured by a clock is always larger than the quantum limit, i.e., larger than the time indeterminacy Δt for the most 'uncertain' component. Thus we have

$$\delta t \geqslant \Delta t \geqslant \frac{\hbar}{\Delta E} \,, \tag{813}$$

where ΔE is the energy indeterminacy of the moving component, and ΔE must be smaller than the total energy $E = mc^2$ of the component itself.* Furthermore, a clock provides information, so signals have to be able to leave it. Therefore the clock must not be a black hole: its mass m must be smaller than the Schwarzschild mass for its size, i.e., $m \leqslant c^2 l/G$, where l is the size of the clock (neglecting factors of order unity). Finally, for a sensible measurement of the time interval δt, the size l of the clock must be smaller than $c\,\delta t$, because otherwise different parts of the clock could not work together to produce the same time display.** If we combine all these conditions, we get

$$\delta t \geqslant \frac{\hbar G}{c^5 \delta t} \tag{814}$$

or

$$\delta t \geqslant \sqrt{\frac{\hbar G}{c^5}} = t_{\mathrm{Pl}} \,. \tag{815}$$

In summary, from three simple properties of any clock – namely, that it is only a single clock, that we can read its dial, and that it gives sensible read-outs – we conclude that *clocks cannot measure time intervals shorter than the Planck time*. Note that this argument is independent of the nature of the clock mechanism. Whether the clock operates by gravitational, electrical, mechanical or even nuclear means, the limit still applies.***

Ref. 1200 The same conclusion can be reached in other ways. For example, any clock small enough to measure small time intervals necessarily has a certain energy indeterminacy due to the indeterminacy relation. Meanwhile, on the basis of general relativity, any en-

* Physically, this condition means being sure that there is only *one* clock: if $\Delta E > E$, it would be impossible to distinguish between a single clock and a clock–anticlock pair created from the vacuum, or a component together with two such pairs, and so on.

** It is amusing to explore how a clock larger than $c\,\delta t$ would stop working, as a result of the loss of rigidity in its components. Challenge 1625 s

*** Note that gravitation is essential here. The present argument differs from the well-known study on the limitations of clocks due to their mass and their measuring time which was published by Salecker and Wigner and summarized in pedagogical form by Zimmerman. Here, both quantum mechanics and gravity are included, and therefore a different, lower, and more fundamental limit is found. Note also that the discovery of black hole radiation does not change the argument: black hole radiation notwithstanding, measurement devices cannot exist inside black holes. Ref. 1198 Ref. 1199

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ergy density induces a deformation of space-time, and signals from the deformed region
Page 535 arrive with a certain delay due to that deformation. The energy indeterminacy of the source leads to an indeterminacy in the deformation, and thus in the delay. The expres-
Ref. 1189 sion from general relativity for the deformation of the time part of the line element due to a mass m is $\delta t = mG/lc^3$. From the mass–energy relation, we see that an energy spread ΔE produces an indeterminacy Δt in the delay:

$$\Delta t = \frac{\Delta E\, G}{l\, c^5} \,. \tag{816}$$

This determines the precision of the clock. Furthermore, the energy indeterminacy of the clock is fixed by the indeterminacy relation for time and energy $\Delta E \geqslant \hbar/\Delta t$, which is in turn fixed by the precision of the clock. Combining all this, we again find the relation $\delta t \geqslant t_{\mathrm{Pl}}$ for the minimum measurable time.

We are forced to conclude that *in nature there is a minimum time interval.* In other words, *at Planck scales the term 'instant of time' has no theoretical or experimental basis.*

Farewell to points in space

In a similar way, we can deduce that it is impossible to make a metre rule, or any other
Ref. 1201 length-measuring device, that is able to measure lengths shorter than the Planck length. Obviously, we can already deduce this from $l_{\mathrm{Pl}} = c\, t_{\mathrm{Pl}}$, but an independent proof is also possible.

For any length measurement, joint measurements of position and momentum are necessary. The most straightforward way to measure the distance between two points is to put an object at rest at each position. Now, the minimal length δl that can be measured must be larger than the position indeterminacy of the two objects. From the indeterminacy principle it is known that neither object's position can be determined with a precision Δl better than that given by the indeterminacy relation $\Delta l\, \Delta p = \hbar$, where Δp is the momentum indeterminacy. The requirement that there be only one object at each end (avoiding pair production from the vacuum) means that $\Delta p < mc$: together, these requirements give

$$\delta l \geqslant \Delta l \geqslant \frac{\hbar}{mc} \,. \tag{817}$$

Furthermore, the measurement cannot be performed if signals cannot leave the objects; thus, they cannot be black holes. Therefore their masses must be small enough for their Schwarzschild radius $r_{\mathrm{S}} = 2Gm/c^2$ to be less than the distance δl separating them. Again omitting the factor of 2, we get

$$\delta l \geqslant \sqrt{\frac{\hbar G}{c^3}} = l_{\mathrm{Pl}} \,. \tag{818}$$

Another way to deduce this limit reverses the roles of general relativity and quantum theory. To measure the distance between two objects, we have to localize the first object with respect to the other within a certain interval Δx. The corresponding energy indeter-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

minacy obeys $\Delta E = c(c^2m^2 + (\Delta p)^2)^{1/2} \geqslant c\hbar/\Delta x$. However, general relativity shows that a small volume filled with energy changes the curvature of space-time, and thus changes the metric of the surrounding space. For the resulting distance change Δl, compared with empty space, we find the expression $\Delta l \approx G\Delta E/c^4$.

Ref. 1179, Ref. 1189 Ref. 1201, Ref. 1202 Ref. 1203

In short, if we localize the first particle in space with a precision Δx, the distance to a second particle is known only with precision Δl. The minimum length δl that can be measured is obviously larger than either of these quantities; inserting the expression for ΔE, we find again that the minimum measurable length δl is given by the Planck length.

Ref. 1204, Ref. 1205 Ref. 1206

We note that every length measurement requires a joint measurement of position and momentum. This is particularly obvious if we approach a metre ruler to an object, but it is equally true for any other length measurement.

We note that, since the Planck length is the shortest possible length, there can be no observations of quantum-mechanical effects for a situation where the corresponding de Broglie or Compton wavelength is smaller than the Planck length. In proton–proton collisions we observe both pair production and interference effects. In contrast, the Planck limit implies that in everyday, macroscopic situations, such as car–car collisions, we cannot observe embryo–antiembryo pair production and quantum interference effects.

In summary, from two simple properties common to all length-measuring devices, namely that they are discrete and that they can be read, we arrive at the conclusion that *lengths smaller than the Planck length cannot be measured*. Whatever method is used, be it a metre rule or time-of-flight measurement, we cannot overcome this fundamental limit. It follows that *the concept of a 'point in space' has no experimental basis*. In the same way, the concept of an 'event', being a combination of a 'point in space' and an 'instant of time', also loses its meaning for the description of nature.

A simple way to deduce the minimum length using the limit statements which structure this ascent is the following. General relativity is based on a maximum force in nature, or alternatively, on a maximum mass change per time, whose value is given by $\mathrm{d}m/\mathrm{d}t = c^3/4G$. Quantum theory is based on a minimum action in nature, given by $L = \hbar/2$. Since a distance d can be expressed as

Page 471

$$d^2 = \frac{L}{\mathrm{d}m/\mathrm{d}t}\,, \tag{819}$$

one sees directly that a minimum action and a maximum rate of change of mass imply a minimum distance. In other words, quantum theory and general relativity, when put together, imply a minimum distance.

These results are often expressed by the so-called *generalized indeterminacy principle*

Ref. 1207

$$\Delta p \Delta x \geqslant \hbar/2 + f\frac{G}{c^3}(\Delta p)^2 \tag{820}$$

or

$$\Delta p \Delta x \geqslant \hbar/2 + f\frac{l_{\mathrm{Pl}}^2}{\hbar}(\Delta p)^2\,, \tag{821}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where f is a numerical factor of order unity. A similar expression holds for the time–energy indeterminacy relation. The first term on the right-hand side is the usual quantum-mechanical indeterminacy. The second term is negligible for everyday energies, and is significant only near Planck energies; it is due to the changes in space-time induced by gravity at these high energies. You should be able to show that the generalized principle (820) implies that Δx can never be smaller than $f^{1/2} l_{\mathrm{Pl}}$.

Challenge 1626 e

The generalized indeterminacy principle is derived in exactly the same way in which Heisenberg derived the original indeterminacy principle $\Delta p \Delta x \geqslant \hbar/2$, namely by studying the deflection of light by an object under a microscope. A careful re-evaluation of the process, this time including gravity, yields equation (820). For this reason, *all* attempts to unify quantum mechanics and gravity must yield this relation. Indeed, it appears in the theory of canonical quantum gravity, in superstring theory, and in the quantum group approach.

Ref. 1207 Ref. 1208 Ref. 1209 Ref. 1210, Ref. 1211 Ref. 1212

Remember that quantum mechanics begins with the realization that the classical concept of action makes no sense below the value of $\hbar/2$; similarly, unified theories begin with the realization that the classical concepts of time and length make no sense below Planck scales. However, the usual description of space-time does contain such small values: it involves intervals smaller than the smallest measurable one. Therefore, *the continuum description of space-time has to be abandoned* in favour of a more appropriate description.

Ref. 1213

The new indeterminacy relation appearing at Planck scales shows that space-time is not well described as a continuum. Inserting $c\Delta p \geqslant \Delta E \geqslant \hbar/\Delta t$ into equation (820), we get

$$\Delta x \Delta t \geqslant \hbar G/c^4 = t_{\mathrm{Pl}} l_{\mathrm{Pl}} \,, \tag{822}$$

which of course has no counterpart in standard quantum mechanics. This shows that space-time events do not exist. A final way to convince oneself that points have no meaning is to observe that a point is an entity with vanishing volume; however, the minimum volume possible in nature is the Planck volume $V_{\mathrm{Pl}} = l_{\mathrm{Pl}}^3$.

Space-time points are idealizations of events – but this idealization is inadequate. The use of the concept of 'point' is similar to the use of the concept of 'ether' a century ago: it is impossible to detect, and it is only useful as a convenient notion until a way to describe nature without it has been found. Like the 'aether', 'points' also lead reason astray.

In other words, the Planck units not only provide natural units; they also provide – within a factor of order one – the *limit* values of space and time intervals.

Farewell to the space-time manifold

The consequences of the Planck limits for measurements of time and space can be taken much further. It is often said that given any two points in space or any two instants of time, there is always a third in between. Physicists sloppily call this property continuity, while mathematicians call it denseness. However, at Planck scales this property cannot hold, since there are no intervals smaller than the Planck time. Thus points and instants are not dense, and *between two points there is not always a third.* This means that *space and time are not continuous.* Of course, at large scales they are – approximately – continuous, in the same way that a piece of rubber or a liquid seems continuous at everyday scales,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

even though it is not at a small scale.

All paradoxes resulting from the infinite divisibility of space and time, such as Zeno's argument on the impossibility of distinguishing motion from rest, or the Banach–Tarski paradox, are now avoided. We can dismiss them straight away because of their incorrect premises concerning the nature of space and time.

But let us go on. Special relativity, quantum mechanics and general relativity all rely on the idea that time can be defined for all points of a given reference frame. However, two clocks a distance l apart cannot be synchronized with arbitrary precision. Since the distance between two clocks cannot be measured with an error smaller than the Planck length l_{Pl}, and transmission of signals is necessary for synchronization, it is not possible to synchronize two clocks with a better precision than $l_{\mathrm{Pl}}/c = t_{\mathrm{Pl}}$, the Planck time. So use of a single time coordinate for a whole reference frame is only an approximation, and cannot be maintained in any precise description of nature.

Moreover, since the time difference between events can only be measured within a Planck time, for two events distant in time by this order of magnitude, it is not possible to say with complete certainty which of the two precedes the other. This is an important fact. If events cannot be ordered, then the very concept of time, which was introduced into physics to describe sequences, makes no sense at Planck scales. In other words, after dropping the idea of a common time coordinate for a complete frame of reference, we are forced to drop the idea of time at a single 'point' as well. The concept of 'proper time' loses its meaning at Planck scales.

Ref. 1214

Similar arguments show that limitations on length measurements imply that we cannot speak of continuous space, except in an approximate sense. As a result of the lack of measurement precision at Planck scales, the concepts of spatial order, translation invariance, isotropy of the vacuum and global coordinate systems have no experimental basis.

But there is more to come. The very existence of a minimum length contradicts the theory of special relativity, in which it is shown that lengths undergo Lorentz contraction when the frame of reference is changed. There is only one conclusion: special relativity cannot be correct at very small distances. Thus, *space-time is neither Lorentz-invariant nor diffeomorphism-invariant nor dilatation-invariant*. All the symmetries that are at the basis of special and general relativity are only approximately valid at Planck scales.

The imprecision of measurement implies that most familiar concepts used to describe spatial relations become useless. For example, the concept of a *metric* loses its usefulness at Planck scales, since distances cannot be measured with precision. So it is impossible to say whether space is flat or curved. The impossibility of measuring lengths exactly is equivalent to fluctuations of the curvature, and thus of gravity.

Ref. 1201, Ref. 1215

Even the number of spatial dimensions makes no sense at Planck scales. Let us remind ourselves how to determine this number experimentally. One possible way is to determine how many points we can choose in space such that all the distances between them are equal. If we can find at most n such points, the space has $n-1$ dimensions. But if reliable length measurement at Planck scales is not possible, there is no way to determine reliably the number of dimensions of space with this method.

Another way to check for three spatial dimensions is to make a knot in a shoe string and glue the ends together: since it stays knotted, we know that space has three dimensions, because there is a mathematical theorem that in spaces with greater or fewer than

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

three dimensions, knots do not exist. Again, at Planck scales, we cannot say whether a string is knotted or not, because measurement limits at crossings make it impossible to say which strand lies above the other.

There are many other methods for determining the dimensionality of space.* In all cases, the definition of dimensionality is based on a precise definition of the concept of neighbourhood. At Planck scales, however, length measurements do not allow us to say whether a given point is inside or outside a given region. In short, whatever method we use, the lack of precise length measurements means that *at Planck scales, the dimensionality of physical space is not defined.* It should not, therefore, come as a surprise that when we *approach* these scales, we may get a scale-dependent answer for the number of dimensions, which may be different from three.

The reasons for the problems with space-time become most evident when we remember Euclid's well-known definition: 'A point is that which has no part.' As Euclid clearly understood, a *physical* point, as an idealization of position, cannot be defined without some measurement method. *Mathematical* points, however, can be defined without reference to a metric. They are just elements of a set, usually called a 'space'. (A 'measurable' or 'metric' space is a set of points equipped with a measure or a metric.)

Ref. 1216

In the case of physical space-time, the concepts of measure and of metric are more fundamental than that of a point. Confusion between physical and mathematical space and points arises from the failure to distinguish a mathematical metric from a physical length measurement.**

Perhaps the most beautiful way to make this point is the Banach–Tarski theorem, which clearly shows the limits of the concept of volume. The theorem states that a sphere made up of *mathematical points* can be cut into five pieces in such a way that the pieces can be put together to form two spheres, each of the same volume as the original one. However, the necessary 'cuts' are infinitely curved and detailed: the pieces are wildly disconnected. For physical matter such as gold, unfortunately – or fortunately – the existence of a minimum length, namely the atomic distance, makes it impossible to perform such a cut. For vacuum, the puzzle reappears. For example, the energy of zero-point fluctuations is given by the density times the volume; following the Banach–Tarski theorem, the zero-point energy content of a single sphere should be equal to the zero-point energy of two similar spheres each of the same volume as the original one. The paradox is

Page 60
Ref. 1217

* For example, we can determine the dimension using only the topological properties of space. If we draw a so-called *covering* of a topological space with open sets, there are always points that are elements of several sets of the covering. Let p be the maximal number of sets of which a point can be an element in a given covering. The minimum value of p over all possible coverings, minus one, gives the dimension of the space.

In fact, if physical space is not a manifold, the various methods for determining the dimensionality may give different answers. Indeed, for linear spaces without norm, the dimensionality cannot be defined in a unique way. Different definitions (fractal dimension, Lyapunov dimension, etc.) are possible.

** Where does the incorrect idea of continuous space-time have its roots? In everyday life, as well as in physics, space-time is a book-keeping device introduced to describe observations. Its properties are extracted from the properties of observables. Since observables can be added and multiplied, like numbers, we infer that they can take continuous values, and, in particular, arbitrarily small values. It is then possible to define points and sets of points. A special field of mathematics, topology, shows how to start from a set of points and construct, with the help of neighbourhood relations and separation properties, first a *topological space*, then, with the help of a metric, a *metric space*. With the appropriate compactness and connectedness relations, a *manifold*, characterized by its dimension, metric and topology, can be constructed.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

resolved by the Planck length, which provides a fundamental length scale even for vacuum, thus making infinitely complex cuts impossible. Therefore, the concept of volume is only well defined at Planck scales if a minimum length is introduced.

To sum up, *physical space-time cannot be a set of mathematical points.* But there are more surprises. At Planck scales, since both temporal and spatial order break down, there is no way to say if the distance between two nearby space-time regions is space-like or time-like. *At Planck scales, time and space cannot be distinguished from each other.*

In addition, we cannot state that the topology of space-time is fixed, as general relativity implies. The topology changes mentioned above that are required for particle reactions do become possible. In this way another of the contradictions between general relativity and quantum theory is resolved.

In summary, space-time at Planck scales is not continuous, not ordered, not endowed with a metric, not four-dimensional, and not made up of points. It satisfies none of the defining properties of a manifold.* We conclude that *the concept of a space-time manifold has no justification at Planck scales.* This is a strong result. Even though both general relativity and quantum mechanics use continuous space-time, the combined theory does not.

> There is nothing in the world but matter in motion, and matter in motion cannot move otherwise than in space and time.
>
> Lenin

Farewell to observables and measurements

If space and time are not continuous, no quantities defined as derivatives with respect to space or time are precisely defined. Velocity, acceleration, momentum, energy and so on are only well defined under the assumption of continuity. That important tool, the evolution equation, is based on derivatives and can thus no longer be used. Therefore the Schrödinger and Dirac equations lose their basis. Concepts such as 'derivative', 'divergence-free' and 'source free' lose their meaning at Planck scales.

In fact, all physical observables are defined using length and time measurements. Each physical unit is a product of powers of length and time (and mass) units. (In the SI system, electrical quantities have a separate base quantity, the ampere, but the argument still holds: the ampere is itself defined in terms of a force, which is measured using the three base units of length, time and mass.) Since time and length are not continuous, *at Planck scales, observables cannot be described by real numbers.*

In addition, if time and space are not continuous, the usual expression for an observable field, $A(t, x)$, does not make sense: we have to find a more appropriate description. *Physical fields cannot exist at Planck scales.*

The consequences for quantum mechanics are severe. It makes no sense to define multiplication of observables by real numbers, but only by a discrete set of numbers. Among other implications, this means that observables do not form a linear algebra. *Observables are not described by operators at Planck scales.*

But quantum mechanics is based on the superposition principle. Without it, everything comes crumbling down. In particular, the most important observables are the

* A manifold is what looks *locally* like a Euclidean space. The exact definition can be found in Appendix B.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

gauge potentials. Since they do not form an algebra, *gauge symmetry is not valid at Planck scales*. Even innocuous-looking expressions such as $[x_i, x_j] = 0$ for $x_i \neq x_j$, which are at the root of quantum field theory, become meaningless at Planck scales. Since at those scales the superposition principle cannot be backed up by experiment, even the famous Wheeler–DeWitt equation, often assumed to describe quantum gravity, cannot be valid.

Similarly, permutation symmetry is based on the premise that we can distinguish two points by their coordinates, and then exchange particles between those locations. As we have just seen, this is not possible if the distance between the two particles is very small. We conclude that *permutation symmetry has no experimental basis at Planck scales*.

Even discrete symmetries, like charge conjugation, space inversion and time reversal, cannot be correct in this domain, because there is no way to verify them exactly by measurement. *CPT symmetry is not valid at Planck scales.*

Finally we note that all types of scaling relations break down at small scales. As a result, *renormalization symmetry is also lost at Planck scales.*

All these results are consistent: if there are no symmetries at Planck scales, there are also no observables, since physical observables are representations of symmetry groups. In fact, the limitations on time and length measurements imply that *the concept of measurement has no significance at Planck scales*.

Can space-time be a lattice? – A glimpse of quantum geometry

Ref. 1218 Ref. 1219 Ref. 1220 Ref. 1221 Ref. 1222

Discrete models of space-time have been studied since the 1940s. Recently, the idea that space-time could be described as a lattice – like a crystal – has been explored most notably by David Finkelstein and by Gerard 't Hooft. The idea of space-time as a lattice is based on the idea that, if there is a minimum distance, then all distances are multiples of this minimum. It is generally agreed that, in order to get an isotropic and homogeneous situation for large, everyday scales, the structure of space-time cannot be periodic, but must be random. In fact, any fixed structure to space-time would violate the result that there are no lengths smaller than the Planck length: as a result of the Lorentz contraction, any moving observer would find lattice distances smaller than the Planck value. Worse still, the lattice idea conflicts with general relativity, in particular with the diffeomorphism-invariance of the vacuum. Finally, where would a particle be during the jump from one lattice point to the next?

Thus, in summary, space-time cannot be a lattice. A minimum distance does exist in nature; however, we cannot hope that all other distances are simple multiples of it. We will discover more evidence for this negative conclusion later on.

If space-time is not a set of points or events, it must be something else. We have three hints at this stage. The first step necessary to improve our description of motion is the recognition that abandoning 'points' means abandoning the *local* description of nature. Both quantum mechanics and general relativity assume that the phrase 'observable at a point' has a precise meaning. Because it is impossible to describe space as a manifold, this expression is no longer useful. The unification of general relativity and quantum physics forces the adoption of a *non-local* description of nature at Planck scales.

The existence of a minimum length implies that there is no way to physically distinguish between locations that are even closer together. We are tempted to conclude that *no* pair of locations can be distinguished, even if they are one metre apart, since on any

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

path joining two points, no two locations that are close together can be distinguished. The problem is similar to the question about the size of a cloud or of an atom. If we measure water density or electron density, we find non-vanishing values at any distance from the centre of the cloud or the atom; however, an effective size can still be defined, because it is very unlikely that the effects of the presence of a cloud or of an atom can be seen at distances much larger than this effective size. Similarly, we can guess that two points in space-time at a macroscopic distance from each other can be distinguished because the probability that they will be confused drops rapidly with increasing distance. In short, we are thus led to a *probabilistic* description of space-time. Space-time becomes a macroscopic observable, a *statistical* or *thermodynamic limit* of some microscopic entities.

We note that a fluctuating structure for space-time would also avoid the problems of fixed structures with Lorentz invariance. This property is of course compatible with a statistical description. In summary, the experimental observations of special relativity – Lorentz invariance, isotropy and homogeneity – together with the notion of a minimum distance, point towards a description of space-time as *fluctuating*. Research efforts in quantum gravity, superstring theory and quantum groups have independently confirmed that a probabilistic and non-local description of space-time at Planck scales, resolves the contradictions between general relativity and quantum theory. This is our first result on quantum geometry. To clarify the issue, we have to turn to the concept of the particle.

Ref. 1223

Farewell to particles

In every example of motion, some object is involved. One of the important discoveries of the natural sciences was that all objects are composed of small constituents, called *elementary particles*. Quantum theory shows that all composite, non-elementary objects have a finite, non-vanishing size. This property allows us to determine whether a particle is elementary or not. If it behaves like a point particle, it is elementary. At present, only the leptons (electron, muon, tau and the neutrinos), the quarks and the radiation quanta of the electromagnetic, weak and strong nuclear interactions (the photon, the W and Z bosons, and the gluons) have been found to be elementary. A few more elementary particles are predicted by various refinements of the standard model. Protons, atoms, molecules, cheese, people, galaxies and so on are all composite, as shown in Table 121. Elementary particles have vanishing size and are characterized by their spin and their mass.

Page 1290

Page 1400

Although the definition of 'elementary particle' as point particle is all we need in the following argument, it is not complete. It seems to leave open the possibility that future experiments could show that electrons or quarks are not elementary. This is not so! In fact, any particle smaller than its own Compton wavelength is elementary. If it were composite, there would be a lighter particle inside it, which would have a larger Compton wavelength than the composite particle. This is impossible, since the size of a composite particle must be larger than the Compton wavelength of its components. (The alternative possibility that all components are heavier than the composite does not lead to satisfying physical properties: for example, it leads to intrinsically unstable components.)

Ref. 1224

The *size* of an object, such as those given in Table 121, is defined as the length at which differences from point-like behaviour are observed. The size d of an object is determined by measuring how it scatters a beam of probe particles. For example, the radius of the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 599 Andrei Sakharov (1921–1989)

atomic nucleus was determined for the first time in Rutherford's experiment using alpha particle scattering. In daily life as well, when we look at objects, we make use of scattered photons. In general, in order for scattering to be useful, the effective wavelength $\lambda = \hbar/mv$ of the probe must be smaller than the object size d to be determined. We thus need $d > \lambda = \hbar/mv \geqslant \hbar/mc$. In addition, in order for a scattering experiment to be possible, the object must not be a black hole, since, if it were, it would simply swallow the approaching particle. This means that its mass m must be smaller than that of a black hole of the same size; in other words, from equation (810) we must have $m < dc^2/G$. Combining this with the previous condition we get

$$d > \sqrt{\frac{\hbar G}{c^3}} = l_{\mathrm{Pl}} \,. \tag{823}$$

In other words, there is no way to observe that an object is smaller than the Planck length. Thus, in principle *there is thus no way to deduce from observations that a particle is point-like*. In fact, the term 'point particle' makes no sense at all! Of course, there is a relation between the existence of a minimum length for empty space and the existence of a minimum length for objects. If the term 'point of space' is meaningless, then the term 'point particle' is also meaningless. As in the case of time, the lower limit on length results from the combination of quantum theory and general relativity.*

The size d of any elementary particle must by definition be smaller than its own (reduced) Compton wavelength $\hbar/mc$. Moreover, the size of a particle is always larger than the Planck length: $d > l_{\mathrm{Pl}}$. Combining these two requirements and eliminating the size d, we get a constraint on the mass m of any elementary particle, namely

$$m < \frac{\hbar}{c\, l_{\mathrm{Pl}}} = \sqrt{\frac{\hbar c}{G}} = m_{\mathrm{Pl}} = 2.2 \cdot 10^{-8}\,\mathrm{kg} = 1.2 \cdot 10^{19}\,\mathrm{GeV/c^2} \,. \tag{824}$$

The limit m_{Pl}, the so-called *Planck mass*, corresponds roughly to the mass of a human embryo that is ten days old, or equivalently, to that of a small flea. In short, *the mass of any elementary particle must be smaller than the Planck mass.* This fact was already

* The existence of a minimum size for a particle has nothing to do with the impossibility, in quantum theory, of localizing a particle to within less than its Compton wavelength.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 1225 noted as 'well known' by Andrei Sakharov* in 1968; he explains that these hypothetical particles are sometimes called 'maximons'. And indeed, the known elementary particles all have masses well below the Planck mass. (In fact, the question why their masses are so very much smaller than the Planck mass is one of the most important questions of high-energy physics. We will come back to it.)

There are many other ways to arrive at the mass limit for particles. For example, in order to measure mass by scattering – and that is the only way for very small objects – the Compton wavelength of the scatterer must be larger than the Schwarzschild radius; otherwise the probe will be swallowed. Inserting the definitions of the two quantities and neglecting the factor 2, we again get the limit $m < m_{\mathrm{Pl}}$. (In fact it is a general property of descriptions of nature that a minimum space-time interval leads to an upper limit for
Ref. 1226 masses of elementary particles.) The importance of the Planck mass will become even clearer shortly.

Another property connected with the size of a particle is its electric dipole moment. This describes the deviation of its charge distribution from spherical. Some predictions from the standard model of elementary particles give as an *upper* limit for the electron
Ref. 1227 dipole moment d_e a value of

$$\frac{|d_e|}{e} < 10^{-39}\,\mathrm{m}\,, \tag{825}$$

where e is the charge of the electron. This value is ten thousand times smaller than the Planck length l_{Pl}. Since the Planck length is the smallest possible length, we seem to
Ref. 1228 have a contradiction here. However, a more careful, recent prediction from the standard model only states

$$\frac{|d_e|}{e} < 3 \cdot 10^{-21}\,\mathrm{m}\,, \tag{826}$$

which is not in contradiction with our minimal length. The issue is still not settled. We will see below that these predictions are expected to be experimentally testable in the foreseeable future.

Planck scales have other strange consequences. In quantum field theory, the difference between a virtual particle and a real particle is that a real particle is 'on shell', obeying $E^2 = m^2c^4 + p^2c^2$, whereas a virtual particle is 'off shell'. Because of the fundamental limits of measurement precision, *at Planck scales we cannot determine whether a particle is real or virtual.*

That is not all. Antimatter can be described as matter moving backwards in time. Since the difference between backwards and forwards cannot be determined at Planck scales, *matter and antimatter cannot be distinguished at Planck scales.*

Particles are also characterized by their spin. Spin describes two properties of a particle: its behaviour under rotations (and if the particle is charged, its behaviour in magnetic fields) and its behaviour under particle exchange. The wave function of a particle with

* Andrei Dmitrievich Sakharov, Soviet nuclear physicist (1921–1989). One of the keenest thinkers in physics, Sakharov, among others, invented the Tokamak, directed the construction of nuclear bombs, and explained the matter–antimatter asymmetry of nature. Like many others, he later campaigned against nuclear weapons, a cause for which he was put into jail and exile, together with his wife, Yelena Bonner. He received the Nobel Peace Prize in 1975.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

spin 1 remains invariant under a rotation of 2π, whereas that of a particle with spin 1/2 changes sign. Similarly, the combined wave function of two particles with spin 1 does not change sign under exchange of particles, whereas for two particles with spin 1/2 it does.

We see directly that both transformations are impossible to study at Planck scales. Given the limit on position measurements, the position of a rotation axis cannot be well defined, and rotations become impossible to distinguish from translations. Similarly, positional imprecision makes it impossible to determine of precise separate positions for exchange experiments. In short, *at Planck scales, spin cannot be defined, and fermions cannot be distinguished from bosons*, or, phrased differently, *matter cannot be distinguished from radiation*. We can thus easily see that supersymmetry, a unifying symmetry between bosons and fermions, somehow becomes natural at Planck scales.

But let us now move on to the main property of elementary particles.

Farewell to mass

The Planck mass divided by the Planck volume, i.e., the Planck density, is given by

$$\rho_{\text{Pl}} = \frac{c^5}{G^2\hbar} = 5.2 \cdot 10^{96}\,\text{kg/m}^3 \tag{827}$$

and is a useful concept in the following. One way to measure the (gravitational) mass M enclosed in a sphere of size R, and thus (roughly) of volume R^3, is to put a test particle in orbit around it at that same distance R. Universal gravitation then gives for the mass M the expression $M = Rv^2/G$, where v is the speed of the orbiting test particle. From $v < c$, we deduce that $M < c^2R/G$; since the minimum value for R is the Planck distance, we get (again neglecting factors of order unity) a limit for the mass density ρ, namely

Challenge 1627 e

$$\rho < \rho_{\text{Pl}} \,. \tag{828}$$

In other words, *the Planck density is the maximum possible value for mass density*.

Interesting things happen when we try to determine the error ΔM of a mass measurement in a Planck volume. Let us return to the mass measurement by an orbiting probe. From the relation $GM = rv^2$ we deduce by differentiation that $G\Delta M = v^2\Delta r + 2vr\Delta v > 2vr\Delta v = 2GM\Delta v/v$. For the error Δv in the velocity measurement we have the indeterminacy relation $\Delta v \geqslant \hbar/m\Delta r + \hbar/MR \geqslant \hbar/MR$. Inserting this in the previous inequality, and again forgetting the factor of 2, we find that the mass measurement error ΔM of a mass M enclosed in a volume of size R is subject to the condition

$$\Delta M \geqslant \frac{\hbar}{cR} \,. \tag{829}$$

Note that for everyday situations, this error is extremely small, and other errors, such as the technical limits of the balance, are much larger.

To check this result, we can explore another situation. We even use relativistic expressions, in order to show that the result does not depend on the details of the situation or the approximations. Imagine having a mass M in a box of size R, and weighing the box

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

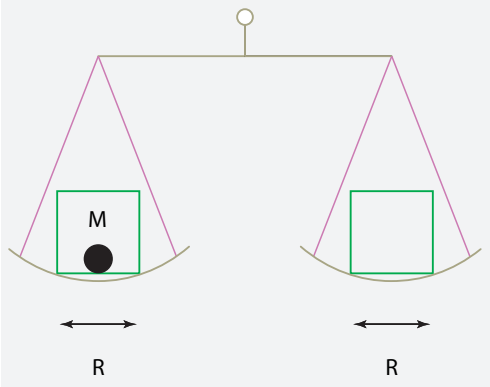

FIGURE 600 A *Gedanken experiment* showing that at Planck scales, matter and vacuum cannot be distinguished

with a scale. (It is assumed that either the box is massless or that its mass is subtracted by the scale.) The mass error is given by $\Delta M = \Delta E/c^2$, where ΔE is due to the indeterminacy in the kinetic energy of the mass inside the box. Using the expression $E^2 = m^2c^4 + p^2c^2$, we get that $\Delta M \geqslant \Delta p/c$, which again reduces to equation (829). Now that we are sure of the result, let us continue.

From equation (829) we deduce that for a box of Planck dimensions, the mass measurement *error* is given by the Planck mass. But from above we also know that the mass that can be put inside such a box must not be larger than the Planck mass. Therefore, for a box of Planck dimensions, the mass measurement *error* is larger than (or at best equal to) the mass contained in it: $\Delta M \geqslant M_{\text{Pl}}$. In other words, if we build a balance with two boxes of Planck size, one empty and the other full, as shown in Figure 600, nature cannot decide which way the balance should hang! Note that even a repeated or a continuous measurement will not resolve the situation: the balance will change inclination at random, staying horizontal on average.

The argument can be rephrased as follows. The largest mass that we can put in a box of size R is a black hole with a Schwarzschild radius of the same value; the smallest mass present in such a box – corresponding to what we call a vacuum – is due to the indeterminacy relation and is given by the mass with a Compton wavelength that matches the size of the box. In other words, inside any box of size R we have a mass m, the limits of which are given by:

$$\text{(full box)}\ \frac{c^2R}{G} > m > \frac{\hbar}{cR}\ \text{(empty box)}\ . \tag{830}$$

We see directly that for sizes R of the order of the Planck scale, the two limits coincide; in other words, we cannot distinguish a full box from an empty box in that case.

To be sure of this strange result, we check whether it also occurs if, instead of measuring the gravitational mass, as we have just done, we measure the inertial mass. The inertial mass for a small object is determined by touching it: physically speaking, by performing a scattering experiment. To determine the inertial mass inside a region of size R, a probe must have a wavelength smaller than R, and a correspondingly high energy. A high energy means that the probe also attracts the particle through gravity. (We thus

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

find the intermediate result that *at Planck scales, inertial and gravitational mass cannot be distinguished.* Even the balance experiment shown in Figure 600 illustrates this: at Planck scales, the two types of mass are always inextricably linked.) Now, in any scattering experiment, for example in a Compton-type experiment, the mass measurement is performed by measuring the wavelength change $\delta\lambda$ of the probe before and after the scattering. The mass indeterminacy is given by

$$\frac{\Delta M}{M} = \frac{\Delta\delta\lambda}{\delta\lambda} \,. \tag{831}$$

In order to determine the mass in a Planck volume, the probe has to have a wavelength of the Planck length. But we know from above that there is always a minimum wavelength indeterminacy, given by the Planck length l_{Pl}. In other words, for a Planck volume the mass error is always as large as the Planck mass itself: $\Delta M \geqslant M_{\mathrm{Pl}}$. Again, this limit is a direct consequence of the limit on length and space measurements.

This result has an astonishing consequence. In these examples, the measurement error is independent of the mass of the scatterer: it is the same whether or not we start with a situation in which there is a particle in the original volume. We thus find that in a volume of Planck size, it is impossible to say whether or not there is something there when we probe it with a beam!

In short, all arguments lead to the same conclusion: *vacuum, i.e., empty space-time, cannot be distinguished from matter at Planck scales.* Another common way to express this state of affairs is to say that when a particle of Planck energy travels through space it will be scattered by the fluctuations of space-time itself, as well as by matter, and the two cases are indistinguishable. These surprising results rely on a simple fact: whatever definition of mass we use, it is always measured via combined length and time measurements. (This is even the case for normal weighing scales: mass is measured by the displacement of some part of the machine.) The error in these measurements makes it *impossible to distinguish vacuum from matter.*

We can put this result in another way. On the one hand, if we measure the mass of a piece of vacuum of size R, the result is always at least $\hbar/cR$: there is no possible way to find a perfect vacuum in an experiment. On the other hand, if we measure the mass of a particle, we find that the result is size-dependent: at Planck scales it approaches the Planck mass for every type of particle, be it matter or radiation.

To use another image, when two particles approach each other to a separation of the order of the Planck length, the indeterminacy in the length measurements makes it impossible to say whether there is something or nothing between the two objects. In short, *matter and vacuum are interchangeable at Planck scales*. This is an important result: since mass and empty space-time cannot be differentiated, we have confirmed that they are made of the same 'fabric'. This idea, already suggested above, is now common to all attempts to find a unified description of nature.

This approach is corroborated by attempts to apply quantum mechanics in highly curved space-time, where a clear distinction between vacuum and particles is impossible, as shown by Fulling–Davies–Unruh radiation. Any accelerated observer, and any observer in a gravitational field, detects particles hitting him, even if he is in a vacuum. The effect shows that for curved space-time the idea of vacuum as particle-free space does not work. Since at Planck scales it is impossible to say whether or not space is flat,

Ref. 1229
Page 1192

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

it is impossible to say whether it contains particles or not.

Curiosities and fun challenges on Planck scales

Observers are made of matter. They are thus biased, because they take a specific standpoint. But at Planck scale, vacuum, radiation and matter cannot be distinguished. Two results follow: first, only at those scales would a description be free of any bias in favour of matter; but secondly, observers do not exist at all at Planck energy.

* *

By the standards of particle physics, the Planck energy is rather large. Suppose we wanted to impart this amount of energy to protons using a particle accelerator. How large would that accelerator have to be? But by the standards of everyday life, the Planck energy is rather small. Measured in litres of gasoline, how much fuel does it correspond to?

Challenge 1628 s
Challenge 1629 s

* *

The usual concepts of matter and of radiation are not applicable at Planck scales. Usually, it is assumed that matter and radiation are made up of interacting elementary particles. The concept of an elementary particle implies an entity that is discrete, point-like, real and not virtual, has a definite mass and a definite spin, is distinct from its antiparticle, and, most of all, is distinct from vacuum, which is assumed to have zero mass. All these properties are lost at Planck scales. *At Planck scales, the concepts of 'mass', 'vacuum', 'elementary particle', 'radiation' and 'matter' do not make sense.*

* *

Do the large errors in mass measurements imply that mass can be negative at Planck energy?

Challenge 1630 s

* *

We now have a new answer to the old question: why is there something rather than nothing? At Planck scales, there is *no difference* between something and nothing. We can now honestly say about ourselves that we are made of nothing.

* *

If vacuum cannot be distinguished from matter or radiation, then it is incorrect to claim that the universe appeared from nothing. Thus, the naive idea of creation is a logical impossibility, resulting from a lack of imagination.

* *

Special relativity implies that no length or energy can be invariant. Since we have come to the conclusion that the Planck energy and the Planck length are invariant, there must be deviations from Lorentz invariance at high energy. Can you imagine what the effects would be? What kind of experiment could measure them? If you find an answer, publish it! Numerous attempts are being explored. We will return to the issue later on, with some interesting insights.

Challenge 1631 r
Ref. 1230

* *

Quantum mechanics alone gives, via the Heisenberg indeterminacy relation, a lower limit to the *spread* of measurements, but, strangely enough, not on their *precision*, i.e., not on the number of significant digits. Jauch gives an example: atomic lattice constants are known to a much higher precision than the positional indeterminacy of single atoms inside the crystal.

Ref. 1231

Ref. 1211

It is sometimes claimed that measurement indeterminacies smaller than the Planck values are possible for large enough numbers of particles. Can you show why this is incorrect, at least for space and time?

Challenge 1632 ny

* *

Of course, the idea that vacuum is not empty is not new. More than two thousand years ago, Aristotle argued for a filled vacuum, although his arguments were incorrect as seen from today's perspective. In the fourteenth century there was much discussion on whether empty space was composed of indivisible entities, but the debate died down again later.

* *

A Planck-energy particle falling in a gravitational field would gain energy. But the Planck energy is the highest energy in nature. What does this apparent contradiction imply?

Challenge 1633 s

* *

One way to generalize the results presented here is to assume that, at Planck energy, nature is *event-symmetric*, i.e., symmetric under exchange of any two events. This idea, developed by Phil Gibbs, provides an additional formulation of the strange behaviour of nature at extreme scales.

Ref. 1200

* *

Because there is a minimum length in nature, so-called naked singularities do not exist. The issue, hotly debated for decades in the twentieth century, thus becomes uninteresting.

Page 617

* *

Since mass density, and thus energy density, are limited, any object of finite volume has only a finite number of degrees of freedom. Calculation of the entropy of black holes has already shown us that entropy values are always finite. This implies that perfect baths do not exist. Baths play an important role in thermodynamics (which must therefore be viewed as only an approximation), and also in recording and measuring devices: when a device measures, it switches from a neutral state to a state in which it shows the result of the measurement. In order not to return to the neutral state, the device must be coupled to a bath. Without a bath, a reliable measuring device cannot exist. In short, perfect clocks and length-measuring devices do not exist, because nature puts a limit on their storage ability.

Page 1206

Ref. 1232

* *

If vacuum and matter cannot be distinguished, we cannot distinguish between objects

Page 32 and their environment. However, this was one the starting points of our journey. Some interesting adventures still await us!

* *

We have seen earlier that characterizing nature as made up of particles and vacuum creates problems when interactions are included, since on the one hand interactions are the difference between the parts and the whole, while on the other hand, according to quan-
Page 855 tum theory, interactions are exchanges of particles. This apparent contradiction can be used to show either that vacuum and particles are not the only components of nature, or that something is counted twice. However, since matter and space-time are both made of the same 'stuff,' the contradiction is resolved.

* *

Challenge 1634 d Is there a smallest possible momentum? And a smallest momentum error?

* *

There is a maximum acceleration in nature. Can you deduce the value of this so-called
Challenge 1635 s Planck acceleration? Does it require quantum theory?

* *

Given that time becomes an approximation at Planck scales, can we still ask whether nature is deterministic?

Let us go back to the beginning. We can define time, because in nature change is not random, but gradual. What is the situation now that we know that time is only approximate? Is non-gradual change possible? Is energy conserved? In other words, are surprises possible?

It is correct to say that time is not defined at Planck scales, and that therefore that determinism is an undefinable concept, but it is not a satisfying answer. What happens at 'everyday' scales? One answer is that at our everyday scales, the probability of surprises is so small that the world indeed is effectively deterministic. Another answer is that nature is not deterministic, but that the departure from determinism is not measurable, since every measurement and observation, by definition, *implies* a deterministic world. The lack of surprises would be due to the limitations of our human nature – more precisely, of our senses and brain. A third answer is that the lack of surprises is only apparent, and that we have just not experienced them yet.

Challenge 1636 s Can you imagine any other possibility? In truth, it is not possible to give an answer at this point. But we need to keep the alternatives in mind. We have to continue searching, considering carefully every step we take.

* *

If matter and vacuum cannot be distinguished, then each has the properties of the other. For example, since space-time is an extended entity, matter and radiation are also extended entities. Furthermore, as space-time is an entity that reaches the borders of the system under scrutiny, particles must also do so. This is our first hint at the *extension of matter*; we will examine this argument in more detail later.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Vacuum has zero mass density at large scales, but Planck mass density at Planck scales. Cosmological measurements show that the universe is flat or almost flat at large scales: in other words, its energy density is low. In contrast, quantum field theory maintains that vacuum has a high energy density (or mass density) at small scales. Since mass is scale-dependent, both viewpoints are right. This hints at a solution to what is usually called the cosmological constant problem. The contradiction is only apparent. We will have more to say about this issue later on.

Ref. 1233

* *

Challenge 1637 s When *can* matter and vacuum be distinguished? At what energy?

* *

If matter and vacuum cannot be distinguished, there is a lack of information, which implies an intrinsic basic entropy associated with any part of the universe. We will come back to this topic shortly, when we discuss the entropy of black holes.

* *

Can we distinguish between a liquid and a gas by looking at a single atom? No, only by looking at many. Similarly, we cannot distinguish between matter and vacuum by looking at one point, but only by looking at many. We must always *average*. However, even averaging is not completely successful. Distinguishing matter from vacuum is like distinguishing clouds from the clear sky: like clouds, matter has no precise boundary.

* *

We have found that space and time are neither continuous nor made up of points. Indeed, the combination of relativity and quantum theory makes this impossible. In order to proceed in our ascent of Motion Mountain, we need to leave behind the usual concept of space-time. *At Planck scales, the concepts of 'space-time point' and 'mass point' are not applicable.*

Farewell to the big bang

A minimum length, or equivalently,* a minimum action, both imply that there is a maximum curvature for space-time. Curvature can be measured in several ways: for example, surface curvature is an inverse area. Within a factor of order one, we find

$$K < \frac{c^3}{G\hbar} = 0.39 \cdot 10^{70}\,\mathrm{m}^{-2} \tag{832}$$

as a limit for the surface curvature K in nature. In other words, the universe has never been a point, never had zero age, never had infinite density, and never had infinite curvature. It is not difficult to get a similar limit for temperature or any other physical quantity.

Challenge 1638 s

In short, since events do not exist, the big bang cannot have been an event. There never was an initial singularity or a beginning of the universe.

* The big bang section was added in summer 2002.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The baggage left behind

In this rapid journey, we have destroyed all the experimental pillars of quantum theory: the superposition principle, space-time symmetry, gauge symmetry, renormalization symmetry and permutation symmetry. We also have destroyed the foundations of general relativity, namely the concepts of the space-time manifold, fields, particles and mass. We have even seen that matter and space-time cannot be distinguished. All these conclusions can be drawn in a simpler manner, by using the minimum action of quantum theory and the maximum force of general relativity.

Page 1458

It seems that we have lost every concept used for the description of motion, and thus made its description impossible. We naturally ask whether we can save the situation.

First of all, since matter and radiation are not distinguishable from vacuum, the quest for unification in the description of elementary particles is correct and necessary.

Moreover, since the concepts of 'mass', 'time' and 'space' cannot be distinguished from each other, a new, *single* entity is necessary to define both particles and space-time. At the beginning of the twenty-first century, three approaches are being pursued to find out more about this new entity. The first, quantum gravity – especially the use of the loop representation and Ashtekar's new variables – starts by generalizing *space-time symmetry*. The second, string theory, starts by generalizing *gauge symmetries* and interactions. The third, using algebraic quantum groups, looks for generalized *permutation symmetries*. We will describe these approaches in more detail later on.

Ref. 1185 Ref. 1186 Ref. 1187

Before we go on, however, we should check what we have deduced so far against experiment.

SOME EXPERIMENTAL PREDICTIONS

At present, there is a race going on both in experimental and in theoretical physics, to devise an experiment to detect quantum gravity effects, i.e., effects sensitive to the Planck energy. (If you can find one, publish it!)

One might think that the fluctuations of space and time could make images from faraway galaxies blurred, or destroy the phase relation between the photons. However, this effect has been shown to be unmeasurable in all possible cases.

Ref. 1234

A better idea is to measure the speed of light at different frequencies in faraway light flashes. There are natural flashes, called gamma ray bursts, which have an extremely broad spectrum, from 100 GeV down to visible light at about 1 eV. These flashes often originate at cosmological distances d. From the difference in arrival time Δt between two frequencies, we can define a characteristic energy by setting

$$E_{\text{char}} = \frac{\hbar(\omega_1 - \omega_2)d}{c\Delta t} \,. \tag{833}$$

This energy value is $8 \cdot 10^{16}$ GeV for the best measurement to date. This is not far from the Planck energy; in fact, it is even closer when the missing factors of order unity are included. It is expected that the Planck scale will be reached in a few years, so that it will become possible to test whether the quantum nature of space-time influences the

Ref. 1235

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 1236, Ref. 1237 dispersion of light signals. Planck-scale effects should produce a dispersion. Detecting it would confirm that Lorentz symmetry breaks down at Planck scales.

Another candidate experiment is the direct detection of distance fluctuations between Ref. 1238, Ref. 1237 bodies. Gravitational wave detectors are sensitive to extremely small noise signals in length measurements. There should be a noise signal due to the distance fluctuations induced near Planck energies. The indeterminacy in measurement of a length l is pre- Ref. 1239 dicted to be

$$\frac{\delta l}{l} \geqslant \left(\frac{l_{\mathrm{Pl}}}{l}\right)^{2/3} . \tag{834}$$

This expression is deduced simply by combining the measurement limit of a ruler, from quantum theory, with the requirement that the ruler not be a black hole. We will discuss Page 1429 this result in more detail in the next section. The sensitivity of the detectors to noise might reach the required level in the early twenty-first century. The noise induced by Ref. 1240 quantum gravity effects is also predicted to lead to detectable quantum decoherence and vacuum fluctuations.

A third candidate experiment for measuring quantum gravity is the detection of the loss of CPT symmetry at high energies. Especially in the case of the decay of certain ele- Ref. 1237 mentary particles, such as neutral kaons, the precision of experimental measurement is approaching the detection of Planck-scale effects.

A fourth possibility is that quantum gravity effects may change the threshold energy Ref. 1241 at which certain particle reactions become possible. It may be that extremely high-energy photons or cosmic rays will make it possible to prove that Lorentz invariance is indeed broken near the Planck scale.

A fifth possibility is that the phase of light that travels over long distances might get washed out. However, the first tests seem to show that this is not the case: light from extremely distant galaxies still interferes. The precise prediction of the phase washing Ref. 1242 effect is still being worked out; most probably, the effect is too small to be measured.

In the domain of atomic physics, it has also been predicted that quantum gravity effects will induce a gravitational Stark effect and a gravitational Lamb shift in atomic Ref. 1240 transitions. Either of these effects could be measurable.

Additional predictions

A few candidates for quantum gravity effects have also been predicted by the author. Let us summarize and clarify the results found so far.* Special relativity starts with the discovery that observable speeds are limited by the speed of light c. Quantum theory starts with the result that observable actions are limited by $\hbar/2$. The theory of gravitation shows that for every system with length L and mass M, the observable ratio L/M is limited by the constant $4G/c^2$. Combining these results, we deduce that all physical observables are *bound*, by what are usually called the Planck values – modified by one or several factors of $\sqrt{2}$. We need to replace $\hbar$ by $\hbar/2$ and G by $4G$ in all the defining expressions for Planck quantities, in order to find the corresponding measurement limits. In particular, the limit for lengths and times is $\sqrt{2}$ times the Planck value, and the limit for energy is the Planck

* This subsection, in contrast to the ones so far, is speculative; it was added in February 2001.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

value divided by $\sqrt{8}$.* Interestingly, the existence of bounds on all observables makes it possible to make several testable predictions for the unification of quantum theory and general relativity. These predictions do not depend on the details of the final theory.

However, first we need to refine the argument that we have just presented. The (corrected) Planck values do not seem to be the actual limits to measurements. The actual measurement limits are stricter.

First of all, for any measurement, we need certain fundamental conditions to be realized. Take the length measurement of an object. We need to be able to distinguish between matter and radiation, since the object to be measured is made up of matter, and since radiation is the measurement tool that is used to read distances from the ruler. For a measurement process, we need an interaction, which implies the use of radiation. Note that this is so even with the use of particle scattering to determine lengths.

In addition, for the measurement of wavelengths we need to distinguish between matter and radiation, because matter is necessary if we wish to compare two wavelengths.
Page 1490 In fact, all length measurements require the distinction between matter and radiation.** However, this distinction is impossible at the energy of grand unification, where the electroweak and the strong nuclear interactions are unified. At and above this energy, particles of matter and particles of radiation transform into each other; in practice they cannot be distinguished.

If all matter and radiation particles were the same, or mixtures of each other, mass could not be defined. Nor could spin, charge or any other quantum numbers. To sum up, no measurement can be performed at energies above the GUT unification energy.

In other words, it is not at the Planck scale that the particle concept (and thus the matter concept) first runs into trouble: it has already done so at the unification scale. It is only below the unification scale that our standard particle and space-time concepts apply, and particles and vacuum can be effectively distinguished.

As a result, the smallest measurable length in nature is $\sqrt{2}$ times the Planck length reduced by the ratio between the maximal energy $E_{\text{Pl}}/\sqrt{8}$ and the unification energy E_{GUT}.
Ref. 1243 Present estimates give $E_{\text{GUT}} \approx 10^{16}$ GeV, implying that the smallest accessible length is at least

$$L_{\text{min}} = \sqrt{2}\, l_{\text{Pl}} \frac{E_{\text{Pl}}}{\sqrt{8}\, E_{\text{GUT}}} \approx 10^{-32}\,\text{m} \approx 800\, l_{\text{Pl}} \,. \tag{835}$$

It is unlikely that measurements at these scales will ever be possible.

So the smallest *measurable* length is significantly larger than the Planck length. The Planck length is that at which particles and vacuum cannot be distinguished, whereas the minimal measurable length is that at which particles of matter and particles of radiation cannot be distinguished. The latter happens at lower energy than the former.

The experimentally determined factor of about 800 is one of the great riddles of physics. It is the high-energy equivalent of the quest to understand why the electromagnetic coupling constant is about 1/137, or more simply, why things have the colours they have. Only the final theory of motion will provide the answer.

* The entropy of a black hole is thus given by the ratio between its horizon and *half* the minimum area. Of course, a detailed investigation also shows that the Planck mass (divided by $\sqrt{8}$) is the limit for elementary particles from *below* and for black holes from *above*. For everyday systems, there is no limit.

** In the modern language of high-energy physics: all measurements require broken supersymmetry.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In particular, the minimum length puts a bound on the electric dipole moment d of elementary particles, i.e., particles without constituents. We get the limit

$$d > d_{\text{min}} = e\, L_{\text{min}} = e\, 10^{-32}\,\text{m} = 1.5 \cdot 10^{-51}\,\text{Cm}\ . \tag{836}$$

Page 1412 This result is in contradiction with one of the predictions of the standard model, but Ref. 1244 not with others. More interestingly, it is within the reach of future experiments. This improved limit may be the simplest possible measurement of yet-unpredicted quantum gravity effects. Measuring the dipole moment could thus be a way to determine the unification energy (the factor 800) independently of high-energy physics experiments, and possibly to a higher precision.

Interestingly, the bound on the measurability of observables also puts a bound on the measurement *precision* for each observable. This bound is of no importance in everyday life, but it is important at high energy. What is the precision with which a coupling constant can be measured? Let us take the electromagnetic coupling constant as an example. This constant α, also called the fine structure constant, is related to the charge q by

$$q = \sqrt{4\pi\varepsilon_0 \hbar c \alpha}\ . \tag{837}$$

Now, any electrical charge is defined and measured by comparing, in an electrical field, the acceleration to which the charged object is subjected with the acceleration of some unit charge q_{unit}. In other words, we have

$$\frac{q}{q_{\text{unit}}} = \frac{ma}{m_{\text{unit}} a_{\text{unit}}}\ . \tag{838}$$

Therefore any error in mass and acceleration measurements implies errors in measurements of charge and the coupling constant.

Page 1194 We found in the part on quantum theory that the electromagnetic, weak and strong interactions are characterized by coupling constants, the inverses of which depend linearly on the logarithm of the energy. It is usually assumed that these three lines meet at Ref. 1243 the unification energy. Measurements put the unification coupling value at about 1/26.

We know from the above discussions that the minimum error for any energy measurement at high energies is given by the ratio between the energy to be measured and the limit energy. If we plot a graph of the coupling constants against energy, we get the result shown in Figure 601. The search for consequences of this *fan-out effect* is delightful. One way to express the result is to say that coupling constants are by definition subject to an error. However, all measurement devices, be they clocks, metre rules, scales or any other devices, use electromagnetic effects at energies of around 1 eV plus the electron rest energy. This is about 10^{-16} times the GUT energy. As a consequence, the measurement precision of any observable should be limited to about 19 digits. The maximum precision currently achieved is 15 digits, and, for the electromagnetic coupling constant, about 9 digits. It will thus be quite some time before this prediction can be tested.

The challenge is to find a system in which the spreading coupling constant value appears more clearly in the measurements. For example, it may be that high-precision mea-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

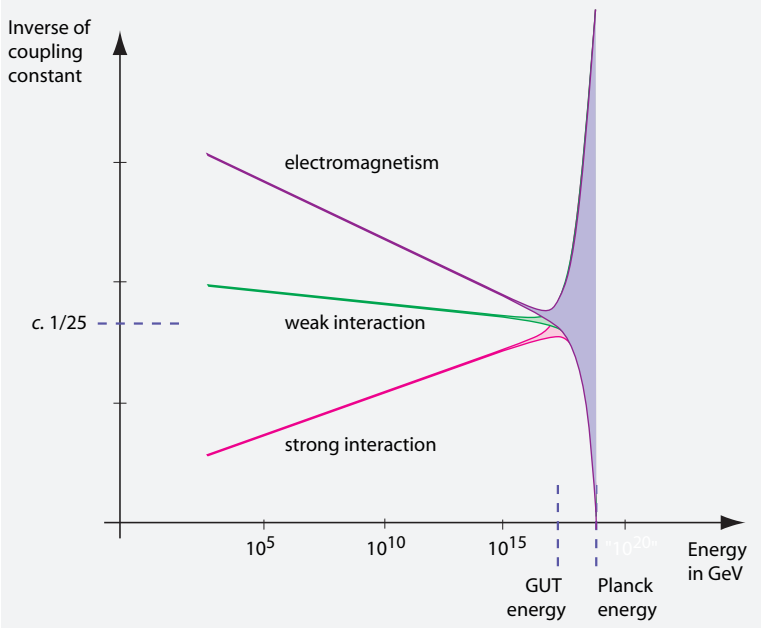

FIGURE 601 Coupling constants and their predicted spread as a function of energy

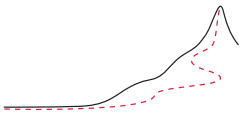
surements of the g-factor of elementary particles or of high-energy cosmic ray reactions will show some effects of the fan-out. The lifetimes of elementary particles could also be affected. Can you find another effect? Challenge 1639 s

In summary, the experimental detection of quantum gravity effects should be possible, despite their weakness, at some time during the twenty-first century. The successful detection of such an effect would be one of the highlights of physics, as it would challenge the usual description of space and time even more than general relativity did.

We now know that the fundamental entity describing space-time and matter that we are looking for is not point-like. What does it look like? To get to the top of Motion Mountain as rapidly as possible, we will make use of some explosive to blast away a few obstacles.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 53

NATURE AT LARGE SCALES – IS THE UNIVERSE SOMETHING OR NOTHING?

> Die Grenze ist der eigentlich fruchtbare Ort der Erkenntnis.*
>
> Paul Tillich, *Auf der Grenze*.

This strange question is the topic of the current leg of our mountain ascent. In the last section we explored nature in the vicinity of Planck scales; but the other limit, namely the description of motion at large, cosmological scales, is equally fascinating. As we proceed, many incredible results will appear, and at the end we will discover a surprising answer to the question in the title.

This section is not standard textbook material; a large part of it is original** and thus speculative and open to question. It aims to explain in simple terms the ongoing research in the domains of quantum gravity and superstring theory. But be warned: with almost every sentence you could find at least one physicist who disagrees.

We have discussed the universe as a whole several times already. In relation to classical physics we enquired about the initial conditions of the universe and whether it is isolated. Page 860 In an earlier chapter we asked whether the universe is a set or a concept, and indeed, whether it exists at all. In relation to general relativity, we gave the classical definition of the term 'universe', as the sum of all matter and space-time; we studied the expansion of the universe and we asked about its size and topology. In the context of quantum theory, we asked whether the universe has a wave function, whether it is born from a quantum fluctuation, and whether the number of particles in it can be defined.

Here we will settle all these issues by combining general relativity and quantum theory at cosmological scales. This will lead us to some of the strangest results we will encounter in our journey.

Cosmological scales

> Hic sunt leones.***

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The description of motion requires the application of general relativity whenever the scale d of the situation is of the order of the Schwarzschild radius, i.e., whenever

$$d \approx r_S = 2Gm/c^2 \,. \tag{839}$$

Challenge 1640 s

It is straightforward to confirm that, with the usually quoted mass m and size d of everything visible in the universe, this condition is indeed fulfilled. We do need general relativity, and thus curved space-time, when talking about the whole of nature.

Similarly, quantum theory is required for the description of the motion of an object whenever we approach it within a distance d of the order of the Compton wavelength λ_C, i.e., whenever

$$d \approx \lambda_C = \frac{h}{mc} \,. \tag{840}$$

Obviously, for the total mass of the universe this condition is not fulfilled. However, we are not interested in the motion of the universe itself; we are interested in the motion of its components. In the description of these components, quantum theory is required whenever pair production and annihilation play a role. This is especially the case in the early history of the universe and near the horizon, i.e., for the most distant events that we can observe in space and time. We are thus obliged to include quantum theory in any precise description of the universe.

Since at cosmological scales we need both quantum theory and general relativity, we start our investigation with the study of time, space and mass, by asking at large scales the same questions that we asked before at Planck scales.

Maximum time

Is it possible to measure time intervals of any imaginable size? General relativity shows that in nature there is a maximum time interval, with a value of about fourteen thousand million years, or 430 Ps, providing an upper limit to the measurement of time. It is called the 'age' of the universe, and has been deduced from two sets of measurements: the expansion of space-time and the age of matter.

We are all familiar with clocks that have been ticking for a long time: the hydrogen atoms in our body. All hydrogen atoms were formed just after the big bang. We can almost say that the electrons in these atoms have been orbiting their nuclei since the dawn of time. In fact, the quarks inside the protons in these atoms have been moving a few hundred thousand years longer than the electrons.

Challenge 1641 s

We thus have an upper time limit for any clock made of atoms. Even 'clocks' made of radiation (can you describe one?) yield a similar maximum time. The study of the spatial expansion of the universe leads to the same maximum. No clock or measurement device was ticking *longer ago* than this maximum time, and no clock could provide a record of having done so.

In summary, it is not possible to measure time intervals greater than the maximum one, either by using the history of space-time or by using the history of matter or radiation.* The maximum time is thus rightly called the 'age' of the universe. Of course, this is

* This implies that so-called 'oscillating universe' models, in which it is claimed that 'before' the big bang

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

not a new idea, although looking at the issue in more detail does reveal some surprises.

Does the universe have a definite age?

> One should never trust a woman who tells one her real age. A woman who would tell one that, would tell one anything.
>
> Oscar Wilde

In light of the above discussion, it may seem silly to talk about the age of the universe. The value is found in many books and tables, including that of Appendix C, and its precise determination is one of the most important quests in modern astrophysics. But is this quest reasonable?

Page 923

In order to measure the duration of a movement or the age of a system, we need a clock that is *independent* of that movement or system, and thus *outside* the system. However, there are no clocks outside the universe, and no clock inside it can be independent. In fact we have just seen that no clock inside the universe can run throughout its history.

Time can be defined only if it is possible to distinguish between matter and space-time. Given this distinction, we can talk either about the age of *space-time*, by assuming that matter provides suitable and independent clocks – as is done in general relativity – or about the age of *matter*, such as stars or galaxies, by assuming that the extension of space-time, or some other matter, provides a good clock. Both possibilities are being explored experimentally in modern astrophysics – and both give the same result, of about fourteen thousand million years, which was mentioned above. However, for the universe as a *whole*, an age cannot be defined.

The issue of the starting point of time makes this difficulty even more apparent. We may imagine that going back in time leads to only two possibilities: either the starting instant $t = 0$ is part of time or it is not. (Mathematically, this means that the segment representing time is either closed or open.) Both these possibilities imply that it is possible to measure arbitrarily small times; but we know from the combination of general relativity and quantum theory that this is *not* the case. In other words, neither possibility is correct: the beginning cannot *be* part of time, nor can it *not be* part of it. There is only one solution to this paradox: there was no beginning at all.

So the situation is consistently muddled. Neither the age of the universe nor its origin makes sense. What is going wrong? Or rather, *how* are things going wrong? What happens if instead of jumping directly to the big bang, we *approach* it as closely as possible? The best way to clarify the issue is to ask about the measurement *error* in our statement that the universe is fourteen thousand million years old. This turns out to be a fascinating topic.

How precise can age measurements be?

> No woman should ever be quite accurate about her age. It looks so calculating.
>

there were other phenomena, cannot be justified on the basis of nature or observations. They are based on beliefs.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The first way to measure the age of the universe* is to look at clocks in the usual sense of the word, namely at clocks made of *matter*. As explained in the part on quantum theory, Ref. 1197, Ref. 1198 Salecker and Wigner showed that a clock built to measure a total time T with a precision Δt has a minimum mass m given by

$$m > \frac{\hbar}{c^2}\frac{T}{(\Delta t)^2} \,. \tag{841}$$

A simple way to incorporate general relativity into this result was suggested by Ng and Ref. 1246 van Dam. Any clock of mass m has a minimum resolution Δt due to the curvature of space that it introduces, given by

$$\Delta t > \frac{Gm}{c^3} \,. \tag{842}$$

If m is eliminated, these two results imply that a clock with a precision Δt can only measure times T up to a certain maximum value, namely

$$T < \frac{(\Delta t)^3}{t_{\mathrm{Pl}}^2} \quad , \tag{843}$$

where $t_{\mathrm{Pl}} = \sqrt{\hbar G/c^5} = 5.4 \cdot 10^{-44}$ s is the Planck time. (As usual, we have omitted factors of order one in this and in all the following results of this section.) In other words, the higher the accuracy of a clock, the shorter the time during which it works dependably. The precision of a clock is limited not only by the expense of building it, but also by nature itself. Nevertheless, it is easy to check that for clocks used in daily life, this limit Challenge 1642 e is not even remotely approached. For example, you may wish to calculate how precisely your own age can be specified.

As a consequence of the inequality (843), a clock trying to achieve an accuracy of one Planck time can do so for at most one Planck time! *A real clock cannot achieve Planck-time accuracy.* If we try to go beyond the limit (843), fluctuations of space-time hinder the working of the clock and prevent higher precision. With every Planck time that passes, the clock accumulates a measurement error of at least one Planck time. Thus, the total measurement error is at least as large as the measurement itself. This conclusion is also Challenge 1643 ny valid for clocks based on radiation: for example on the background radiation.

In short, measuring age with a clock always involves some errors. Whenever we try to reduce these errors to Planck level, the clock becomes so imprecise over large times that age measurements become impossible.

* Note that the age t_0 is not the same as the Hubble time $T = 1/H_0$. The Hubble time is only a computed quantity and (almost) always larger than the age; the relation between the two depends on the values of the cosmological constant, the density and other parameters of the universe. For example, for the standard 'hot big bang' scenario, i.e., for the matter-dominated Einstein–de Sitter model, we have the simple relation Ref. 1245 $T = (3/2)\, t_0$.

Does time exist?

> Time is waste of money.
>
> Oscar Wilde

Ever since people began to study physics, the concept of 'time' has designated what is measured by a clock. But the inequality (843) implies that perfect clocks do not exist, and thus that time is only an approximate concept: perfect time does not exist. Thus there is no 'idea' of time, in the Platonic sense. In fact, all the discussion in the previous and present sections can be seen as proof that there are no perfect or 'ideal' examples of any classical or everyday concept.

Page 45

Time does not exist. Yet it is obviously a useful concept in everyday life. The key to understanding this is *energy*. Any clock – in fact, any system of nature – is characterized by a simple number, namely the highest ratio of its kinetic energy to the rest energy of its components. In daily life, this ratio is about $1\,\mathrm{eV}/10\,\mathrm{GeV} = 10^{-10}$. Such *low-energy* systems are well suited for building clocks. The more precisely the motion of the main moving part – the pointer of the clock – can be kept constant, and monitored, the higher the precision of the clock. To achieve very high precision, the pointer must have very high mass. Indeed, both the position and the speed of the pointer must be measured, and the two measurement errors are related by the quantum-mechanical indeterminacy relation $\Delta v\,\Delta x > \hbar/m$. High mass implies low intrinsic fluctuation. Furthermore, in order to screen the pointer from outside influences, even more mass is needed. This connection between mass and accuracy might explain why more accurate clocks are usually more expensive.

Challenge 1644 e

The standard indeterminacy relation quoted above is valid only at everyday energies. We cannot achieve ever higher precision simply by increasing the mass, since general relativity changes the indeterminacy relation to $\Delta v\,\Delta x > \hbar/m + G(\Delta v)^2 m/c^3$. The additional term on the right-hand side, negligible at everyday scales, is proportional to energy. Increasing it by a large amount limits the achievable precision of the clock. The smallest measurable time interval turns out to be the Planck time.

Page 1398

Page 1404

Challenge 1645 e

In summary, time exists, as a good approximation, only for *low-energy* systems. Any increase in precision beyond a certain limit requires an increase in the energy of the components; at Planck energy, this increase will prevent an increase in precision.

What is the error in the measurement of the age of the universe?

It is now straightforward to apply our discussion about the measurement of time to the age of the universe. The inequality (843) implies that the highest precision possible for a clock is about 10^{-23} s, or about the time light takes to move across a proton. The finite age of the universe also yields a maximum *relative* measurement precision. Inequality (843) can be written as

$$\frac{\Delta t}{T} > \left(\frac{t_{\mathrm{Pl}}}{T}\right)^{2/3} \tag{844}$$

Challenge 1646 e

which shows that no time interval can be measured with a precision of more than about 40 decimals.

To clarify the issue, we can calculate the error in measurement as a function of the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

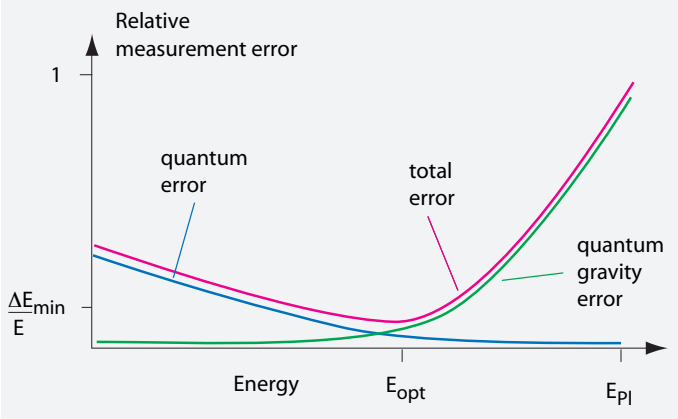

FIGURE 602 Measurement errors as a function of measurement energy

observation energy E_{meas}, the energy of the measurement probe. There are two limit cases. For *low* energies, the error is due to quantum effects and is given by

$$\frac{\Delta t}{T} \sim \frac{1}{E_{\text{meas}}} \tag{845}$$

which decreases with increasing measurement energy. For *high* energies, however, the error is due to gravitational effects and is given by

$$\frac{\Delta t}{T} \sim \frac{E_{\text{meas}}}{E_{\text{Pl}}} \tag{846}$$

so that the total error varies as shown in Figure 602. In particular, very high energies do not reduce measurement errors: any attempt to reduce the measurement error for the age of the universe below 10^{-23} s would require energies so high that the limits of space-time would be reached, making the measurement itself impossible.

We reached this conclusion through an argument based on clocks made of particles. We will see below that trying to determine the age of the universe using space-time expansion leads to the same limit.

Imagine observing a tree which, as a result of some storm or strong wind, has fallen towards second tree, touching it at the very top, as shown in Figure 603. It is possible to determine the heights of both trees by measuring their separation and the angles at the base. The *error* in the heights will depend on the errors in measurement of the separation and angles.

Similarly, the age of the universe can be calculated from the present distance and speed of objects – such as galaxies – observed in the night sky. The distance d corresponds to separation of the trees at ground level, and the speed v to the angle between the two trees. The Hubble time T of the universe (which is usually assumed to be larger than the age of the universe) then corresponds to the height at which the two trees meet. This age – in a naive sense, the time since the galaxies 'separated' – is given, within a factor of order

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

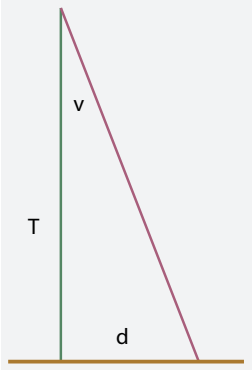

FIGURE 603 Trees and galaxies

one, by

$$T = \frac{d}{v} \,. \tag{847}$$

In simple terms, this is the method used to determine the age of the universe from the expansion of space-time, for galaxies with red-shifts below unity.* The (positive) measurement error ΔT becomes

$$\frac{\Delta T}{T} = \frac{\Delta d}{d} + \frac{\Delta v}{v} \,. \tag{848}$$

It is worthwhile to explore this in more detail. For any measurement of T, we have to choose the object, i.e., a distance d, as well as an observation time Δt, or, equivalently, an observation energy $\Delta E = 2\pi\hbar/\Delta t$. We will now investigate the consequences of these choices for equation (848), always taking into account both quantum theory and general relativity.

At everyday energies, the result of the determination of the age t_0 is about $(13.7 \pm 0.2) \cdot 10^9$ Ga. This value is deduced by measuring red-shifts, i.e., velocities, and distances, using stars and galaxies in distance ranges, from some hundred thousand light years up to a red-shift of about 1. Measuring red-shifts does not produce large velocity errors. The main source of experimental error is the difficulty in determining the distances of galaxies.

What is the smallest possible error in distance? Obviously, inequality (844) implies

$$\frac{\Delta d}{T} > \frac{l_{\mathrm{Pl}}^{2/3}}{d^{2/3}} \tag{849}$$

thus giving the same indeterminacy in the age of the universe as the one we found above in the case of material clocks.

Challenge 1647 e

We can try to reduce this error in two ways: by choosing objects at either small or

* At higher red-shifts, the speed of light, as well as the details of the expansion, come into play. To continue with the analogy of the trees, we find that the trees are not straight all the way up to the top and that they grow on a slope, as suggested by Figure 604.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

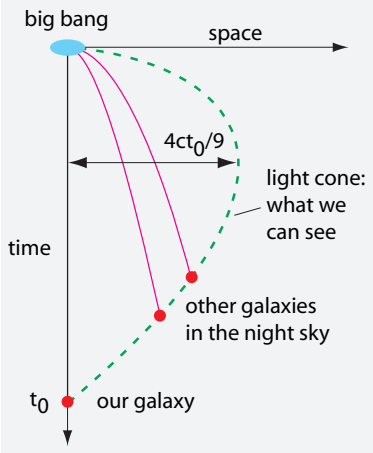

FIGURE 604 The speed and distance of remote galaxies

large distances. Let us start with small distances. In order to get high precision at small distances, we need high observation energies. It is fairly obvious that at observation energies near the Planck value, $\Delta T/T$ approaches unity. In fact, both terms on the right-hand side of equation (848) become of order one. At these energies, Δv approaches c and the maximum value for d approaches the Planck length, for the same reason that at Planck energies the maximum measurable time is the Planck time. In short, *at Planck scales it is impossible to say whether the universe is old or young*.

Challenge 1648 e

Let us consider the other extreme, namely objects extremely far away, say with a redshift of $z \gg 1$. Relativistic cosmology requires the diagram of Figure 603 to be replaced by the more realistic diagram of Figure 604. The 'light onion' replaces the familiar light cone of special relativity: light converges near the big bang. In this case the measurement error for the age of the universe also depends on the distance and velocity errors. At the largest possible distances, the signals an object sends out must be of high energy, because the emitted wavelength must be smaller than the universe itself. Thus, inevitably, we reach Planck energies. However, we have seen that in such high-energy situations, the emitted radiation, as well as the object itself, is indistinguishable from the space-time background. In other words, the red-shifted signal we would observe today would have a wavelength as large as the size of the universe, with a correspondingly small frequency.

Ref. 1245

There is another way to describe the situation. At Planck energies or near the horizon, the original signal has an error of the same size as the signal itself. When measured at the present time, the red-shifted signal still has an error of the same size as the signal. As a result, the error in the horizon distance becomes as large as the value to be measured.

In short, even if space-time expansion and large scales are used, the instant of the so-called beginning of the universe cannot be determined with an error smaller than the age of the universe itself: a result we also found at Planck distances. If we aim for perfect precision, we just find that the universe is 13.7 ± 13.7 thousand million years old! In other words, *in both extremal situations, it is impossible to say whether the universe has a non-vanishing age*.

We have to conclude that the anthropocentric concept of 'age' does not make any sense

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

for the universe as a whole. The usual textbook value is useful only for ranges of time, space and energy in which matter and space-time are clearly distinguished, namely at everyday, human-scale energies; the value has no more general meaning.

Challenge 1649 ny You may like to examine the issue of the *fate* of the universe using the same arguments. But we will continue on the path outlined at the start of this section: the next topic is the measurement of length.

Maximum length

General relativity shows that in the standard cosmological model, for hyperbolic (open) and parabolic (marginal) evolutions of the universe, the *size* of the universe is infinite. It is only the *horizon distance*, i.e., the distance of objects with infinite red-shift, that is finite.* For elliptical evolution, the total size is finite and depends on the curvature. Page 587 However, in this case also the present measurement limit yields a minimum size for the universe many times larger than the horizon distance.

Quantum field theory, on the other hand, is based on flat and infinite space-time. Let us see what happens when the two theories are combined. What can we say about measurements of length in this case? For example, would it be possible to construct and use a metre rule to measure lengths larger than the distance to the horizon?

It is true that we would have no time to push it out that far, since in the standard Ref. 1245 Einstein–de Sitter big bang model the horizon moves away from us faster than the speed of light. (We should have started using the metre rule right at the big bang.) But just for fun, let us assume that we have actually managed to do this. How far away can we read off distances? In fact, since the universe was smaller in the past, and since every observation of the sky is an observation of the past, Figure 604 shows that the maximum Ref. 1245 *spatial distance* away from us at which an object can be seen is only $(4/9)ct_0$. Obviously, for space-time intervals, the maximum remains ct_0.

Thus, in all cases it turns out to be impossible to measure lengths larger than the horizon distance, even though general relativity predicts such distances. This result is unsurprising, and in obvious agreement with the existence of a limit for measurements of time intervals. The real surprises come next.

Is the universe really a big place?

Ref. 1247 Astronomers and Hollywood films answer this question in the affirmative. Indeed, the Page 923 distance to the horizon of the universe is often included in tables. Cosmological models specify that the scale factor R, which fixes the distance to the horizon, grows with time t; for the case of the standard mass-dominated Einstein–de Sitter model, i.e., for a vanishing cosmological constant and flat space, we have

$$R(t) = C\, t^{2/3} \,, \tag{850}$$

* In cosmology, we need to distinguish between the scale factor R, the Hubble radius $c/H = cR/\dot{R}$, the horizon distance h and the size d of the universe. The Hubble radius is a computed quantity giving the distance at which objects move away with the speed of light. It is always *smaller* than the horizon distance, at which in the standard Einstein–de Sitter model, for example, objects move away with *twice* the speed of Ref. 1245 light. However, the horizon itself moves away with *three* times the speed of light.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where the numerical constant C relates the commonly accepted horizon distance to the commonly accepted age. Indeed, observation shows that the universe is large, and is getting larger. But let us investigate what happens if we add some quantum theory to this result from general relativity. Is it really possible to measure the distance to the horizon?

We look first at the situation at high (probe) energies. We saw above that space-time and matter are not distinguishable at Planck scales. Therefore, at Planck energies we cannot state whether or not objects are *localized*. At Planck scales, the distinction between matter and vacuum – so basic to our thinking – disappears.

Another way to say this is that we cannot claim that space-time is *extended* at Planck scales. Our concept of extension derives from the possibility of measuring distances and time intervals, and from observations such as the ability to align several objects behind one another. Such observations are not possible at Planck scales and energies, because of the inability of probes to yield useful results. In fact, all of the everyday observations from which we deduce that space is extended are impossible at Planck scales, where *the basic distinction between vacuum and matter, namely between extension and localization, disappears*. As a consequence, at Planck energies the size of the universe cannot be measured. It cannot even be called larger than a matchbox.

The problems encountered with probes of high probe energies have drastic consequences for the size measurement of the universe. All the arguments given above for the errors in measurement of the age can be repeated for the distance to the horizon. To reduce size measurement errors, a measurement probe needs to have high energy. But at high energy, measurement errors approach the value of the measurement results. At the largest distances and at Planck energies, the measurement errors are of the same magnitude as the measured values. If we try to determine the size of the universe with high precision, we get no precision at all.

Challenge 1650 ny

The inability to get precise values for the size of the universe should not come unexpected. For a reliable measurement, the standard must be different, independent, and outside the system to be measured. For the universe this is impossible.

Studying the size of the big bang also produces strange results. The universe is said to have been much smaller near the big bang because, on average, all matter is moving away from all other matter. But if we try to follow the path of matter into the past with high precision, using Planck energy probes, we get into trouble: since measurement errors are as large as measurement data, we cannot claim that the universe was smaller near the big bang than it is today: there is no way to reliably distinguish size values.

There are other confirmations too. If we had a metre rule spanning the whole universe, even beyond the horizon, with zero at the place where we live, what measurement *error* would it produce for the horizon? It does not take long to work out that the expansion of space-time, from Planck scales to the present size, implies an expansion in the error from Planck size to a length of the order of the present distance to the horizon. Again, the error is as large as the measurement result. Again, the size of the universe turns out not to be a meaningful property.

Challenge 1651 ny

Since this reasoning also applies if we try to measure the diameter of the universe instead of its radius, it is impossible to say whether the antipodes in the sky really are distant from each other!

We can summarize the situation by noting that anything said about the size of the universe is as limited as anything said about its age. *The height of the sky depends on the*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

observation energy. If we start measuring the sky at standard observation energies, and try to increase the precision of measurement of the distance to the horizon, the measurement error increases beyond all bounds. At Planck energies, the volume of the universe is indistinguishable from the Planck volume - and vice versa.

The boundary of space-time – is the sky a surface?

The horizon of the universe – essentially, the black part of the night sky – is a fascinating entity. Everybody interested in cosmology wants to know what happens there. In newspapers the horizon is sometimes called the *boundary of space-time*. Some surprising insights – which have not yet made it to the newspapers – appear when we combine general relativity and quantum mechanics.

We saw above that the errors in measuring the distance of the horizon are substantial. They imply that we cannot pretend that all points of the sky are equally far away from us. Thus we cannot say that the sky is a surface; it could be a volume. In fact, there is no way to determine the dimensionality of the horizon, or the dimensionality of space-time near the horizon.*

Thus measurements do not allow us to determine whether the boundary is a point, a surface, or a line. It may be a very complex shape, even knotted. In fact, quantum theory tells us that it must be all of these from time to time: that *the sky fluctuates in height and shape*. In short, it is impossible to determine the topology of the sky. But that is nothing new. As is well known, general relativity is unable to describe pair creation particles with spin 1/2. The reason for this is the change in space-time topology required by the process. The universe is full of such processes, implying that it is impossible to define a topology for the universe and, in particular, for the horizon. Can you find at least two other arguments to show this?

Challenge 1653 ny

Worse still, quantum theory shows that space-time is not continuous at a horizon: this can easily be deduced using the Planck-scale arguments from the previous section. Time and space are not defined there.

Page 1398

Finally, there is no way to decide whether the various boundary points are *different* from each other. The distance between two points in the night sky is undefined. Therefore it is unclear what the *diameter* of the horizon is.

In summary, the horizon has no specific distance or shape. The horizon, and thus the universe, cannot be shown to be manifolds. This leads us to the next question.

Does the universe have initial conditions?

Ref. 1248

One often reads about the quest for the initial conditions of the universe. But before joining this search, we should ask *whether* and *when* such initial conditions make any sense.

Obviously, our everyday description of motion requires knowledge of initial conditions, which describe the *state* of a system, i.e., all those aspects that differentiate it from

* The measurement errors also imply that we cannot say anything about translational symmetry at cosmological scales. Can you confirm this? In addition, at the horizon it is impossible to distinguish between spacelike and timelike distances. Even worse, concepts such as 'mass' or 'momentum' become muddled at the horizon. This means that, as at Planck energies, we are unable to distinguish between object and background, and between state and intrinsic properties. We will come back to this important point shortly.

Challenge 1652 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

a system with the same intrinsic properties. Initial conditions – like the state – are attributed to a system by an *outside* observer.

Quantum theory tells us that initial conditions, or the state of a system, can only be defined by an outside observer with respect to an environment. It is already difficult to be outside the universe – but even inside the universe, a state can only be defined if matter can be distinguished from vacuum. This is impossible at Planck energies, near the big bang, or at the horizon. Thus the universe has no state. This means also that it has *no wave function*.

Page 1398 The limits imposed by the Planck values confirm this conclusion in other ways. First of all, they show that the big bang was not a singularity with infinite curvature, density or temperature, because infinitely large values do not exist in nature. Secondly, since instants of time do not exist, it is impossible to define the state of any system at a given time. Thirdly, as instants of time do not exist, neither do events, and so the big bang was not an event, and neither an initial state nor an initial wave function can be ascribed to the universe. (Note that this also means that the universe cannot have been created.)

In short, *there are no initial conditions for the universe*. Initial conditions make sense only for subsystems, and only far from Planck scales. Thus, for initial conditions to exist, the system must be far from the horizon and it must have evolved for some time 'after' the big bang. Only when these two requirements are fulfilled can objects *move* in space. Of course, this is always the case in everyday life.

At this point in our mountain ascent, where neither time nor length is clearly defined at cosmological scales, it should come as no surprise that there are similar difficulties concerning the concept of mass.

Does the universe contain particles and stars?

The total number of stars, about $10^{23\pm1}$, is included in every book on cosmology, as it is Page 923 in the table of Appendix C. A smaller number can be counted on clear nights.

We can ask the same question about particles instead of stars. The commonly quoted numbers are is $10^{81\pm1}$ baryons and $10^{90\pm1}$ photons. However, the issue is not settled. Neither quantum theory nor general relativity alone makes predictions about the number of particles, either inside or outside the horizon. What happens if we combine them?

In order to define the number of particles in a region, quantum theory first of all re- Page 1055 quires a vacuum state to be defined. The number of particles is defined by comparing the system with the vacuum. If we neglect or omit general relativity by assuming flat space-time, this procedure poses no problem. However, if we include general relativity, and thus a curved space-time, especially one with a strangely behaved horizon, the answer is simple: there is *no* vacuum state with which we can compare the universe, for two reasons. First, nobody can explain what an empty universe would look like. Secondly, and more importantly, there is no way to define a state of the universe. The number of particles in the universe thus becomes undefinable. Only at everyday energies and for finite dimensions are we able to speak of an approximate number of particles.

Comparison between a system and the vacuum is also impossible, in the case of the universe, for purely practical reasons. The particle counter would have to be outside the Challenge 1654 ny system. (Can you confirm this?) In addition, it is impossible to remove particles from the universe.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The impossibility of defining a vacuum state, and thus the number of particles in the universe, is not surprising. It is an interesting exercise to investigate the measurement errors that appear when we try to determine the number of particles despite this fundamental impossibility.

Challenge 1655 ny

Can we count the stars? In principle, the same conclusion applies as for particles. However, at everyday energies the stars can be counted *classically*, i.e., without taking them out of the volume in which they are enclosed. For example, this is possible if the stars are differentiated by mass, colour or any other individual property. Only near Planck energies or near the horizon are these methods inapplicable. In short, the number of stars is only defined as long as the observation energy is low, i.e., as long as we stay away from Planck energies and from the horizon.

So, despite appearances on human scales, *there is no definite number of particles in the universe*. The universe cannot be distinguished from vacuum by counting particles. Even though particles are necessary for our own existence and functioning, a complete count of them cannot be made.

This conclusion is so strange that we should try to resist it. Let us try another method of determining the content of matter in the universe: instead of counting particles, let us weigh them.

Does the universe contain masses and objects?

Page 923

The average density of the universe, about $10^{-26}\,\mathrm{kg/m^3}$, is often cited in texts. Is it different from a vacuum? Quantum theory shows that, as a result of the indeterminacy relation, even an empty volume of size R has a mass. For a zero-energy photon inside such a vacuum, we have $E/c = \Delta p > \hbar/\Delta x$, so that in a volume of size R, we have a minimum mass of at least $m_{\min}(R) = \hbar/cR$. For a spherical volume of radius R there is thus a minimal mass density given approximately by

$$\rho_{\min} \approx \frac{m_{\min}(R)}{R^3} = \frac{\hbar}{cR^4} \,. \tag{851}$$

For the universe, if the standard horizon distance R_0 of 14 000 million light years is inserted, the value becomes about $10^{-142}\,\mathrm{kg/m^3}$. This describes the density of the vacuum. In other words, the universe, with a density of about $10^{-26}\,\mathrm{kg/m^3}$, seems to be clearly different from vacuum. But are we sure?

We have just deduced that the radius of the horizon is undefined: depending on the observation energy, it can be as small as the Planck length. This implies that the density of the universe lies somewhere between the lowest possible value, given by the density of vacuum just mentioned, and the highest possible one, namely the Planck density.* In short, the relation (851) does not really provide a clear statement.

---

* In fact, at everyday energies the density of the universe lies midway between the two values, yielding the strange relation

Challenge 1656 ny

$$m_0^2/R_0^2 \approx m_{\mathrm{Pl}}^2/R_{\mathrm{Pl}}^2 = c^4/G^2 \,. \tag{852}$$

Page 1217

But this is nothing new. The approximate equality can be deduced from equation 16.4.3 (p. 620) of Steven Weinberg, *Gravitation and Cosmology*, Wiley, 1972, namely $Gn_b m_p = 1/t_0^2$. The relation is required by several cosmological models.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Another way to measure the mass of the universe would be to apply the original definition of mass, as given by Mach and modified by special relativity. Thus, let us try to collide a standard kilogram with the universe. It is not hard to see that whatever we do, using either low or high energies for the standard kilogram, the mass of the universe cannot be constrained by this method. We would need to produce or to measure a velocity change Δv for the rest of the universe after the collision. To hit all the mass in the universe at the same time, we need high energy; but then we are hindered by Planck energy effects. In addition, a properly performed collision measurement would require a mass outside the universe, which is rather difficult to achieve.

Page 439

Challenge 1657 ny

Yet another way to measure the mass would be to determine the gravitational mass of the universe through straightforward weighing. But the lack of balances outside the universe makes this an impractical solution, to say the least.

Another way out might be to use the most precise definition of mass provided by general relativity, the so-called *ADM mass*. However, the definition of this requires a specified behaviour at infinity, i.e., a background, which the universe lacks.

We are then left with the other general-relativistic method: determining the mass of the universe by measuring its average curvature. Let us take the defining expressions for average curvature κ for a region of size R, namely

Page 543

$$\kappa = \frac{1}{r_{\text{curvature}}^2} = \frac{3}{4\pi}\,\frac{4\pi R^2 - S}{R^4} = \frac{15}{4\pi}\,\frac{4\pi R^3/3 - V}{R^5}\,. \tag{853}$$

We have to insert the horizon radius R_0 and either its surface area S_0 or its volume V_0. However, given the error margins on the radius and the volume, especially at Planck energies, we again find no reliable result for the radius of curvature.

Challenge 1658 ny

An equivalent method starts with the usual expression provided by Rosenfeld for the indeterminacy $\Delta\kappa$ in the scalar curvature for a region of size R, namely

Ref. 1249

$$\Delta\kappa > \frac{16\pi l_{\text{Pl}}^2}{R^4}\,. \tag{854}$$

However, this expression also shows that the error in the radius of curvature behaves like the error in the distance to the horizon.

In summary, *at Planck energies, the average radius of curvature of nature lies between infinity and the Planck length*. This implies that the density of matter lies between the minimum value and the Planck value. There is thus no method to determine the mass of the universe at Planck energies. (Can you find one?) The concept of mass cannot be applied to the universe as a whole. Thus, *the universe has no mass*.

Challenge 1659 ny

Do symmetries exist in nature?

We have already seen that at the horizon, space-time translation symmetry breaks down. Let us have a quick look at the other symmetries.

What happens to permutation symmetry? Permutation is an operation on objects in space-time. It thus necessarily requires a distinction between matter, space and time. If we cannot distinguish positions, we cannot talk about exchange of particles. Therefore, at

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the horizon, general relativity and quantum theory together make it impossible to define permutation symmetry.

The same is true of CPT symmetry. As a result of measurement errors or of limiting maximum or minimum values, it is impossible to distinguish between the original and the transformed situations. Therefore we cannot claim that that CPT is a symmetry of nature at horizon scales. In other words, matter and antimatter cannot be distinguished at the horizon.

Challenge 1660 ny

The same is true of gauge symmetry, as you may wish to check in detail yourself. For its definition, the concept of gauge field requires a distinction between time, space and mass; at the horizon this is impossible. We therefore also deduce that at the horizon, concepts such as algebras of observables cannot be used to describe nature. Renormalization breaks down too.

All symmetries of nature break down at the horizon. None of the vocabulary we use to talk about observations – including terms such as such as 'magnetic field', 'electric field', 'potential', 'spin', 'charge', or 'speed' – can be used at the horizon.

Does the universe have a boundary?

It is common to take 'boundary' and 'horizon' as synonyms in the case of the universe, because they are the same for all practical purposes. Knowledge of mathematics does not help us here: the properties of mathematical boundaries – for example, that they themselves have no boundary – are not applicable to the universe, since space-time is not continuous. We need other, physical arguments.

The boundary of the universe is supposed to represent the boundary between *something* and *nothing*. There are three possible interpretations of 'nothing':

— 'Nothing' could mean 'no matter'. But we have just seen that this distinction cannot be made at Planck scales. So either the boundary will not exist at all or it will encompass the horizon *as well as* the whole universe.
— 'Nothing' could mean 'no space-time'. We then have to look for those domains where space and time cease to exist. These occur at Planck scales and at the horizon. Again, either the boundary will not exist or it will encompass the whole universe.
— 'Nothing' could mean 'neither space-time nor matter.' The only possibility is a boundary that encloses domains *beyond* the Planck scale and *beyond* the horizon; but again, such a boundary would also encompass all of nature.

This is puzzling. When combining quantum theory and relativity, we do not seem to be able to find a conceptual definition of the horizon that distinguishes it from what it includes. (If you find one, publish it!) A distinction *is* possible in general relativity alone, and in quantum theory alone; but as soon as we combine the two, the boundary becomes indistinguishable from its content. *The interior of the universe cannot be distinguished from its horizon*. There is no boundary.

Challenge 1661 ny

This difficulty in distinguishing the horizon from its contents is interesting: it suggests that nature may be *symmetric* under transformations that exchange interiors and boundaries. This connection is called *holography*, because it vaguely recalls the working of credit-card holograms. It is a busy research field in high-energy physics. However, for the time being, we shall continue with our original theme, which leads us to our next

Ref. 1250

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

question.

Is the universe a set? – Again

> Domina omnium et regina ratio.*
>
> Cicero

We are used to thinking of the universe the sum of all matter and all space-time. In doing so, we imply that the universe is a set of mutually distinct components. This idea has been assumed in three situations: in claiming that matter consists of particles; that space-time consists of events (or points); and that different states consist of different initial conditions. However, our discussion shows that the universe is *not* a set of such distinguishable elements. We have encountered several proofs: at the horizon, at the big bang and at Planck scales, it becomes impossible to distinguish between events, between particles, between observables, and between space-time and matter. In those domains, distinctions of any kind become impossible. We have found that distinguishing between two entities – for example, between a toothpick and a mountain – is only *approximately* possible. It is approximately possible because we live at energies well below the Planck energy. The approximation is so good that we do not notice the error when we distinguish cars from people and from toothpicks. Nevertheless, our discussion of the situation at Planck energies shows that a perfect distinction is impossible in principle. *It is impossible to split the universe into separate entities.*

Another way to reach this result is the following. Distinguishing between two entities requires different measurement results: for example, different positions, masses or sizes. Whatever quantity we choose, at Planck energies the distinction becomes impossible. Only at everyday energies is it approximately possible.

In short, since the universe contains no distinguishable entities, there are no elements in nature. Simply put: *the universe is not a set*. We envisaged this possibility earlier on; now it is confirmed. The concepts of 'element' and 'set' are already too specialized to describe the universe. *The universe must be described by a mathematical concept that does not contain any set.* The new concept must be more general than that of a set.

Page 860

This is a powerful result: it means that no precise description of the universe can use any concept that presupposes the use of sets. But all the concepts we have used so far to describe nature, such as space-time, metric, phase space, Hilbert space and its generalizations (Fock space and particle space), are based on elements and sets. They must all be abandoned at Planck energies, and in any precise description.

Furthermore, many speculations about unified descriptions do depend on sets. In particular, all studies of quantum fluctuations, mathematical categories, posets, complex mathematical spaces, computer programs, Turing machines, Gödel's theorem, creation of any sort, space-time lattices, quantum lattices and Bohm's unbroken wholeness presuppose sets. In addition, almost none of the speculations about the origin of the universe can be correct. For example, you may wish to check the religious explanations you know against this result. In fact, no approach used by theoretical physicists in the year 2000 satisfies the requirement that elements and sets must be abandoned. Perhaps a future

version of string or M theory will do so. The task is not easy: do you know of a single concept not based on elements or sets? Challenge 1663 s

Note that this radical conclusion is deduced from only two statements: the necessity of using quantum theory whenever the dimensions are of the order of the Compton wavelength, of using general relativity whenever the dimensions are of the order of the Schwarzschild radius. Together, they mean that no precise description of nature can contain elements and sets. We have reached this result after a long and interesting, but in a sense unnecessary, digression. The difficulties in complying with this result may explain why the unification of the two theories has not so far been successful. Not only does unification require that we stop using space, time and mass for the description of nature; it also requires that all distinctions, of any kind, should be only approximate. But all physicists have been educated on the basis of exactly the opposite creed!

Note that, because it is not a set, *the universe is not a physical system*. Specifically, it has no state, no intrinsic properties, no wave function, no initial conditions, no density, no entropy and no cosmological constant. The universe is thus neither thermodynamically closed nor open; and it contains no information. All thermodynamic quantities, such as entropy, temperature and free energy, are defined using *ensembles*. Ensembles are limits of systems which are thermodynamically either open or closed. As the universe is neither open nor closed, no thermodynamic quantity can be defined for it.* All physical properties are defined only for parts of nature which are approximated or idealized as sets, and thus are physical systems.

Curiosities and fun challenges about the universe

> Insofern sich die Sätze der Mathematik auf die Wirklichkeit beziehen, sind sie nicht sicher, und sofern sie sicher sind, beziehen sie sich nicht auf die Wirklichkeit.**
>
> Albert Einstein

In mathematics, 2 + 2 = 4. This statement is an idealization of statements such as 'two apples plus two apples makes four apples.' However, we now know that at Planck energies this is not a correct statement about nature. At Planck energies, objects cannot be counted. Can you confirm this? Challenge 1664 ny

* *

In 2002, Seth Lloyd estimated how much information the universe can contain, and how many calculations it has performed since the big bang. This estimate is based on two ideas: that the number of particles in the universe is a well-defined quantity, and that the universe is a computer, i.e., a physical system. We now know that neither assumption is correct. This shows the power of the criteria that we have deduced for any precise or complete description of motion. Ref. 1252

* Some people knew this long before physicists. For example, the belief that the universe is or contains information was ridiculed most thoroughly in the popular science-fiction parody by Douglas Adams, *The Hitchhiker's Guide to the Galaxy*, 1979, and its sequels.

** 'In so far as mathematical statements describe reality, they are not certain, and as far as they are certain, they are not a description of reality.'

People take pictures of the cosmic background radiation and its variations. Is it possible that these photographs will show that the spots in one direction of the sky are exactly the same as those in the diametrically opposite direction? Challenge 1665 ny

* *

In 1714, Leibniz published his *Monadologie*. In it he explores what he calls a simple substance, which he defined to be a substance that has no parts. He called it a *monade* and describes some of its properties. However, mainly thanks to his incorrect deductions, the term has not been generally adopted. What is the physical concept most closely related to that of a monade? Ref. 1253 Challenge 1666 s

* *

We usually speak of *the* universe, implying that there is only one of them. Yet there is a simple case to be made that 'universe' is an observer-dependent concept, since the idea of 'all' is observer-dependent. Does this mean that there are many universes? Challenge 1667 ny

* *

If all particles were removed (assuming one knew where to put them), there wouldn't be much of a universe left. True? Challenge 1668 ny

* *

At Planck energies, interactions cannot be defined. Therefore, 'existence' cannot be defined. In short, at Planck energies we cannot say whether particles exist. True? Challenge 1669 ny

Hilbert's sixth problem settled

In the year 1900, David Hilbert gave a famous lecture in which he listed 23 of the great challenges facing mathematics in the twentieth century. Most of these provided challenges to many mathematicians for decades afterwards. A few are still unsolved, among them the sixth, which challenged mathematicians and physicists to find an *axiomatic* treatment of physics. Page 833 Ref. 1254

Since the universe is not even a set, we can deduce that such an axiomatic description of nature is *impossible*. The reasoning is simple: all mathematical systems, be they algebraic systems, order systems or topological systems, are based on elements and sets. Mathematics does not have axiomatic systems that do not contain elements and sets. The reason for this is simple: any (mathematical) concept contains at least one element and one set. However, nature does not.

The impossibility of an axiomatic system for physics is also confirmed in another way. Physics starts with a *circular* definition: space-time is defined with the help of objects and objects are defined with the help of space-time. Thus physics has *never* been fully modelled on the basis of mathematics. Physicists have always had to live with logical problems. Mathematics helps physics, but mathematics is not the foundation of physics. Page 317

The situation is similar to a child's description of the sky as 'made of air and clouds'. Looking closely, we discover that clouds are made up of water droplets. However, there is air inside clouds, and there is also water vapour elsewhere in the air. When clouds and

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

air are viewed through a microscope, there is no clear boundary between the two. We cannot define either of the terms 'cloud' and 'air' without the other.

Objects and vacuum are also indistinguishable in this sense. Virtual particles are found in vacuum, and vacuum is found inside objects. At Planck scales there is no clear boundary between the two; we cannot define either without the other. Despite the lack of a precise definition, and the logical problems that ensue, in both cases the description works well at large, everyday scales.

The result does not mean that physics has to abandon mathematics. This is not necessary. The way out will become clear as we continue in our ascent of motion mountain.

We note that, since the universe is not a set and since it contains no information, the Page 316 paradox of the physics book containing a full description of nature disappears. Such a book *could* exist, as it does not contradict any property of the universe. But then a further question arises.

Does the universe make sense?

> Drum hab ich mich der Magie ergeben,
> [...]
> Daß ich erkenne, was die Welt
> Im Innersten zusammenhält.*
>
> Goethe, *Faust*

Is the universe really the sum of matter–energy and space-time? Or of particles and vacuum? We have heard these statements so often that we may forget to check them. We do not need magic, as Faust thought: we only need to list what we have found so far, es- Page 804 pecially in this section, in the section on Planck scales, and in the chapter on brain and language. Table 122 shows the result.

Not only are we unable to state that the universe is made of space-time and matter; we are unable to say anything about the universe at all!** It is not even possible to say that it exists, since it is impossible to interact with it. The term 'universe' does not allow us to Challenge 1671 r make a single sensible statement. (Can you find one?) We are only able to list properties it does *not* have. We are unable to find any property that the universe *does* have. Thus, the universe has no properties! We cannot even say whether the universe is something or nothing. *The universe isn't anything in particular.* In other words, the term 'universe' is not at all useful for the description of motion.

Page 821 We can obtain a confirmation of this strange conclusion from an earlier chapter. There we found that any concept needs defined content, defined limits and a defined domain of application. In this section, we have found that the term 'universe' has none of these; there is thus no such concept. If somebody asks why the universe exists, the answer is: not only does the use of the word 'why' wrongly suggest that something may exist outside the universe, providing a reason for it and thus contradicting the definition of the term 'universe' itself; but more importantly, the universe does not exist. In summary, any sentence containing the word 'universe' is meaningless. The word only *seems* to express

* 'Thus I have devoted myself to magic, [...] that I understand how the innermost world is held together.'

** There is another well-known, non-physical concept about which nothing can be said. Many scholars have Challenge 1670 s explored it in detail. What is it?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 122 Physical statements about the universe

The universe has no age.	The universe has no beginning.
The universe has no size.	The universe has no volume.
The universe has no shape.	The universe's particle number is undefined.
The universe has no mass.	The universe has no energy.
The universe has no density.	The universe contains no matter.
The universe has no cosmological constant.	The universe has no initial conditions.
The universe has no state.	The universe has no wave function.
The universe is not a physical system.	The universe contains no information.
The universe is not isolated.	The universe is not open.
The universe has no boundaries.	The universe does not interact.
The universe cannot be measured.	The universe cannot be said to exist.
The universe cannot be distinguished from nothing.	The universe cannot be distinguished from a single event.
The universe contains no moments.	The universe is not composite.
The universe is not a set.	The universe is not a concept.
The universe cannot be described.	There is no plural for 'universe'.
The universe cannot be distinguished from vacuum.	The universe was not created.

something.*

This conclusion may be interesting, even strangely beautiful, but does it help us to understand motion more precisely? Yes, it does.

Abandoning sets and discreteness eliminates contradictions

Our discussion of the term 'universe' shows that the term cannot include any element or set. Nature cannot be made of atoms. Nature cannot be made of space-time points. Nature cannot be made of separate, distinct and discrete entities. This conclusion will help us on the way to a precise description of nature. We will see how later on.

The difficulties in giving a sharp definition of 'universe' also show that the fashionable term 'multiverse' makes no sense. There is no way to define such a term, since there is no empirical way and no logical way to distinguish one universe from another.

By taking into account the limits on length, time, mass and all the other quantities we have encountered, we have reached a number of almost painful conclusions about nature. However, we have also received something in exchange: all the contradictions between general relativity and quantum theory that we mentioned at the beginning of this chapter are now resolved. Although we have had to leave many cherished habits behind us, in exchange we have the promise of a description of nature without contradictions. But we get even more.

Challenge 1672 e

* Of course, the term 'universe' still makes sense if it is defined more restrictively: for example, as everything interacting with a particular human or animal observer in everyday life. But such a definition is not useful for our quest, as it lacks the precision required for a description of motion.

EXTREMAL SCALES AND OPEN QUESTIONS IN PHYSICS

Page 1340

In the chapter *Quantum physics in a nutshell* we listed all the unexplained properties of nature left open either by general relativity or by quantum theory. The present conclusions provide us with new connections among them. Indeed, many of the cosmological results of this section sound surprisingly familiar. Let us compare them systematically with those of the section on Planck scales. Both sections explored topics from the list of unexplained properties of nature, some in more detail than others.

First, Table 123 shows that *none* of the unexplained properties makes sense at *both* limits of nature, the small and the large. All open questions are open at both extremes. Secondly, and more importantly, nature behaves in the same way at horizon scales and at Planck scales. In fact, we have not found any difference between the two cases. (can you discover one?) We are thus led to the hypothesis that nature does not distinguish between the large and the small. Nature seems to be characterized by *extremal identity*.

Challenge 1673 r

IS EXTREMAL IDENTITY A PRINCIPLE OF NATURE?

The principle of extremal identity incorporates some rather general points:

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— All open questions about nature appear at its two extremes.
— Any description of nature requires both general relativity and quantum theory.
— Nature, or the universe, is not a set.
— Initial conditions and evolution equations make no sense at nature's limits.
— There is a relation between local and global issues in nature.
— The concept of 'universe' has no content.

Extremal identity thus looks like a good candidate tool for use in the search for a unified description of nature. To be a bit more provocative, it may be the *only* known principle incorporating the idea that the universe is not a set, and thus might be the only candidate tool for use in the quest of unification. Extremal identity is beautiful in its simplicity, in its unexpectedness and in the richness of its consequences. You might enjoy exploring it by yourself. Challenge 1674 ny

The study of the consequences of extremal identity is currently the focus of much activity in high-energy particle physics, although often under different names. Ref. 1255 The simplest approach to extremal identity – in fact, one that is too simple to be correct – is *inversion*. It looks as if extremal identity implies a connection such as

$$r \leftrightarrow \frac{l_{\mathrm{Pl}}^2}{r} \quad \text{or} \quad x_\mu \leftrightarrow \frac{l_{\mathrm{Pl}}^2 \, x_\mu}{x_\mu \, x^\mu} \tag{855}$$

relating distances r or coordinates x_μ with their inverse values using the Planck length l_{Pl}. Can this mapping be a symmetry of nature? At every point of space? For example, if the horizon distance is inserted, the relation (855) implies that lengths smaller than $l_{\mathrm{Pl}}/10^{61} \approx 10^{-96}$ m never appear in physics. Is this the case? What would inversion imply for the big bang? Challenge 1675 ny

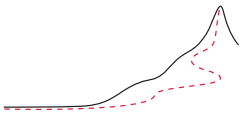
Numerous fascinating questions are contained in the simple hypothesis of extremal identity. They lead to two main directions for investigation.

First, we have to search for some stronger arguments for the validity of extremal identity. We will discover a number of simple arguments, all showing that extremal identity is indeed a property of nature, and producing many beautiful insights.

The other quest then follows. We need to find the correct version of the relation (855). That oversimplified expression is neither sufficient nor correct. It is not sufficient because it does not explain *any* of the issues left open by general relativity and quantum theory. It only *relates* some of them, thus reducing their number, but it does not *solve* any of them. (You may wish to check this for yourself.) In other words, we need to find the precise description of quantum geometry and of elementary particles. Challenge 1676 ny

However, inversion is also simply wrong. Inversion is not the correct description of extremal identity because it does not realize a central result discovered above: it does not connect *states* and *intrinsic properties*, but keeps them distinct. This means that inversion does not take *interactions* into account. And most open issues at this point of our mountain ascent concern properties of interactions.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 54

THE PHYSICS OF LOVE – A SUMMARY OF THE FIRST FIVE-AND-A-HALF PARTS

> Sex is the physics urge sublimated.
>
> Graffito

Maybe you have once met a physicist who has told you, in one of those moments of confidentiality, that studying physics is even more beautiful than making love.* At this statement, many will simply shake their head in disbelief and probably disapproval. In this section we will argue that it is possible to learn so much about physics while making love that discussions about their relative beauty can be put aside altogether.

Imagine being with your partner on a beautiful tropical island, just after sunset, and looking together at the evening sky. Imagine, as well, that you know little of what is taught at school nowadays – for example, that your knowledge is that of the late Renaissance (which is probably about the average level of modern scientific education anyway).

You are busy enjoying each other's company. The most important results of physics can be deduced from the following experimental facts:**

Love is communication.	Love is tiring.
Love is an interaction between moving bodies.	Love takes time.
Love is attractive.	Love is repulsive.
Love makes noise.	In love, size matters.
Love is for reproduction.	Love can hurt.
Love needs memory.	Love is Greek.
Love uses the sense of sight.	Love is animal.
Love is motion.	Love is holy.
Love is based on touch.	Love uses motion.
Love is fun.	Love is private.
	Love makes one dream.

* This section is based on a talk, with the title 'The physics of sex', given in 1998 at the Delft University of Technology.

** Here we deduce physics from love. We could also deduce physics from sexuality. The modern habit of saying 'sex' instead of 'sexuality' confuses two completely different concepts. In fact, studying the influences of *sex* on physics is almost a complete waste of time. Maybe one day we will understand why there do not seem to be any female crackpots proposing pet physical theories.

Ref. 1256
Ref. 1257

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Let us see what these observations imply for the description of nature.

* *

Love is *communication*. Communication is possible because nature looks similar from different standpoints and because there are no surprises in nature. Without similarity we could not understand each other, and a world of surprises would even make thinking impossible: it would not be possible to form concepts to describe observations. But fortunately, the world is regular; it thus allows us to use concepts such as time and space for its description.

* *

Love is an *interaction between moving bodies*. Together with the previous result, this implies that we can and need to describe moving bodies with *mass*, *energy* and *momentum*.
Challenge 1677 s That is not a small feat. For example, it implies that the Sun will rise tomorrow.

* *

Love is *attractive*. When feeling attracted to your partner, you may wonder if this attraction is the same as that which keeps the Moon going around the Earth. You make a quick calculation and find that applying the expression for universal gravity

$$E_{\text{pot}} = -\frac{GMm}{r} \tag{856}$$

to both of you, the energy involved is about as much as the energy added by the leg of a fly on the skin. (M and m are your masses, r your distance apart, and the gravitational constant has the value $G = 6.7 \cdot 10^{-11}\,\mathrm{m^3/kg\,s^2}$.) In short, your partner teaches you that in nature there are other attractive interactions apart from gravity.

Nevertheless, this first equation is important: it allows us to predict the position of the planets, the time of the tides, the time of eclipses, the return of comets, and so on, to a high accuracy, thousands of years in advance.

* *

Love *makes noise*. That is not news. However, even after making love, even when everybody and everything is quiet, in a completely silent environment, we do hear something. The noises we hear are produced within the ear, partly by the blood flowing through the head, partly by the electrical noise generated in the nerves. That is strange. If matter were continuous, there would be no noise even for low signal levels. In fact, all proofs of the discreteness of matter, of electric current, of energy, or of light are based on the increase of fluctuations with the smallness of the system under consideration. The persistence of noise thus makes us suspect that matter is made of smallest entities. Making love confirms this suspicion in several ways.

* *

Love is for *reproduction*. We owe our life to love, as we are all results of reproduction. But the reproduction of a structure is possible only if it can be constructed, in other words if the structure can be built from small standard entities. Thus we again suspect ourselves

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to be made of smallest, discrete entities.

Love is also a complicated method of reproduction. Mathematics provides a much simpler one. If matter objects were not made of particles, but were continuous, it would be possible to perform reproduction by cutting and reassembling. A famous mathematical theorem by Banach and Tarski proves that it is possible to take a continuous solid, cut it into five pieces and rearrange the pieces to obtain *two* copies of the same size and volume as the original. In fact, volumes can be increased in this way, thus achieving growth without any need for food. Mathematics thus provides some interesting methods for growth and reproduction. However, they assume that matter is continuous, without a smallest length scale. The observation that these methods do not work in nature is compatible with the idea that matter is not continuous.

* *

Ref. 1258 Love *needs memory*. If you could not recognize your partner among all possible ones, your love life would be quite complicated. A memory is a device which, in order to store information, must have *small* internal fluctuations. Fluctuations in systems get smaller as the number of components in them increases. Since our memory works so well, we must be made of a large number of small particles.

In summary, love shows that we are made of some kind of Lego bricks: depending on the level of magnification, these bricks are called molecules, atoms, or elementary particles. It is possible to estimate their size using the sea around the tropical island and Challenge 1678 s a bit of oil. Can you imagine how?

* *

Love *uses the sense of sight*. It is only possible for us to see each other because we are cold whereas the Sun is hot. If we and our environment all had the same temperature as the Ref. 1259 Sun, we would not see each other. This can be checked experimentally: looking into a glowing oven filled with glowing objects, it is impossible to discern the objects against the background.

* *

Love *is motion*. Bodies move against each other. Moreover, their speed can be measured. Since measurement is a comparison with a standard, there must be a velocity standard in nature: some special velocity that stands out. Such a standard must be either the minimum or the maximum possible value. Now, we know from daily life that there is no minimum velocity, so we must look for a maximum value. To estimate the value of the maximum, just take out your mobile phone and ring home from the island to your family. From the delay in the line and the height of the satellite, you can deduce the telephone speed c and get $3 \cdot 10^8$ m/s.

The existence of a maximum speed c implies that time is different for different observers. Looking into the details, we find that this effect becomes noticeable at energies

$$E_{\text{different time}} \approx mc^2 \,, \tag{857}$$

where m is the mass of the object. For example, this applies to electrons inside a television tube.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Love is based on *touch*. When we touch our partner, we sometimes get small shocks. The energies involved are larger than than those of touching fly legs. In short, people are electric.

In the dark, we observe that discharges emit light. Light is thus related to electricity. In addition, touching proves that light is a wave: simply observe the dark lines between two fingers near your eye in front of a bright background. The lines are due to interference effects. Thus light does not move with infinite speed. In fact, it moves with the same speed as mobile phone calls.

Challenge 1679 s

* *

Love is *fun*. People like to make love in different ways – for example, in a dark room. But rooms get dark when the light is switched off only because we live in a space with an odd number of dimensions. In even-dimensional space, a lamp would not turn off directly after the switch is flicked, but only dim slowly.

Page 234

Love is also fun because with our legs, arms and bodies we can make knots. Knots are possible only in three dimensions. In short, love is fun only because we live in three dimensions.

* *

Love is *tiring*. The reason is gravity. But what is gravity? A little thinking shows that since there is a maximum speed, gravity is the curvature of space-time. Curved space also means that a *horizon* – a largest possible visible distance – can appear. From equations (856) and (857), we deduce that this happens when distances are of the order of

$$R_{\text{horizon}} \approx Gm/c^2 \,. \tag{858}$$

For example, it is only because of a horizon – albeit one appearing in a different way – that the night sky is dark.

* *

Love *takes time*. It is known that men and women have different opinions on durations. It is also known that love happens between your ears. Indeed, biological research has shown that we have a clock inside the brain, which depends on circulating electrical currents. This clock provides our normal sense of time. Since this clock exists, there must be a time standard in nature. Such a standard must be either a minimum or a maximum time interval. We shall discover it later on.

Ref. 1260

* *

Love is *repulsive*. And in love, *size matters*. These facts turn out to be two sides of the same coin. Love is based on touch, and touch needs repulsion. Repulsion needs a length scale, but neither gravity nor classical electrodynamics provides one. Classical physics only allows for the measurement of speed. It cannot explain how the measurement of length, time, or mass is possible.* Classically, matter cannot be hard: it should be possible

* Note that the classical electron radius is not an exception: it depends on the elementary charge e, which

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to compress it. But love shows us that this is not the case. Love shows us that lengths scales do exist, and thus that classical physics is not sufficient for the description of nature.

* *

Love can *hurt*. For example, it can lead to injuries. Atoms can get ripped apart. That happens when energies are concentrated on small volumes: a few attojoule per atom. Investigating such situations more precisely, we finds that strange phenomena appear at distances r if energies exceed the value

$$E \approx \frac{\hbar\, c}{r} \quad . \tag{859}$$

In particular, energy becomes chunky, things become fuzzy, boxes are not tight, and particles get confused. These are called *quantum* phenomena. The new constant $\hbar = 10^{-34}$ Js is important: it determines the size of things, because it allows us to define distance and time units. In other words, objects tear and break because in nature there is a minimum action, given roughly by $\hbar$.

If even more energy is concentrated in small volumes – of the order of mc^2 per particle – one even observes transformation of energy into matter, or *pair production*. From equations (857) and (859), we deduce that this happens at distances of

$$r_{\text{pair production}} \approx \frac{\hbar}{m\, c} \, . \tag{860}$$

At such small distances we cannot avoid using the quantum description of nature.

* *

Love is not only *Greek*. The Greeks were the first to make theories above love, as Plato did in his *Phaedrus*. But they also described it in another way. Before Plato, Democritus said that making love is an example of particles moving and interacting in a vacuum. If we change 'a vacuum' to 'curved 3+1-dimensional space' and 'particle' to 'quantum particle', we do indeed make love in the way Democritus described 2,500 years ago.

It seems that physics has not made much progress in the mean time. Take the statement made in 1939 by the British astrophysicist Arthur Eddington:

Ref. 1261

> I believe there are 15,747,724,136,275,002,577,605,653,961,181,555,468,044,717,914, 527,116,709,366,231,425,076,185,631,031,296 protons in the universe and the same number of electrons.

Compare it with the version of 2009:

> Baryons in the universe: $10^{81\pm2}$. Total charge: near zero.

depends on a length scale, as shown on page 620.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The second version is more honest, but which of the two is less sensible? Both statements show that there are unexplained facts in the Greek description nature, in particular the number of particles.

* *

Love is *animal*. We have seen that we can learn a lot about nature from the existence of love. We could be tempted to see this approach to understanding nature as a case of the so-called *anthropic principle*. However, some care is required here. We could have learned exactly the same if we had taken as our starting point the observation that *apes* or *pigs* have love. There is no 'law' of nature which distinguishes between them and humans. In fact, there is a simple way to determine whether any 'anthropic' statement makes sense: the reasoning must be equally true for humans, apes, and pigs.

One famous anthropic deduction was stated by the British astrophysicist Fred Hoyle. While studying stars, he predicted a resonance in the carbon-12 nucleus. If it did not exist, he argued, stars could not have produced the carbon which afterwards was spread out by explosions into interstellar space and collected on Earth. Since apes or pigs might also reason in this way, Hoyle's statement does make sense.

On the other hand, claiming that the universe is made *especially* for people is not sensible: pigs would say that it is made for pigs. The existence of either humans or pigs requires all 'laws' of nature. In summary, the anthropic principle is valid only in so far as its consequences are indistinguishable from those of the porcine or the simian principle. In short, the animal side of love imposes limits on the philosophy of physics.

* *

Love is *holy*. According to the famous definition by the theologian Rudolf Otto, holiness results from a mixture of a *mysterium tremendum* and a *mysterium fascinans*. *Tremendum* means that it makes one tremble. Indeed, love produces heat and is a dissipative process. All systems in nature that produce heat have a finite lifetime. That is true for machines, stars, animals, lightning, fire, lamps and people. Through heat, love shows us that we are going to die. Physicists call this the second principle of thermodynamics.

Ref. 1262

But love also fascinates. Everything that fascinates has a story. Indeed, this is a principle of nature: every dissipative structure, every structure which appears or is sustained through the release of energy, has a story. Take atoms, for example. All the protons we are made of formed during the big bang. Most of the hydrogen we are made of is also that old. The other elements were formed in stars and then blown into the sky during nova or supernova explosions. They then regrouped during planet formation. We really are made of stardust.

Why do such stories fascinate? If you only think about how you and your partner met, you will discover that it was through a chain of incredible coincidences. If only one of these coincidences had not taken place, you and your partner would not be together. And of course, we all owe our existence to such chains of coincidences, which brought our parents together, and our grandparents, and made life appear on Earth.

The realization of the importance of coincidences automatically produces two kinds of questions: *why?* and *what if?* Physicists have produced a list of answers to all the repeated 'why' questions, and many are working on the 'what if' questions. The first list, the 'why' list of Table 124, gives all facts still unexplained. It can also be called the list of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

all surprises in nature. (We said above that there are no surprises in nature about *what* happens. However, there still are a few surprises about *how* all these things happen.)

TABLE 124 *Everything* quantum field theory and general relativity do *not* explain; in other words, a list of *the only* experimental data and criteria available for tests of the unified description of motion

OBSERVABLE	PROPERTY UNEXPLAINED SO FAR
Local quantities, from quantum theory	
α_{em}	the low energy value of the electromagnetic coupling constant
α_w	the low energy value of the weak coupling constant
α_s	the value of the strong coupling constant at one specific energy value
m_q	the values of the 6 quark masses
m_l	the values of 6 lepton masses
m_W	the value of the mass of the W vector boson
m_H	the value of the mass of the scalar Higgs boson
θ_w	the value of the weak mixing angle
$\theta_{12}, \theta_{13}, \theta_{23}$	the value of the three quark mixing angles
δ	the value of the CP violating phase for quarks
$\theta^\nu_{12}, \theta^\nu_{13}, \theta^\nu_{23}$	the value of the three neutrino mixing angles
$\delta^\nu, \alpha_1, \alpha_2$	the value of the three CP violating phases for neutrinos
3	the number of particle generations
3 + 1	the number of space and time dimensions
Global quantities, from general relativity	
$1.2(1) \cdot 10^{26}$ m (?)	the distance of the horizon, i.e., the 'size' of the universe (if it makes sense)
10^{82} (?)	the number of baryons in the universe (if it makes sense), i.e., the average matter density in the universe
10^{92} (?)	the initial conditions for more than 10^{92} particle fields in the universe (if or as long as they make sense), including those at the origin of galaxies or stars
ρ_{de} =0.5 nJ/m^3	the value and nature of the observed vacuum energy density, dark energy or cosmological constant
ρ_{dm}	the nature of dark matter
Local structures, from quantum theory	
$S(n)$	the origin of particle identity, i.e., of permutation symmetry
Ren. group	the renormalization properties, i.e., the existence of point particles
SO(3,1)	the origin of Lorentz (or Poincaré) symmetry (i.e., of spin, position, energy, momentum)
C^*	the origin of the algebra of observables
Gauge group	the origin of gauge symmetry, in particular:
U(1)	the origin of the electromagnetic gauge group (i.e., of the quantization of electric charge, as well as the vanishing of magnetic charge)
SU(2)	the origin of weak interaction gauge group
SU(3)	the origin of strong interaction gauge group

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Observable	Property unexplained so far
Global structures, from general relativity	
maybe $R \times S^3$ (?)	the unknown topology of the universe (if it makes sense)

This 'why' list is fascinating because it is so short, and many researchers are still trying to reduce it further. But it is equally interesting to study what the consequences would be if any of the values from Table 124 were just a tiny bit different. Small changes in nature would lead to completely different observations, as shown in Table 125.

TABLE 125 A small selection of consequences of changing aspects of nature

Observable	Change	Result
Moon size	smaller	small Earth magnetic field; too much cosmic radiation; widespread child cancers
Moon size	larger	large Earth magnetic field; too little cosmic radiation; no evolution into humans
Jupiter	smaller	many comet impacts on Earth; extinction of animal life
Jupiter	larger	few comet impacts on Earth; no Moon; no dinosaur extinction
Oort belt	smaller	no comets, no irregular asteroids, no Moon; still dinosaurs
Star distance	smaller	irregular planetary motion; supernova dangers
Strong coupling constant	smaller	proton decay; leukaemia

The large number of coincidences of life forces our mind to realize that we are only a *tiny* part of nature. We are a small droplet shaken around in the ocean of nature. Even the tiniest changes in nature would prevent the existence of humans, apes and pigs. In other words, making love tells us that the universe is much larger than we are, and how much we are dependent on and connected to the rest of the universe.

* *

We said above that love uses *motion*. This fact contains a remarkable mystery, worth a second look.

Motion is the change of position with time of some bodies. Position is what we measure with a ruler. Time is what we measure with a clock. Both rulers and clocks are bodies.

A body is an entity distinct from its environment by its shape or its mass. Shape is the extension of a body in space (and time). Mass is measured by measuring speed or acceleration, i.e., by measuring space and time.

This means that we define space-time in terms of bodies – as in general relativity – and we define bodies in terms of space-time – as in quantum theory. This circular reasoning shows that making love is truly a mystery. It has not yet been eliminated yet: modern theoretical physicists are busy with the attempt. In the year 2000, the most promising

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

approach seems to be M-theory, an extension of string theory. But any such attempt has to overcome major difficulties – which can also be experienced while making love.

* *

Love is *private*. But is it? The concept of privacy assumes that a person can separate from the rest, without important interactions, at least for a given time, and come back later. This is possible only if there is enough *empty space* between the person and others. In other words, privacy is based on the idea that objects can be distinguished from vacuum. Let us check whether this is always possible.

Ref. 1263 What is the smallest measurable distance? This question was *almost* answered by Max Planck in 1899. The distance δl between two objects of mass m is surely larger than their position indeterminacy $\hbar/\Delta p$; and the momentum indeterminacy must be smaller that the momentum leading to pair production, i.e., $\Delta p < mc$. Thus

$$\delta l \geqslant \Delta l \geqslant \frac{\hbar}{mc} \,. \tag{861}$$

In addition, measurement requires that signals leave the objects, so the two masses must not be black holes. Their masses must be small enough to ensure that the Schwarzschild radius is smaller than the distance to be measured. This means that $r_S \approx Gm/c^2 < \delta l$, or

$$\delta l \geqslant \sqrt{\frac{\hbar G}{c^3}} = l_{\text{Pl}} = 1.6 \cdot 10^{-35}\,\text{m} \,. \tag{862}$$

This expression defines a minimum length in nature, the so-called *Planck length*. Every other Gedanken experiment leads to this characteristic length as well. In fact, this minimum distance (and the corresponding minimum time interval) provides the measurement standard we were looking for at the beginning of our musings about length and time measurements.

A more detailed discussion shows that the smallest *measurable* distance is somewhat larger, because measurements require a distinction to be made between matter and radiation. This happens at scales of about 800 times the Planck length.

In other words, privacy has its limits. In fact, the issue becomes even more muddled when we explore the consequences for bodies. A body (even a human one) is something we can touch, throw, hit, carry or weigh. Physicists say that a body is something with energy or momentum. Vacuum has none of these properties. In addition, vacuum is unbounded, whereas objects are bounded.

What happens if we try to weigh objects at Planck scales? Quantum theory makes a simple prediction. If we put an object of mass M in a box of size R onto a scale – as in Figure 605 – equation (859) implies that there is a minimal mass error ΔM given by

$$\Delta M \approx \frac{\hbar}{cR} \,. \tag{863}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

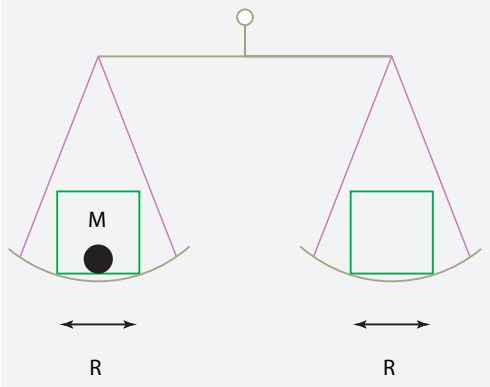


FIGURE 605 A Gedanken experiment showing that at Planck scales, matter and vacuum cannot be distinguished

If the box has Planck size, the mass error is the Planck mass

$$\Delta M = M_{\mathrm{Pl}} = \sqrt{\hbar c/G} \approx 22\,\mu\mathrm{g}\,. \tag{864}$$

How large a mass can we put into a box of Planck size? Obviously one with the maximum possible mass density. To determine this, imagine a planet with a satellite in orbit around it, just skimming its surface. The density ρ of the planet with radius r is given by

$$\rho \approx \frac{M}{r^3} = \frac{v^2}{Gr^2}\,. \tag{865}$$

Using equation (861) we find that the maximum mass density in nature, within a factor of order one, is the so-called *Planck density*, given by

$$\rho_{\mathrm{Pl}} = \frac{c^5}{G^2\hbar} = 5.2 \cdot 10^{96}\,\mathrm{kg/m^3}\,. \tag{866}$$

Therefore the maximum mass that can be contained inside a Planck box is the Planck mass. But that was also the measurement *error* for that situation. This implies that we cannot say whether the original box we measured was empty or full: vacuum *cannot* be distinguished from matter at Planck scales. This astonishing result is confirmed by every other Gedanken experiment exploring this issue. Ref. 1263

It is straightforward to deduce with similar arguments that objects are not bound in size at Planck scales, i.e., that they are not localized, and that the vacuum is not necessarily extended at those scales. In addition, the concept of particle number cannot be defined at Planck scales. Challenge 1680 s

So, why is there something instead of nothing? Making love shows that there is no difference between the two options!

* *

Love makes us *dream*. When we dream, especially at night, we often look at the sky. How

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

far away is it? How many atoms does it enclose? How old is it? These questions have an answer for small distances and for large distances; but for the whole of the sky, or the whole of nature, they cannot have an answer, as there is no way to be outside the sky in order to measure it. In fact, the impossibility of measuring nature at the smallest scales is found again at the largest scales. There seems to be a fundamental equivalence, or a *duality*, between the very large and the very small.

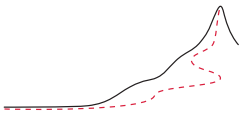
Ref. 1264

Hopefully, the coming years will show how we can translate these results into an even more precise description of motion and of nature. In particular, this description should allow us to reduce the number of unexplained properties of nature.

Summary on love and physics

In short, making love is a good physics lesson. Enjoy the rest of your day.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 55

MAXIMUM FORCE AND MINIMUM DISTANCE – PHYSICS IN LIMIT STATEMENTS

The principle of maximum force or power allows us to summarize each of the major physical theories – special relativity, quantum theory and general relativity – in one fundamental limit principle. The three principles are fully equivalent to the standard formulations of the theories. In particular, we show that the maximum force $c^4/4G$ implies and is equivalent to the field equations of general relativity. The combination of this limit with the speed limit of special relativity and the action–angular momentum limit of quantum theory implies a bound for every physical observable, from acceleration to size. The new, precise limit values differ from the usual Planck values by numerical factors of order unity.* Continuing with this approach, we show that every observable in nature has both a lower and an upper limit value.

Because of the maximum force and minimum length, the non-continuity of space-time is an inevitable consequence of the unification of quantum theory and relativity. Furthermore, the limits imply the maximum entropy bound, including the correct numerical factor. They also imply a maximum possible measurement precision, thus showing that any description of nature in terms of the real numbers is only approximate. Finally, the limits show that nature cannot be described by sets. As a result, the limit principles point to a solution to Hilbert's sixth problem. They also show that vacuum and matter cannot be fully distinguished in detail: they are two limiting cases of the same entity. These fascinating results provide the basis for any search for a unified theory of motion.

FUNDAMENTAL LIMITS TO ALL OBSERVABLES

At dinner parties, physicists are regularly asked to summarize physics in a few sentences. It is useful to have a few simple statements ready to answer such a request.** We propose some here. We are already familiar with each statement from our exploration of motion thus far. But by putting them all together, we will get direct insight into the results of modern research on unification.

The main lesson of modern physics is the following: *nature limits the possibilities of motion*. Such limits lie at the origin of special relativity, general relativity and quantum theory. In fact, we will see that nature limits *every* aspect of motion – but let us put first things first.

* These limits were given for the first time in 2003, in this section of the present text.

** Stimulating discussions with Saverio Pascazio, Corrado Massa and Steve Carlip helped shape this section.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Special relativity in one statement

The step from everyday, or Galilean, physics to special relativity can be summarized in a single limit statement on motion. It was popularized by Hendrik Antoon Lorentz: *There is a maximum energy speed in nature.* For all physical systems and all observers,

$$v \leqslant c \,. \tag{867}$$

A few well-known facts set the framework for the discussion that follows. The speed v is less than or equal to the speed of light c for *all* physical systems;* in particular, this limit is valid both for composite systems and for elementary particles. The speed limit is also valid for *all* observers. Indeed, only a maximum speed ensures that cause and effect can be distinguished in nature, or that sequences of observations can be defined. The opposite hypothesis, that speeds greater than c are possible, which implies the existence of (real) tachyons, has been explored and tested in great detail; it leads to numerous conflicts with observations.

The maximum speed forces us to use the concept of *space-time* to describe nature. The existence of a maximum speed implies that space and time mix. It also implies observer-dependent time and space coordinates, length contraction, time dilation, mass–energy equivalence, and all the other effects that characterize special relativity. Only this principle leads to the principle of maximum ageing that governs special relativity; and only this principle leads to the principle of least action at low speeds. In addition, only with a finite speed limit is it possible to define a *unit* of speed that is valid at all places and at all times. If there were no global speed limit, there could be no natural measurement standard for speed, independent of all interactions; speed would not then be a measurable quantity.

Page 409

Special relativity also limits the size of systems – whether composite or elementary. Indeed, the limit speed implies that acceleration a and size l cannot be increased independently without bounds, because the two ends of a system must not interpenetrate. The most important case concerns massive systems, for which we have

$$l \leqslant \frac{c^2}{a} \,. \tag{868}$$

This size limit is induced by the speed of light c; it is also valid for the *displacement* d of a system, if the acceleration measured by an external observer is used. Finally, the speed limit implies a relativistic 'indeterminacy relation'

$$\Delta l \, \Delta a \geqslant c^2 \tag{869}$$

for the length and acceleration indeterminacies. You may wish to take a minute to deduce this relation from the time–frequency indeterminacy. All this is standard knowledge.

Challenge 1681 s

* A *physical system* is a region of space-time containing mass–energy, the location of which can be followed over time and which interacts incoherently with its environment. This definition excludes images, geometrical points or incomplete entangled situations.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.net Copyright © Christoph Schiller November 1997–January 2009

Quantum theory in one statement

In the same way, the difference between Galilean physics and quantum theory can be summarized in a single statement on motion, due to Niels Bohr: *There is a minimum action in nature.* For all physical systems and all observers,

Ref. 1265 Page 976

$$S \geqslant \frac{\hbar}{2} \,. \tag{870}$$

Half the Planck constant $\hbar$ is the smallest observable action or angular momentum. This statement is valid for both composite and elementary systems.

The action limit is used less frequently than the speed limit. It starts from the usual definition of the action, $S = \int (T - U) \mathrm{d}t$, and states that between two observations performed at times t and $t + \Delta t$, even if the evolution of a system is not known, the action is at least $\hbar/2$. Physical action measures the change in the state of a physical system. Thus there is always a minimum change of state between two observations of a system. The quantum of action expresses the fundamental fuzziness of nature at a microscopic scale.

It can easily be checked that no observation – whether of photons, electrons or macroscopic systems – gives a smaller action than this. The minimum action has been verified for fermions, bosons, laser beams and matter systems, and for any combination of these. The opposite hypothesis, implying the existence of arbitrary small change, has been explored in detail: Einstein's long discussion with Bohr, for example, can be seen as a repeated attempt by Einstein to find experiments that would make it possible to measure arbitrarily small changes in nature. In every case, Bohr found that this could not be achieved.

The principle of minimum action can be used to deduce the indeterminacy relation, the tunnelling effect, entanglement, permutation symmetry, the appearance of probabilities in quantum theory, the information-theoretic formulation of quantum theory, and the existence of elementary particle reactions. It implies that, in quantum theory, the three concepts of state, measurement operation and measurement result need to be distinguished from each other; this is done be means of a so-called *Hilbert space*. The minimal action is also part of the Einstein–Brillouin–Keller quantization. The details of these connections can be found in the chapter on quantum theory.

Ref. 1266 Page 976

The existence of a quantum of action has been known from the very beginning of quantum theory. It is at the basis of – and completely equivalent to – all the standard formulations of quantum theory, including the many-path and the information-theoretic formulations.

Note also that only a finite action limit makes it possible to define a *unit* of action. If there were no action limit, there could be no natural measurement standard for action: action would not then be a measurable quantity.

The action bound $S \leqslant pd \leqslant mcd$, together with the quantum of action, implies a limit on the displacement d of a system between any two observations:

$$d \geqslant \frac{\hbar}{2mc} \,. \tag{871}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In other words, (half) the (reduced) Compton wavelength of quantum theory appears as the lower limit on the displacement of a system, whenever gravity plays no role. Since the quantum displacement limit applies in particular to an elementary system, it also applies to the *size* of a *composite* system. However, the limit is *not* valid for the sizes of elementary particles.

The action limit of quantum theory also implies Heisenberg's well-known indeterminacy relation for the displacement d and momentum p of systems:

Page 983

$$\Delta d \, \Delta p \geqslant \frac{\hbar}{2} \,. \tag{872}$$

This is valid for both massless and massive systems. All this is textbook knowledge.

General relativity in one statement

Much less well known is the possibility of summarizing the step from universal gravity to general relativity in a single statement on motion: *There is a maximum force or power in nature*. For all physical systems and all observers,

$$F \leqslant \frac{c^4}{4G} = 3.0 \cdot 10^{43}\,\mathrm{N} \quad \text{or} \quad P \leqslant \frac{c^5}{4G} = 9.1 \cdot 10^{51}\,\mathrm{W} \,. \tag{873}$$

These limit statements contain both the speed of light c and the gravitational constant G; they thus qualify as statements about relativistic gravitation. Like the other limit statements described above, they are valid for *all* observers.

This formulation of general relativity is not common; in fact, it seems that it was only discovered 80 years after the theory of general relativity had first been proposed.* A detailed discussion is given in the chapter on general relativity.

Ref. 1267
Page 471

The value of the force limit is the energy of a Schwarzschild black hole divided by its diameter; here the 'diameter' is defined as the circumference divided by π. The power limit is realized when such a black hole is radiated away in the time that light takes to travel along a length corresponding to the diameter.

Force is change of momentum; power is change of energy. Since momentum and energy are conserved, force or power can be pictured as the flow of momentum or energy through a given surface. The maximum force, as well as being the mass–energy of a black hole divided by its diameter, is also the surface gravity of a black hole times its mass. Thus the force limit means that no physical system of a given mass can be concentrated in a region of space-time smaller than a (non-rotating) black hole of that mass. In fact, the mass–energy concentration limit can easily be transformed algebraically into the force limit: they are equivalent.

Challenge 1682 e

It is easily checked that the maximum force is valid for all systems observed in nature, whether they are microscopic, macroscopic or astrophysical. Neither the 'gravitational force' (as long as it is operationally defined) nor the electromagnetic or nuclear interactions are ever found to exceed this limit.

Challenge 1683 e

* It may be that the present author was the first to point it out, in this very text. Gary Gibbons found the limit independently.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

But is it possible to *imagine* a system that exceeds the limit? An extensive discussion Page 471 shows that this is impossible, if the proper size of observers or test masses is taken into account. Even for a moving observer, when the force is increased by the (cube of the) relativistic dilation factor, or for an accelerating observer, when the observed acceleration is increased by the acceleration of the observer itself, the force limit must hold. The limit can never be exceeded, because for high accelerations a, horizons appear at distance a/c^2, and a mass m has a minimum diameter given by $l \geqslant 4Gm/c^2$.

The force and power limits are achieved only at horizons. They are valid for all observers and for all interactions.

As an alternative to the maximum force and power limits, we can take as a basic principle the statement: *There is a maximum rate of mass change in nature.* For all systems and observers, one has

$$\frac{\mathrm{d}m}{\mathrm{d}t} \leqslant \frac{c^3}{4G} = 1.0 \cdot 10^{35}\mathrm{kg/s} \,. \tag{874}$$

Equivalently, we can state: *There is a maximum mass-to-length ratio in nature.* For all systems and observers, one has

$$\frac{\mathrm{d}m}{\mathrm{d}l} \leqslant \frac{c^2}{4G} = 3.4 \cdot 10^{26}\mathrm{kg/m} \,. \tag{875}$$

Both the force and the power limits state that the flow of momentum or of energy through any *physical surface* (a term defined below) of any size, for any observer, in any coordinate system, never exceeds the limit value.

Because of the lack of nearby black holes or horizons, neither limit value is exceeded in any physical system found so far. This is the case at everyday length scales, in the microscopic world and in astrophysical systems. But even in Gedanken experiments the limits Page 471 cannot be exceeded. In fact, the limits become evident only when in such Gedanken experiments the sizes of observers or of test masses are taken into account. Otherwise, Page 471 apparent exceptions can be constructed, which are, however, unphysical.

Deducing general relativity*

In order to elevate the force or power limit to a principle of nature, we have to show that, just as special relativity follows from the maximum speed, so general relativity follows from the maximum force.

Ref. 1268 The maximum force and the maximum power are only realized at horizons. Horizons are regions of space-time where the curvature is so high that it limits the possibility of observation. The name 'horizon' is due to an analogy with the usual horizon of everyday life, which also limits the distance to which one can see. However, in general relativity horizons are surfaces, not lines. In fact, we can *define* the concept of horizon in general relativity as a region of maximum force; it is then easy to prove that it is always a two-dimensional surface, and that it has all the properties usually associated with it.

The connection between horizons and the maximum force or power allows us to deduce the field equations in a simple way. First, there is always a flow of energy at a horizon.

* This section can be skipped at first reading.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Horizons cannot be planes, since an infinitely extended plane would imply an infinite energy flow. To characterize the finite extension of a given horizon, we use its radius R and its total area A.

The energy flow through a horizon is characterized by an energy E and a proper length L of the energy pulse. When such an energy pulse flows perpendicularly through a horizon, the momentum change $\mathrm{d}p/\mathrm{d}t = F$ is given by

$$F = \frac{E}{L} \,. \tag{876}$$

Since we are at a horizon, we need to insert the maximum possible values. In terms of the horizon area A and radius R, we can rewrite the limit case as

$$\frac{c^4}{4G} = \frac{E}{A} 4\pi R^2 \frac{1}{L} \tag{877}$$

where we have introduced the maximum force and the maximum possible area $4\pi R^2$ of a horizon of (maximum local) radius R. The ratio E/A is the energy per unit area flowing through the horizon.

Horizons are often characterized by the so-called surface gravity a instead of the radius R. In the limit case, two are related by $a = c^2/2R$. This leads to

$$E = \frac{1}{4\pi G} a^2 A L \,. \tag{878}$$

Ref. 1269 Special relativity shows that at horizons the product aL of proper length and acceleration is limited by the value $c^2/2$. This leads to the central relation for the energy flow at horizons:

$$E = \frac{c^2}{8\pi G} a A \,. \tag{879}$$

This equation makes three points. First, the energy flowing through a horizon is limited. Secondly, this energy is proportional to the area of the horizon. Thirdly, the energy flow is proportional to the surface gravity. These are fundamental, and characteristic, statements of general relativity.

Taking differentials, the last relation can be rewritten as

$$\delta E = \frac{c^2}{8\pi G} a \, \delta A \,. \tag{880}$$

In this form, the result can also be applied to general horizons, including those that are curved or time-dependent.*

* Relation (880) is well known, though with different names for the observables. Since no communication is possible across a horizon, the detailed fate of energy flowing through a horizon is also unknown. Energy whose detailed fate is unknown is often called *heat*. Relation (880) therefore states that the heat flowing through a horizon is proportional to the horizon area. When quantum theory is introduced into the discussion, the area of a horizon can be called 'entropy' and its surface gravity can be called 'temperature'; relation

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 1270 In a well-known paper, Jacobson has given a beautiful proof of a simple connection: if energy flow is proportional to horizon area for all observers and all horizons, then general relativity follows. To see the connection to general relativity, we generalize relation (880) to general coordinate systems and general energy-flow directions.

The proof uses tensor notation. One introduces the general surface element $\mathrm{d}\Sigma$ and the local boost Killing vector field k that generates the horizon (with suitable norm). Jacobson rewrites the left-hand side of relation (880) as

$$\delta E = \int T_{ab} k^a \mathrm{d}\Sigma^b \,, \tag{882}$$

where T_{ab} is the energy–momentum tensor. This is valid in arbitrary coordinate systems and for arbitrary energy flow directions. Jacobson's main result is that the essential part of the right-hand side of relation (880) can be rewritten, using the (purely geometric) Raychaudhuri equation, as

$$a\delta A = c^2 \int R_{ab} k^a \mathrm{d}\Sigma^b \,, \tag{883}$$

where R_{ab} is the Ricci tensor describing space-time curvature.

Combining these two steps, we find that the energy–area relation (880) for horizons can be rewritten as

$$\int T_{ab} k^a \mathrm{d}\Sigma^b = \frac{c^4}{8\pi G} \int R_{ab} k^a d\Sigma^b \,. \tag{884}$$

Jacobson shows that this equation, together with local conservation of energy (i.e., vanishing divergence of the energy–momentum tensor), can only be satisfied if

$$T_{ab} = \frac{c^4}{8\pi G} \left(R_{ab} - (\frac{1}{2}R + \Lambda) g_{ab} \right) \,, \tag{885}$$

where Λ is a constant of integration whose value is not determined by the problem. These are the full field equations of general relativity, including the cosmological constant Λ.

The field equations are thus shown to be valid at horizons. Since it is possible, by choosing a suitable coordinate transformation, to position a horizon at any desired space-time event, the field equations must be valid over the whole of space-time.

Since it is possible to have a horizon at every event in space-time, at every event in nature there is the same maximum possible force (or power). This maximum force (or power) is thus a constant of nature.

In other words, the field equations of general relativity are a direct consequence of the limited energy flow at horizons, which in turn is due to the existence of a maximum force or power. One can thus speak of the maximum force *principle*. Conversely, the field equations imply maximum force. Maximum force and general relativity are thus equivalent.

(880) can then be rewritten as

$$\delta Q = T\delta S \,. \tag{881}$$

However, this translation of relation (880), which requires the quantum of action, is unnecessary here. We only cite it to show the relation between horizon behaviour and quantum gravity.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The bounds on force and power have important consequences. In particular, they imply statements on cosmic censorship, the Penrose inequality, the hoop conjecture, the non-existence of plane gravitational waves, the lack of space-time singularities, new experimental tests of the theory, and the elimination of competing theories of relativistic gravitation. These consequences are presented elsewhere. Ref. 1271

Deducing universal gravitation

Universal gravitation can be derived from the force limit in the case where both forces and speeds are much smaller than the maximum values. The first condition implies $\sqrt{4GMa} \ll c^2$, the second $v \ll c$ and $al \ll c^2$. Let us apply this to a specific case. Consider a satellite circling a central mass M at distance R with acceleration a. This system, with length $l = 2R$, has only one characteristic speed. Whenever this speed v is much smaller than c, v^2 must be proportional both to $al = 2aR$ and to $\sqrt{4GMa}$. Taken together, these results imply that $a = fGM/R^2$, for some numerical factor f. A quick check, for example using the observed escape velocity values, shows that $f = 1$. Forces and speeds much smaller than the limit values thus imply that the inverse square law of gravity holds. In other words, nature's limit on force implies the universal law of gravity. Challenge 1684 e

The size of physical systems in general relativity

General relativity, like the other theories of modern physics, implies a limit on the *size* of systems. There is a limit to the amount of matter that can be concentrated into a small volume:

$$l \geqslant \frac{4Gm}{c^2} \,. \tag{886}$$

The size limit is only achieved for black holes, those well-known systems which swallow everything that is thrown into them. It is fully equivalent to the force limit. All *composite* systems in nature comply with the lower size limit. Whether elementary particles fulfil or even match this limit remains one of the open questions of modern physics. At present, neither experiment nor theory allows clear statements on their size. More about this issue below.

General relativity also implies an 'indeterminacy relation': Ref. 1272

$$\frac{\Delta E}{\Delta l} \leqslant \frac{c^4}{4G} \,. \tag{887}$$

Since experimental data are available only for composite systems,* we cannot yet say whether this inequality also holds for elementary particles. This relation is not as well known as the previous one. In fact, tests of it – for example with binary pulsars – may distinguish general relativity from competing theories.

* For example, the latest measurements for the Sun give $T_\odot = GM_\odot/c^3 = 4.925\,490\,947\,\mu s$; the error in E is thus much smaller than the (scaled) error in its radius. Ref. 1273

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

A MECHANICAL ANALOGY FOR THE MAXIMUM FORCE

The maximum force is central to the theory of general relativity. Indeed, its value (adorned with a factor 2π) appears in the field equations. Its importance becomes clearer when we return to our old image of space-time as a deformable mattress. Like any material body, a mattress is described by a material constant that relates the deformation values to the values of applied energy. Similarly, a mattress, like any material, is described by the maximum stress it can bear before it breaks. These two values describe crystals as well as mattresses. In fact, for perfect crystals (without dislocations), these two material constants are the same.

Empty space-time somehow behaves like a perfect crystal, or a perfect mattress: it has a deformation-energy constant that is equal to the maximum force that can be applied to it. The constant of gravitation thus determines the elasticity of space-time. Now, crystals are not homogeneous, but are made up of atoms, while mattresses are made up of foam bubbles. What is the corresponding structure of space-time? This is a central question in the rest of our adventure. One thing is sure: unlike crystals, vacuum has no preferred directions. In fact, all these analogies suggest that the appearance of matter might be nature's way of preventing space-time from ripping apart. We have to patient for a while, before we can judge this opinion. By putting all the limits together, we take first step towards answering the question of the structure of space-time.

UNITS AND LIMIT VALUES FOR ALL PHYSICAL OBSERVABLES

The existence of a maximum force in nature is equivalent to general relativity. As a result, physics can now be seen as making three simple statements on motion:

$$\begin{aligned} &\text{quantum theory on action:} && S \geqslant \frac{\hbar}{2} \\ &\text{special relativity on speed:} && v \leqslant c \\ &\text{general relativity on force:} && F \leqslant \frac{c^4}{4G} \,. \end{aligned} \tag{888}$$

These limits are valid for all physical systems, whether composite or elementary, and for all observers. Note that the limit quantities of special relativity, quantum theory and general relativity can also be seen as the right-hand sides of the respective indeterminacy relations. Indeed, the set (869, 872, 887) of indeterminacy relations or the set (868, 871, 886) of length limits is each fully equivalent to the three limit statements (888). Each set of limits can be taken as a (somewhat selective) summary of twentieth-century physics.

Challenge 1685 e

By combining the three fundamental limits, we can obtain limits on a number of physical observables. The following limits are valid generally, for both composite and elementary systems:

$$\text{time interval:} \qquad t \geqslant \sqrt{\frac{2G\hbar}{c^5}} \quad = \quad 7.6 \cdot 10^{-44}\,\text{s} \tag{889}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$\text{time-distance product:} \quad td \geqslant \frac{2G\hbar}{c^4} = 1.7 \cdot 10^{-78}\,\text{ms} \tag{890}$$

$$\text{acceleration:} \quad a \leqslant \sqrt{\frac{c^7}{2G\hbar}} = 4.0 \cdot 10^{51}\,\text{m/s}^2 \tag{891}$$

$$\text{angular frequency:} \quad \omega \leqslant 2\pi\sqrt{\frac{c^5}{2G\hbar}} = 8.2 \cdot 10^{43}\,\text{/s} \tag{892}$$

With the additional knowledge that space and time can mix, we get

$$\text{distance:} \quad d \geqslant \sqrt{\frac{2G\hbar}{c^3}} = 2.3 \cdot 10^{-35}\,\text{m} \tag{893}$$

$$\text{area:} \quad A \geqslant \frac{2G\hbar}{c^3} = 5.2 \cdot 10^{-70}\,\text{m}^2 \tag{894}$$

$$\text{volume:} \quad V \geqslant \left(\frac{2G\hbar}{c^3}\right)^{3/2} = 1.2 \cdot 10^{-104}\,\text{m}^3 \tag{895}$$

$$\text{curvature:} \quad K \leqslant \frac{c^3}{2G\hbar} = 1.9 \cdot 10^{69}\,\text{/m}^2 \tag{896}$$

$$\text{mass density:} \quad \rho \leqslant \frac{c^5}{8G^2\hbar} = 6.5 \cdot 10^{95}\,\text{kg/m}^3 \tag{897}$$

Of course, speed, action, angular momentum, power and force are also limited, as already stated. Up to a numerical factor, the limit for every physical observable corresponds to the Planck value. (The limit values are deduced from the commonly used Planck values simply by substituting $4G$ for G and $\hbar/2$ for $\hbar$.) These limit values are the true *natural units* of nature. In fact, the ideal would be to redefine the usual Planck values for all observables to these extremal values, by absorbing the numerical factors into the respective definitions. In the following, we call the limit values the *(corrected) Planck limits* and assume that the factors have been properly included. In other words, *every natural unit or (corrected) Planck unit is the limit value of the corresponding physical observable.*

Page 1398

Most of these limit statements are found throughout the literature, though the numerical factors are often different. Each limit has attracted a string of publications. The

Ref. 1274

existence of a smallest measurable distance and time interval of the order of the Planck values is discussed in quantum gravity and string theory. The maximum curvature has

Ref. 1275

been studied in quantum gravity; it has important consequences for the 'beginning' of the universe, where it excludes any infinitely large or small observable. The maximum mass density appears regularly in discussions on the energy of the vacuum.

With our present deduction of the limits we have achieved two results. First, the various arguments used in the literature are reduced to three generally accepted principles. Secondly, the confusion about the numerical factors is resolved. In the history of the Planck units, there has been much variation in the numerical factors employed. For example, the founding fathers of quantum theory forgot the 1/2 in the definition of the quantum of action. Similarly, the early relativists omitted the factor 4. With the present framework, the question of the correct factors in the Planck units can be considered set-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tled.

Note that the dimensional independence of the three limits in nature means that quantum effects cannot be used to overcome the force limit; similarly, the power limit cannot be used to overcome the speed limit. The same is true for any other combination of limits: they are mutually independent and consistent.

Limits to space and time

> Those are my principles, and if you don't like them... well, I have others.
>
> Groucho Marx

The three limits of nature (888) result in a minimum distance and a minimum time interval. These minimum intervals arise directly from the *unification* of quantum theory and relativity: they do not appear if the theories are kept separate. In short, unification implies that there is a smallest length in nature. This result is important: the formulation of physics as a set of limit statements shows that *the continuum model of space and time is not correct.* Continuity and manifolds are only approximations, valid for large actions, low speeds and small forces. The reformulation of general relativity and quantum theory with limit statements makes this especially clear. No other assumptions are needed.

Ref. 1276 In fact, the connection between minimum length and gravity is not new. In 1969, Andrei Sakharov pointed out that a minimum length implies gravity. He showed that regularizing quantum field theory on curved space with a cut-off will induce counter-terms that include to lowest order the cosmological constant and then the Einstein–Hilbert action.

Page 1398 The existence of limit values for the length observable (and all others) has numerous consequences, discussed in detail elsewhere. In particular, the existence of a smallest length – and a corresponding shortest time interval – implies that no surface is *physical* if any part of it requires a localization in space-time to scales below the minimum length. (In addition, a physical surface must not cross any horizon.) Only by insisting on this condition can we eliminate unphysical examples that contravene the force and power limits. For example, this condition was overlooked in Bousso's early discussion of Ref. 1277 Bekenstein's entropy bound – though not in his more recent ones.

Ref. 1278 The corrected value of the Planck length should also appear in the so-called theories of 'doubly special relativity'. These theories try to expand special relativity in such a way that an invariant length appears.

The existence of a force limit in nature implies that no physical system can be smaller than a Schwarzschild black hole of the same mass. In particular, *point particles do not exist*. In addition, elementary particles are predicted to be larger than the corrected Planck length. So far, this prediction has not been tested by observations, as the scales in question are so small that they are beyond experimental reach. Detecting the sizes of elementary particles – for example, with electric dipole measurements – would make it possible Page 1398 to check the force limit directly. If quantum theory is taken into account, the bound is sharpened.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Mass and energy limits

Mass plays a special role in all these arguments. The set of limits (888) does not make it possible to extract a limit statement on the mass of physical systems. To find one, we have to restrict our aim somewhat.

The Planck limits mentioned so far apply to *all* physical systems, whether composite or elementary. Other limits apply only to elementary systems. In quantum theory, the distance limit is a size limit only for *composite* systems. A particle is elementary if the system size l is smaller than any conceivable dimension:

$$\text{for elementary particles:} \quad l \leqslant \frac{\hbar}{2mc} \,. \tag{898}$$

Using this new limit, valid only for elementary particles, we find the well-known mass, energy and momentum limits:

$$\begin{aligned}
&\text{for elementary particles:} \quad m \leqslant \sqrt{\frac{\hbar c}{8G}} &&= 7.7 \cdot 10^{-9}\,\text{kg} = 0.42 \cdot 10^{19}\,\text{GeV/c}^2 \\
&\text{for elementary particles:} \quad E \leqslant \sqrt{\frac{\hbar c^5}{8G}} &&= 6.9 \cdot 10^{8}\,\text{J} = 0.42 \cdot 10^{19}\,\text{GeV} \\
&\text{for elementary particles:} \quad p \leqslant \sqrt{\frac{\hbar c^3}{8G}} &&= 2.3\,\text{kg m/s} = 0.42 \cdot 10^{19}\,\text{GeV/c}
\end{aligned} \tag{899}$$

These single-particle limits, corresponding to the corrected Planck mass, energy and momentum, were discussed in 1968 by Andrei Sakharov, though with different numerical factors. They are regularly cited in elementary particle theory. All known measurements comply with them. It is also known that the unification of the electromagnetic and the two nuclear interactions takes place at an energy near, but still clearly below, the maximum particle energy.

Ref. 1279

Virtual particles – a new definition

In fact, there are physical systems that exceed all three limits. Nature does contain systems that move faster than light, that show actions below half the quantum of action, and that experience forces larger than the force limit.

We know from special relativity that the virtual particles exchanged in collisions move faster than light. We know from quantum theory that virtual particle exchange implies actions below the minimum action. Virtual particles also imply an instantaneous change of momentum; they thus exceed the force limit. Thus *virtual particles* are those particles that exceed all the limits that hold for (real) physical systems.

Page 444

Page 1037

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Limits in thermodynamics

Thermodynamics can also be summarized in a single statement about motion: *There is a smallest entropy in nature.*

$$S \geqslant \frac{k}{2} \,. \tag{900}$$

The entropy S is limited by half the Boltzmann constant k. This result is almost 100 years old; it was stated most clearly by Leo Szilard, though with a different numerical factor. Like the other limit statements we have examined, this result can also be phrased as a indeterminacy relation:

Ref. 1280

$$\Delta \frac{1}{T} \, \Delta U \geqslant \frac{k}{2} \,. \tag{901}$$

This relation was given by Bohr and discussed by Heisenberg and many others (though with k instead of $k/2$). It is mentioned here in order to complete the list of indeterminacy relations and fundamental constants. With the single-particle limits, the entropy limit leads to an upper limit for temperature:

Ref. 1281

$$T \leqslant \sqrt{\frac{\hbar c^5}{2Gk^2}} = 1.0 \cdot 10^{32}\,\mathrm{K} \,. \tag{902}$$

This corresponds to the temperature at which the energy per degree of freedom is given by the (corrected) Planck energy. A more realistic value would have to take account of the number of degrees of freedom of a particle at Planck energy. This would change the numerical factor.

Electromagnetic limits and units

Our discussion of limits can be extended to include electromagnetism. Using the (low-energy) electromagnetic coupling constant α, one gets the following limits for physical systems interacting electromagnetically:

electric charge: $$q \geqslant \sqrt{4\pi\varepsilon_0 \alpha c \hbar} = e = 0.16\,\mathrm{aC} \tag{903}$$

electric field: $$E \leqslant \sqrt{\frac{c^7}{64\pi\varepsilon_0 \alpha \hbar G^2}} = \frac{c^4}{4Ge} = 2.4 \cdot 10^{61}\,\mathrm{V/m} \tag{904}$$

magnetic field: $$B \leqslant \sqrt{\frac{c^5}{64\pi\varepsilon_0 \alpha \hbar G^2}} = \frac{c^3}{4Ge} = 7.9 \cdot 10^{52}\,\mathrm{T} \tag{905}$$

voltage: $$U \leqslant \sqrt{\frac{c^4}{32\pi\varepsilon_0 \alpha G}} = \frac{1}{e}\sqrt{\frac{\hbar c^5}{8G}} = 1.5 \cdot 10^{27}\,\mathrm{V} \tag{906}$$

inductance: $$L \geqslant \frac{1}{8\pi\varepsilon_0 \alpha}\sqrt{\frac{2\hbar G}{c^7}} = \frac{1}{e^2}\sqrt{\frac{\hbar^3 G}{2c^5}} = 4.4 \cdot 10^{-40}\,\mathrm{H} \tag{907}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

With the additional assumption that in nature at most one particle can occupy one Planck volume, one gets

$$\text{charge density:} \quad \rho_e \leqslant \sqrt{\frac{\pi\varepsilon_0\alpha}{2G^3}}\,\frac{c^5}{\hbar} = e\sqrt{\frac{c^9}{8G^3\hbar^3}} = 1.3\cdot 10^{85}\,\mathrm{C/m^3} \tag{908}$$

$$\text{capacitance:} \quad C \geqslant 8\pi\varepsilon_0\alpha\sqrt{\frac{2\hbar G}{c^3}} = e^2\sqrt{\frac{8G}{c^5\hbar}} = 1.0\cdot 10^{-46}\,\mathrm{F} \tag{909}$$

For the case of a single conduction channel, one gets

$$\text{electric resistance:} \quad R \geqslant \frac{1}{8\pi\varepsilon_0\alpha c} = \frac{\hbar}{2e^2} = 2.1\,\mathrm{k\Omega} \tag{910}$$

$$\text{electric conductivity:} \quad G \leqslant 8\pi\varepsilon_0\alpha c = \frac{2e^2}{\hbar} = 0.49\,\mathrm{mS} \tag{911}$$

$$\text{electric current:} \quad I \leqslant \sqrt{\frac{2\pi\varepsilon_0\alpha c^6}{G}} = e\sqrt{\frac{c^5}{2\hbar G}} = 7.4\cdot 10^{23}\,\mathrm{A} \tag{912}$$

Many of these limits have been studied already. The magnetic field limit is significant in the study of extreme stars and black holes. The maximum electric field plays a role in the theory of gamma ray bursters. For current, conductivity and resistance in single channels, the limits and their effects were studied extensively in the 1980s and 1990s by researchers who will probably win a Nobel Prize in the not too distant future.

Ref. 1282
Ref. 1283

The observation of quarks and of collective excitations in semiconductors with charge $e/3$ does not necessarily invalidate the charge limit for physical systems. In neither case is there is a physical system – defined as localized mass–energy interacting incoherently with the environment – with charge $e/3$.

Vacuum and mass–energy – two sides of the same coin

We have found that there is a fixed limit to every physical observable. Many consequences have been discussed already in previous sections. We have seen that the existence of a limit to every observable implies that at Planck scales no physical observable can be described by real numbers, and that no low-energy symmetry is valid.

Page 1396
Page 1425

One conclusion is especially important for the rest of our adventure. We saw that there is a limit to the precision of length measurements in nature. This limit is valid both for length measurements of empty space and for length measurements of matter (or radiation). Now let us recall what we do when we measure the length of a table with a ruler. To find the ends of the table, we must be able to distinguish the table from the surrounding air. In more precise terms, we must be able to distinguish matter from vacuum. But at Planck energy we cannot do this. At this scale, the intrinsic measurement limitations of nature mean that we cannot say whether we are measuring vacuum or matter.

Page 1398

We have explored this conclusion in detail, and seen that it is the only consistent description at Planck scales. You can pick any observable you want to use to distinguish vacuum from matter – for example, colour, mass, size, charge, speed or angular momentum.

Page 471

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

At Planck scales, the limits to observables lead to limits to measurement precision. Furthermore, the measurement limits are of the same size as the observable to be measured. Therefore, at Planck scales it is impossible to distinguish between matter and vacuum, and you cannot tell whether a box is full or empty.

To state the conclusion in the sharpest possible terms: *vacuum and matter do not differ at Planck scales*. This counter-intuitive result is one of the charms of theoretical high-energy physics. It has inspired many researchers in the field and some have written best-sellers about it. Brian Greene was particularly successful in presenting this side of quantum geometry to the wider public. Ref. 1284

At this point of our adventure, many questions are still open. The precise manner in which a minimum distance leads to a homogeneous and isotropic vacuum is unclear. We still have to find a way to describe matter and vacuum with the same concepts. And of course, there is still the list of open questions in physics given above. However, these conceptual results give hope: there are interesting ideas awaiting us.

Curiosities and fun challenges about Planck limits

The (corrected) Planck limits are statements about properties of nature. There is no way to measure values exceeding these limits, with any kind of experiment. Naturally, such a claim provokes the search for counter-examples and leads to many paradoxes.

* *

The minimum angular momentum may come as a surprise at first, especially when one thinks about particles with spin zero. However, the angular momentum in question is *total* angular momentum, including the orbital part with respect to the observer. The total angular momentum is never smaller than $\hbar/2$.

* *

How can the maximum force be determined by gravity alone, which is the weakest interaction? It turns out that in situations near the maximum force, the other interactions are negligible. This is the reason why gravity must be included in a unified description of nature.

* *

At first sight, it seems that electric charge can be used in such a way that the acceleration of a charged body towards a charged black hole is increased to a value, when multiplied with the mass, exceeding the force limit. However, the changes in the horizon for charged black holes prevent this. Challenge 1686 ny

* *

The general fact that to every limit value in nature there is a corresponding indeterminacy relation is valid in particular for electricity. Indeed, there is an indeterminacy relation for capacitors, of the form

$$\Delta C \, \Delta U \geqslant e \tag{913}$$

where e is the positron charge, C capacity and U potential difference; there is also an

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

indeterminacy relation between electric current I and time t

$$\Delta I \, \Delta t \geqslant e \; . \tag{914}$$

Ref. 1285 Both these relations may be found in the literature.

* *

The gravitational attraction between two masses never yields force values high enough to exceed the force limit. Why? First of all, masses m and M cannot come closer together than the sum of their horizon radii. Using $F = GmM/r^2$ with the distance r given by the (naive) sum of the two black hole radii as $r = 2G(M + m)/c^2$, one gets

$$F \leqslant \frac{c^4}{4G} \frac{Mm}{(M+m)^2} \; , \tag{915}$$

which is never larger than the force limit. Thus even two attracting black holes cannot exceed the force limit – in the inverse-square approximation of universal gravity. In short, the minimum size of masses means that the maximum force cannot be exceeded.

* *

It is well known that gravity bends space. Therefore, if they are to be fully convincing, our calculation needs to be repeated taking into account the curvature of space. The simplest way is to study the force generated by a black hole on a test mass hanging from a wire that is lowered towards a black hole horizon. For an *unrealistic point mass*, the force would Ref. 1286 diverge at the horizon. Indeed, for a point mass m lowered towards a black hole of mass M at (conventionally defined radial) distance d, the force would be

$$F = \frac{GMm}{d^2 \sqrt{1 - \frac{2GM}{dc^2}}} \; . \tag{916}$$

This diverges at $d = 0$, the location of the horizon. However, even a test mass cannot be smaller than its own gravitational radius. If we want to reach the horizon with a *realistic* test mass, we need to choose a small test mass m: only a small mass can get near the horizon. For vanishingly small masses, however, the resulting force tends to zero. Indeed, letting the distance tend to the smallest possible value by letting $d = 2G(m + M)/c^2 \to 2GM/c^2$ requires $m \to 0$, which makes the force $F(m, d)$ vanish. If on the other hand, we remain away from the horizon and look for the maximum force by using a mass as large as can possibly fit into the available distance (the calculation is straightforward), then again the force limit is never exceeded. In other words, for *realistic* test masses, expression (916) is *never* larger than $c^4/4G$. Taking into account the minimal size of test masses, we thus see that the maximum force is never exceeded in gravitational systems.

* *

An absolute power limit implies a limit on the energy that can be transported per unit time through any imaginable surface. At first sight, it may seem that the combined power

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

emitted by two radiation sources that each emit 3/4 of the maximum value should give 3/2 times the maximum value. However, the combination forms a black hole, or at least prevents part of the radiation from being emitted by swallowing it between the two sources.

* *

One possible system that actually achieves the power limit is the final stage of black hole evaporation. But even in this case, the power limit is not exceeded.

* *

The maximum force limit states that the stress–energy tensor, when integrated over any physical surface, does not exceed the limit value. No such integral, over any physical surface, of any tensor component in any coordinate system, can exceed the force limit, provided that it is measured by a nearby observer or a test body with a realistic proper size. The maximum force limit thus applies to any component of any force vector, as well as to its magnitude. It applies to gravitational, electromagnetic, and nuclear forces; and it applies to all realistic observers. It is not important whether the forces are real or fictitious; nor whether we are discussing the 3-forces of Galilean physics or the 4-forces of special relativity. Indeed, the force limit applied to the zeroth component of the 4-force is the power limit.

Ref. 1267

* *

In terms of mass flows, the power limit implies that flow of water through a tube is limited in throughput. This limit seems to be unrecorded in the literature.

* *

The force limit cannot be overcome with Lorentz boosts. A Lorentz boost of any non-vanishing force value seems to allow the force limit to be exceeded at high speeds. However, such a transformation would create a horizon that makes any point with a potentially higher force value inaccessible.

* *

The power limit is of interest if applied to the universe as a whole. Indeed, it can be used to explain Olbers' paradox: the sky is dark at night because the combined luminosity of all light sources in the universe cannot be brighter than the maximum value.

* *

The negative energy volume density $-\Lambda c^4/4\pi G$ introduced by the positive cosmological constant Λ corresponds to a negative pressure (both quantities have the same dimensions). When multiplied by the minimum area it yields a force value

$$F = \frac{\Lambda\hbar c}{2\pi} = 4.8 \cdot 10^{-79}\,\mathrm{N}\,. \tag{917}$$

This is also the gravitational force between two corrected Planck masses located at the cosmological distance $\sqrt{\pi/4\Lambda}$. If we make the (wishful) assumption that this is the smallest

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

possible force in nature (the numerical prefactor is not yet known for sure), we arrive at the fascinating conjecture that the full theory of general relativity, including the cosmological constant, might be defined by the combination of a maximum and a minimum force in nature.

UPPER AND LOWER LIMITS TO OBSERVABLES

In our quest to understand motion, we have focused our attention on the limitations to which it is subject. Special relativity posits a limit to speed, namely the speed of light c. Page 471 General relativity limits force and power respectively by $c^4/4G$ and $c^5/4G$, and quantum theory introduces a smallest value $\hbar/2$ for angular momentum or action. We have seen that nature imposes the limit k on entropy and the limit e on electrical charge. Together, all these limits induce extremal values for *all* physical observables, given by the corresponding (corrected) Planck values. Page 1458 We explored the Planck limits in the last section.

A question arises: does nature also impose limits on physical observables at the opposite end of the measurement scale? For example, there is a highest force and a highest power in nature. Is there also a lowest force and a lowest power? Is there also a lowest speed?

We will show that there are indeed such limits, for all observables. We give the general method to generate such bounds, and explore several examples.* This exploration will take us on an interesting survey of modern physics.

Size and energy dependence

While looking for additional limits in nature, we note a fundamental fact. Any upper limit for angular momentum, and any lower limit for power, must be *system-dependent*. Such limits will not be absolute, but will depend on properties of the system. Now, a physical system is a part of nature characterized by a boundary and its content.** Thus the simplest properties shared by all systems are their size (characterized in the following by the diameter) L and their energy E. With these characteristics we can deduce system-dependent limits for every physical observable. The general method is straightforward: we take the known inequalities for speed, action, power, charge and entropy, and then extract a limit for any observable, by inserting the length and energy as required. We then have to select the strictest of the limits we find.

Angular momentum, action and speed

It only takes a moment to check that the ratio of angular momentum D to mass times length has the dimensions of speed. Since speeds are limited by the speed of light, we get

$$D_{\text{system}} \leqslant \frac{1}{c} LE \,. \tag{918}$$

* This results were added in June 2004.

** Quantum theory refines this definition: a physical system is a part of nature that in addition interacts *incoherently* with its environment. Page 1081 In the following discussion we will assume that this condition is satisfied.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Indeed, there do not seem to be any exceptions to this limit in nature. In no known system, from atoms to molecules, from ice skaters to galaxies, does the angular momentum exceed this value. Even the most violently rotating objects, the so-called extremal black holes, are limited in angular momentum by $D \leqslant LE/c$. (Actually, this limit is correct only if the energy is taken as the irreducible mass times c^2; if the usual mass is used, the limit is too large by a factor of 4.) The limit deduced from general relativity, given by $D \leqslant L^2c^3/4G$, is not stricter than the one just given. No system-dependent lower limit for angular momentum can be deduced.

Ref. 1287

The maximum value for angular momentum is also interesting when it is seen as an action limit. Action is the time integral of the difference between kinetic and potential energy. Since nature always seeks to minimize the action W, it seems strange to search for systems that maximize it. You might check for yourself that the action limit $W \leqslant LE/c$ is not exceeded in any physical process.

Challenge 1687 ny

Similarly, speed times mass times length is an action. Since action values in nature are limited from below by $\hbar/2$, we get

$$v_{\text{system}} \geqslant \frac{\hbar c^2}{2} \frac{1}{LE} \,. \tag{919}$$

This is not a new result: it is just a form of the indeterminacy relation of quantum theory. It gives a minimum speed for any system of energy E and diameter L. Even the extremely slow radius change of a black hole by evaporation just realizes this minimal speed. Continuing with the same method, one also finds that the limit deduced from general relativity, $v \leqslant (c^2/4G)(L/E)$, gives no new information. Therefore, no *system-dependent* upper speed limit exists.

Challenge 1688 ny

Challenge 1689 e

For *single particles*, we get the absolute lower speed limit given by

$$v_{\text{particle}} \geqslant \frac{\sqrt{G\hbar c^3}}{2L_{\text{universe}}} = \frac{L_{\text{c.Planck}}}{L_{\text{universe}}} c \approx 7 \cdot 10^{-53}\,\text{m/s} \,. \tag{920}$$

It has never been reached or approached by any observation.

Incidentally, the limits are not unique. Other limits can be found in a systematic way. Upper limits can be multiplied, for example, by factors of $(L/E)(c^4/4G)$ or $(LE)(2/\hbar c)$, yielding less strict upper limits. A similar rule can be given for lower limits.*

With the same approach, we can now systematically deduce all size- and energy-dependent limits for physical observables. We embark on a tour of the most important ones.

* The strictest upper limits are those with the smallest exponent for length, and the strictest lower limits are those with the largest exponent of length.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Force, power and luminosity

We have seen that force and power are central to general relativity. Thanks to the connection $W = FLT$ between action W, force F, distance L and time T, we can deduce

$$F_{\text{system}} \geqslant \frac{\hbar}{2c}\,\frac{1}{T^2}\,. \tag{921}$$

Experiments do not reach this limit. The smallest forces measured in nature are those in atomic force microscopes, where values as small as 1 aN are observed. But even these values are above the lower force limit.

The power P emitted by a system of size L and mass M is limited by

$$c^3\,\frac{M}{L} \geqslant P_{\text{system}} \geqslant 2\hbar G\,\frac{M}{L^3}\,. \tag{922}$$

The limit on the left is the upper limit for any engine or lamp, as deduced from relativity; not even the universe exceeds it. The limit on the right is the minimum power emitted by any system through quantum gravity effects. Indeed, no system is completely tight. Even black holes, the systems with the best ability to keep components inside their enclosure, radiate. The power radiated by black holes should just meet this limit, provided the length L is taken to be the circumference of the black hole. Thus the claim of the quantum gravity limit is that the power emitted by a black hole is the smallest power that is emitted by any composite system of the same surface gravity. (However, the numerical factors in the black hole power appearing in the literature are not yet consistent.)

Acceleration

The acceleration a of a system of size L and mass M, as measured by a *nearby* inertial observer, is limited by

$$c^2\,\frac{1}{L} \geqslant a_{\text{system}} \geqslant 4G\,\frac{M}{L^2}\,. \tag{923}$$

The lower limit (on the right) gives the acceleration due to universal gravity. Indeed, the relative acceleration between a system and an observer has at least this value. The upper limit (on the left) is due to special relativity. No exception to either of these limits has ever been observed. Using the limit on the size of masses, the upper limit can be transformed into the equivalent acceleration limit

Ref. 1288

$$\frac{2c^3}{\hbar}\,M \geqslant a \tag{924}$$

which has also never been approached, despite many attempts. Thus the upper limit to acceleration is a quantum limit, the lower one a gravitational limit.

The acceleration of the radius of a black hole due to evaporation can be much lower than the limit $a \geqslant 4GM/L^2$. Why is this not a counter-example?

Challenge 1690 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Momentum

The momentum p of a system of size L is limited by

$$\frac{c^3}{4G}\, L \geqslant p_{\text{system}} \geqslant \frac{\hbar}{2}\,\frac{1}{L}\,. \tag{925}$$

The lower limit is due to quantum theory; experiments have confirmed it for all radiation and matter. The upper limit is due to general relativity; it has never been exceeded.

Ref. 1289 For particles, the absolute limit is

$$p_{\text{particle}} \geqslant \frac{\hbar}{2L_{\text{universe}}} = \frac{L_{\text{c.Planck}}}{2L_{\text{universe}}}\, p_{\text{c.Planck}} \approx 8 \cdot 10^{-61}\,\text{kgm/s}\,. \tag{926}$$

Lifetime, distance and curvature

Time is something special. What are the limits to time measurements? As before, we find that any measured time interval t in a system in thermal equilibrium is limited by

$$\frac{2}{\hbar}\, ML^2 \geqslant t_{\text{thermal system}} \geqslant \frac{4G}{c^3}\, M\,. \tag{927}$$

The lower time limit is the gravitational time. No clock can measure a time shorter than this. Similarly, no system can produce signals of shorter duration. Black holes, for example, emit radiation with a frequency given by this minimum value.

The upper time limit is expected to be the exact lifetime of a black hole. (There is not yet a consensus in the literature on the numerical factor.) The upper limit to time measurements is due to quantum theory. It leads to an obvious question: what happens to a single atom in space after the limit time has passed by? As a composite system, an atom is not comparable with a black hole. The formula for the lifetime assumes that decay can take place in the tiniest energy steps. If there is no decay mechanism, the formula does not apply. Thus the expression (927) does not apply to atoms.

Distance limits are straightforward:

$$\frac{2c}{\hbar}\, ML^2 \geqslant d \geqslant \frac{4G}{c^2}\, M\,. \tag{928}$$

Since curvature is an inverse square of distance, also the curvature of space-time is limited.

Mass change

The rate of mass change $\mathrm{d}M/\mathrm{d}t$ of a system of size L and mass M is limited by

$$\frac{c^5}{16G^2}\,\frac{L}{M} \geqslant \frac{\mathrm{d}M}{\mathrm{d}t} \geqslant \frac{\hbar}{2}\,\frac{1}{L^2}\,. \tag{929}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The limits apply to systems in thermal equilibrium. The upper limit (on the left) is due to general relativity; it is never exceeded. The lower limit (on the right) is due to quantum theory. Again, all experiments are consistent with these limit values.

Mass and density

Limits for rest mass only make sense if the system is characterized by a size L only. We then have

$$\frac{c^2}{4G}\, L \geqslant M \geqslant \frac{\hbar}{2c}\,\frac{1}{L}\,. \tag{930}$$

We have discussed the upper limit for mass in relation to general relativity. Adding mass or energy to a black hole always increases its size. The mass of a system can never exceed this value – indeed, no such system is even imaginable. The lower limit on mass is due to quantum theory: it follows directly from the quantum of action.

The mass density ρ of a system of size L is limited by

$$\frac{c^2}{4G}\,\frac{1}{L^2} \geqslant \rho \geqslant \frac{\hbar}{2c}\,\frac{1}{L^4}\,. \tag{931}$$

The upper limit, due to general relativity, is only achieved for black holes. The lower limit is due to quantum theory. It also applies to the vacuum, if a piece of vacuum of size L is taken as a physical system. Again, many other (less strict) limits can be formulated by using the transformation rules mentioned above. Page 1476

The strange charm of the entropy bound

Ref. 1290 In 1973, Bekenstein discovered a famous limit that connects the entropy S of a physical system with its size and mass. No system has a larger entropy than one bounded by a horizon. The larger the horizon surface, the larger the entropy. We write

$$\frac{S}{S_{\text{limit}}} \leqslant \frac{A}{A_{\text{limit}}} \tag{932}$$

which gives

$$S \leqslant \frac{kc^3}{4G\hbar}\, A\,, \tag{933}$$

where A is the surface of the system. Equality is realized only for black holes. The old question of the origin of the factor 4 in the entropy of black holes is thus answered here: it is due to the factor 4 in the force or power bound in nature (provided that the factors from the Planck entropy and the Planck action cancel). Time will tell whether this explanation will be generally accepted. Ref. 1291 Page 290 Stay tuned.

We can also derive a more general relation by using a mysterious assumption, which we will discuss afterwards. We assume that the limits for vacuum are opposite to those

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

for matter. We can then write $c^2/4G \leqslant M/L$ for the vacuum. This gives

$$S \leqslant \frac{\pi kc}{\hbar} ML = \frac{2\pi kc}{\hbar} MR \,. \tag{934}$$

In other words, we used

$$\frac{S}{S_{\text{c.Planck}}} \leqslant \frac{M}{M_{\text{c.Planck}}} \frac{A}{A_{\text{c.Planck}}} \frac{L_{\text{c.Planck}}}{L} \,. \tag{935}$$

Expression (934) is called *Bekenstein's entropy bound*. No exception has ever been found or constructed, despite many attempts. Again, the limit value itself is only realized for black holes. Ref. 1277

We need to explain the strange assumption used above. We are investigating the entropy of a horizon. Horizons are not matter, but limits to empty space. The entropy of horizons is due to the large number of virtual particles found at them. In order to deduce the maximum entropy of expression (935) one therefore has to use the properties of the vacuum. In other words, *either* we use a mass-to-length ratio for vacuum *above* the Planck limit, *or* we use the Planck entropy as the *maximum* value for vacuum.

Other, equivalent limits for entropy can be found if other variables are introduced. For example, since the ratio of the shear viscosity η to the volume density of entropy (times k) has the dimensions of action, we can directly write Ref. 1292

$$S \leqslant \frac{k}{\hbar} \eta V \,. \tag{936}$$

Again, equality is only attained in the case of black holes. In time, no doubt, the list of similar bounds will grow longer.

Is there also a smallest entropy? So far, there does not seem to be a system-dependent minimum value for entropy: the present approach gives no expression that is larger than k. Challenge 1691 ny

The establishment of the entropy limit is an important step towards making our description of motion consistent. If space-time can move, as general relativity maintains, it also has an entropy. How could entropy be limited if space-time were continuous? Clearly, because of the existence of a minimum distance and minimum time in nature, space-time cannot be continuous, but must have a finite number of degrees of freedom, and thus a finite entropy.

The Bekenstein limit also leads to some interesting speculations. Let us speculate that the universe itself, being surrounded by a horizon, meets the Bekenstein bound. The entropy bound gives a bound to all degrees of freedom inside a system: it tells us that the number $N_{\text{d.o.f.}}$ of degrees of freedom of the universe is roughly Challenge 1692 e

$$N_{\text{d.o.f.}} \approx 10^{132} \,. \tag{937}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Compare this with the number $N_{\text{Pl. vol.}}$ of Planck volumes in the universe

$$N_{\text{Pl. vol.}} \approx 10^{183} \tag{938}$$

and with the number $N_{\text{part.}}$ of particles in the universe

$$N_{\text{part.}} \approx 10^{91} \,. \tag{939}$$

We see that particles are only a tiny fraction of what moves around. Most motion must be movement of space-time. But also, space-time moves much less than naively expected. To find out how all this happens is the challenge of the unified description of motion.

Temperature

A lower limit for the temperature of a thermal system can be found using the idea that the number of degrees of freedom of a system is limited by its surface, or more precisely, by the ratio between the surface and the Planck surface. One gets the limit

$$T \geqslant \frac{4G\hbar}{\pi kc} \frac{M}{L^2} \,. \tag{940}$$

Alternatively, using the method given above, one can use the limit on the thermal energy $kT/2 \geqslant \hbar c/2\pi L$ (the thermal wavelength must be smaller than the size of the system) together with the limit on mass $c^2/4G \geqslant M/L$, and deduce the same result.

We have met this limit already: when the system is a black hole, it gives the temperature of the emitted radiation. In other words, the temperature of black holes is the lower limit for all physical systems for which a temperature can be defined, provided they share the *same boundary gravity*. The latter condition makes sense: boundary gravity is accessible from the outside and describes the full physical system, since it depends on both its boundary and its content. So far, no exception to this claim is known. All systems from everyday life comply with it, as do all stars. Even the coldest known systems in the universe, namely Bose–Einstein condensates and other cold matter produced in laboratories, are much hotter than the limit, and thus much hotter than black holes of the same surface gravity. (We saw earlier that a consistent Lorentz transformation for temperature is not possible; so the minimum temperature limit is only valid for an observer at the same gravitational potential as the system under consideration and stationary relative to it.)

Challenge 1693 s
Page 438

There seems to be no consistent way to define an upper limit for a system-dependent temperature. Limits for other thermodynamic quantities can be found, but we will not discuss them here.

Challenge 1694 ny

Electromagnetic observables

When electromagnetism plays a role in a system, the system also needs to be characterized by a charge Q. Our method then gives the following lower limit for the electric field

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

E:

$$E \geqslant 4Ge\,\frac{M^2}{Q^2L^2}\,. \tag{941}$$

We write the limit in terms of the elementary charge e, though it would be more appropriate to write it using the fine structure constant via $e = \sqrt{4\pi\varepsilon_0\alpha\hbar c}$. In observations, this limit has never been exceeded. Can you show whether it is attained by maximally charged black holes? Challenge 1695 ny

For the magnetic field we get

$$B \geqslant \frac{4Ge}{c}\,\frac{M^2}{Q^2L^2}\,. \tag{942}$$

Again, this limit is satisfied by all known systems in nature.

Similar limits can be found for the other electromagnetic observables. In fact, several of the limits given earlier are modified when electrical charge is included. Can you show how the size limit changes when electric charge is taken into account? There is an entire research field dedicated to the deduction of the most general limits valid in nature. Challenge 1696 ny

Curiosities and fun challenges about limits to observables

These limits yield a plethora of interesting paradoxes that can be discussed in lectures and student exercises. All paradoxes can be solved by carefully taking into account the combination of effects from general relativity and quantum theory. Apparent violations only occur when one of the two aspects is somehow forgotten. We will study a few examples.

* *

Several black hole limits are of importance to the universe itself. For example, the observed average mass density of the universe is not far from the corresponding black hole limit. The black hole lifetime limit provides an upper limit for the age of the universe. However, the age of the universe is far from that limit by a large factor. In fact, since the universe's size and age are increasing, the age limit is pushed further into the future with every second that passes. The universe evolves so as to escape its own decay.

* *

The content of a system is characterized not only by its mass and charge, but also by its strangeness, isospin, colour charge, charge and parity. Can you deduce the limits for these quantities? Challenge 1697 r

* *

In our discussion of black hole limits, we silently assumed that they interact, like any thermal system, in an incoherent way with the environment. Which of the results of this section change when this condition is dropped, and how? Which limits can be overcome? Challenge 1698 s

* *

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1699 e Can you find a general method to deduce all limits?

* *

Brushing aside some important details, we can give the following summary of our study of nature. For Galilean physics, there is no difference between composite and elementary systems; for quantum theory, there are no (really large) composite systems; for general relativity, there are no elementary systems. Now, a unified theory of nature has to unify quantum theory and general relativity. Since quantum theory affirms that no (really large) composite systems exist, while general relativity affirms that no elementary systems exist, a unified theory should affirm that *no* systems exist. This indeed seems to be a valid conclusion. It is corroborated by the result that in a unified description of nature, the observables time, space and mass cannot be clearly distinguished from each other, which implies that systems cannot be clearly distinguished from their surroundings. More precisely, systems do not really exist at unification energy. We will come back to this issue.

Page 1458

LIMITS TO MEASUREMENT PRECISION AND THEIR CHALLENGE TO THOUGHT

We now know that in nature, every physical measurement has a lower and an upper bound. One of the bounds is size-dependent, the other is absolute. So far, no exception to these claims is known.

The smallest relative measurement error possible in nature is thus the ratio of the two bounds. In short, the existence of a smallest length, a highest force and a smallest action, taken together, imply that *all measurements are limited in precision.*

The existence of a fundamental limit to measurement precision is not a new result. But it raises many issues. If the mass and the size of any system are themselves imprecise, what happens to the limit formulae given above?

Challenge 1700 r

Because of the fundamental limits to measurement precision, *the measured values of physical observables do not require the full set of real numbers.* In fact, limited precision implies that no observable can be described by the real numbers. We thus recover a result that appears whenever quantum theory and gravity are brought together.

In addition, we found that measurement errors increase when the characteristic measurement energy approaches the Planck energy. In that domain, the measurement errors of any observable are comparable with the measurement values themselves.

Page 1398

Limited measurement precision thus implies that at the Planck energy it is impossible to speak about points, instants, events or dimensionality. Similarly, at the Planck length it is impossible to distinguish between positive and negative time values: so particles and antiparticles are not clearly distinguished at Planck scales. The minimum length implies that there is no way to define the exact boundaries of objects or elementary particles. But a boundary is what separates matter from vacuum. In short, a minimum measurement error means that, at Planck scales, it is impossible to distinguish objects from vacuum with complete precision. To put it bluntly, at Planck scales, neither systems nor time and space do exist.

Page 1398

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

These conclusions are in complete agreement with the conclusions of modern research on unified theories. The limit principles imply the same conceptual results as are found in string theory and the various approaches to quantum gravity. To show the power of the maximum force limit, we now explore a few conclusions that go beyond such approaches.

Measurement precision and the existence of sets

The impossibility of completely eliminating measurement errors has an additional and important consequence. In physics, it is generally assumed that nature is a *set* of components. These components are assumed to be separable from each other. This tacit assumption is introduced in three main situations: it is assumed that matter consists of separable particles, that space-time consists of separable events or points, and that the set of states consists of separable initial conditions. So far, physics has built the whole of its description of nature on the concept of a *set*.

A fundamental limit to measurement precision implies that nature is *not* a set of such separable elements. It implies that physical entities can be distinguished only approximately. The approximate distinction is only possible at energies much lower than the Planck energy. As humans, we do live at such relatively small energies, and we can safely make the approximation. Indeed, the approximation is excellent; we do not notice any error. But at Planck energies, a perfect separation is impossible in principle. In particular, at the cosmic horizon, at the big bang, and at Planck scales, any precise distinction between two events or two particles becomes impossible.

Page 1398

Another way to reach this result is the following. Separation of two entities requires *different measurement results* – for example, different positions, different masses or different velocities. Whatever observable is chosen, at the Planck energy the distinction becomes impossible because of the large measurements errors. Only at everyday energies is a distinction approximately possible. Any distinction between two physical systems – for example, between a toothpick and a mountain – is possible only *approximately*: at Planck scales, a boundary cannot be drawn.

Page 1398

A third argument is the following. In order to *count* any entities in nature – a set of particles, a discrete set of points, or any other discrete set of physical observables – the entities have to be separable. But the inevitable measurement errors contradict separability. Thus at the Planck energy it is impossible to count physical objects with precision. *Nature has no parts.*

Page 1398

In short, at Planck energies, perfect separation is impossible in principle. We cannot distinguish observations. *At Planck scales it is impossible to split nature into separate entities.* In nature, elements of sets cannot be defined. Neither discrete nor continuous sets can be constructed. *Nature does not contain sets or elements.*

Page 1398

Since sets and elements are only approximations, the concept of a 'set', which assumes separable elements, is too specialized to describe nature. Nature cannot be described at Planck scales – i.e., with full precision – if any of the concepts used for its description presupposes sets. However, all concepts used in the past 25 centuries to describe nature – space, time, particles, phase space, Hilbert space, Fock space, particle space, loop space or moduli space – are based on sets. They must all be abandoned at Planck energy.

Nature is one and has no parts. *No correct mathematical model of nature can be based*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

on sets. But none of the approach used so far in theoretical physics – not even string theory or the various quantum gravity approaches – has abandoned sets. This requirement must guide us in the future search for the unification of relativity and quantum theory.

> Es ist fast unmöglich, die Fackel der Wahrheit durch ein Gedränge zu tragen, ohne jemandem den Bart zu sengen.*
>
> Georg Christoph Lichtenberg (1742–1799)

Why are observers needed?

Some papers on quantum theory give the impression that observers are indispensable for quantum physics. We have debunked this belief already, showing that the observer in quantum theory is mainly a bath with a definite interaction. Often, humans are observers.

Page 1096

At Planck scales, quantum theory is mandatory. The exploration of these domains shows that observers must satisfy an additional requirement: they must function at low energies. Only at low energy can an observer introduce sets for the description of nature. Introducing observers is thus the same as introducing sets.

To put it in another way, the limitation of human observers is that they cannot avoid using sets. However, human observers are not unique in this respect: they share this limitation with video recorders, cameras, computers, and pencil and paper.

In simple terms, observers are needed to describe nature at Planck scales only in so far as they are and use sets. We should not have too inflated a view of our own importance.

A solution to Hilbert's sixth problem

In the year 1900, David Hilbert gave a well-known lecture in which he listed 23 of the great challenges facing mathematics in the twentieth century. Most of these problems provided challenges to mathematicians for decades afterwards. Among those that are still unsolved is Hilbert's sixth problem, which challenges mathematicians and physicists to find an *axiomatic* treatment of physics. It has remained in the minds of many physicists since that time.

Ref. 1293

Since nature does not contain sets, such an axiomatic description of nature cannot exist. The reasoning is simple: we only have to look at the axiomatic systems found in mathematics. Axiomatic systems define mathematical structures. These structures are of three main types: algebraic systems, order systems or topological systems. Most mathematical structures – such as symmetry groups, vector spaces, manifolds or fields – are combinations of all three. But all mathematical structures are based on elements and sets. Elements and sets are common to all axiomatic systems in mathematics. The underlying reason is that every mathematical concept contains at least one set.

Page 1398

Furthermore, all concepts used so far in physics depend on elements and sets. For humans, it is difficult even to *think* without first defining a set of possibilities. Yet nature does not contain sets. Therefore, *an axiomatic formulation of physics is impossible*. Of course, this conclusion does not rule out unification; however, it does rule out an axiomatic version of it. This is surprising at first. However, as separate axiomatic treatments of quantum theory and general relativity *are* possible. *Axiomatic systems in physics are*

* 'It is almost impossible to carry the torch of truth through a crowd without scorching somebody's beard.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

always approximate. The need to abandon them is one of the reasons why reaching a unified description of nature is so difficult.

Summary

Physics can be summarized in a few limit statements. They imply that in nature every physical observable is limited by a value near the Planck value. The speed limit is equivalent to special relativity, the force limit to general relativity, and the action limit to quantum theory. Although this summary could have been made (or at least conjectured) by Planck, Einstein or the fathers of quantum theory, it is actually much more recent. The numerical factors for most of the limit values are new. The limits suggest interesting Gedanken experiments, none of which leads to their violation. However, the force limit is not yet within direct experimental reach.

The existence of limit values to all observables implies that the description of space-time as a continuous manifold is not correct at Planck scales: it is only an approximation. For the same reason, is predicted that elementary particles are not point-like. Nature's limits also imply that matter and vacuum are in principle indistinguishable. The structure of particles and of space-time remains to be clarified. So far, we can conclude that nature can be described by sets only approximately. The limit statements show that Hilbert's sixth problem cannot be solved, and that unification requires entirely new, untested approaches.

We have seen that at Planck scales there is no time and no space, and there are no particles. Motion is a low-energy phenomenon: it only appears for low-energy observers, in other words, for observers who use sets. The (inaccurate) citation of Zeno at the beginning of our walk, stating that motion is an illusion, turns out to be correct. We now need to find out how motion actually arises.

Page 22

Our discussion so far suggests that motion appears as soon as sets are introduced. To check this hypothesis, we need a description of nature without sets. The only way to avoid the use of sets seems to be a description of empty space-time, radiation and matter as being made of the same underlying entity. It is probably necessary to include space-time dualities and interaction dualities. Indeed, both string theory and modern quantum gravity attempt this, though possibly not yet with the full radicalism necessary. To realize this unification is our next task.

Chapter 56

THE SHAPE OF POINTS – EXTENSION IN NATURE

> Nil tam difficile est, quin quaerendo investigari possiet.
>
> Terence*

The expressions for the Compton wavelength $\lambda = h/mc$ and for the Schwarzschild radius $r_s = 2Gm/c^2$ imply a number of arguments which lead to the conclusion that at Planck energies, what we call space-time 'points' and 'point' particles must actually be described by *extended* entities. These arguments point towards a connection between microscopic and macroscopic scales, confirming the results of modern string theory and quantum gravity. At the same time, they provide a pedagogical summary of this aspect of present-day theoretical physics. Here is a summary of what follows.**

1 – Any experiment trying to measure the size or the shape of an elementary particle with high precision inevitably leads to the result that at least one dimension of the particle is of macroscopic size.

2 – There is no evidence that empty space-time is continuous, but plenty of evidence that it is not. In order to build up an entity, such as the vacuum, that is extended in three dimensions, one needs extended building blocks.

3 – The existence of minimum measurable distances and time intervals implies the existence of space-time duality: a symmetry between very large and very small distances. Space-time duality in turn implies that the fundamental entities that make up vacuum and matter are extended.

4 – The constituents of the universe, and thus of space-time, matter and radiation, cannot form a set. As a consequence, any precise description of nature must use extended entities.

5 – The Bekenstein–Hawking expression for the entropy of black holes – in particular its surface dependence – confirms that both space-time and particles are composed of extended entities.

6 – The attempt to extend statistical properties to Planck scales shows that both particles and space-time points behave as braids at high energies – a fact which also requires extended entities.

7 – The Dirac construction for spin provides a model for fermions which is consistent with experiments and which points to extended entities.

* 'Nothing is so difficult that it could not be investigated.' Terence is Publius Terentius Afer (*c.* 190–159 BCE), important roman poet. He writes this in his play *Heauton Timorumenos*, verse 675.

** This section describes a research topic, and is *not* a compendium of generally accepted results (yet). It was written between December 2001 and May 2002.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

An overview of other arguments in favour of extended entities provided by present research efforts is also given. To complete the discussion, experimental and theoretical checks for the idea of extended building blocks of nature are presented.

The starting point – vacuum and particles

> Our greatest pretenses are built up not to hide the evil and the ugly in us, but our emptyness. The hardest thing to hide is something that is not there.
>
> Eric Hoffer, *The Passionate State of Mind*

We can only use continuous space-time and point particles as basic entities when our description of nature is separated into general relativity and quantum theory. When the two theories are united, what we usually call a 'point' turns out to have quite counter-intuitive properties. We explore a few of them in the following.

We have already given a standard argument showing that points do not exist in nature. The Compton wavelength and the Schwarzschild radius together determine a minimal length and a minimal time interval in nature. They are given (within a factor of order one, which we will usually omit) by the Planck length and the Planck time, with the values

Ref. 1294, Ref. 1295

$$\begin{aligned} l_{\mathrm{Pl}} = \sqrt{\hbar G/c^3} &= 1.6 \cdot 10^{-35}\,\mathrm{m} \\ t_{\mathrm{Pl}} = \sqrt{\hbar G/c^5} &= 5.4 \cdot 10^{-44}\,\mathrm{s}\,. \end{aligned} \tag{943}$$

The existence of minimal length and time intervals in nature implies that 'points' in space, time or space-time do not really exist, and forces us to give up the traditional idea of continuity. Even though, properly speaking, points do not exist, and thus space points, events and point particles do not exist either, we can still study these entities in detail. The results provide many fascinating surprises.

Page 1413

Using a simple Gedanken experiment, we found earlier that particles and space-time cannot be distinguished from each other at Planck scales. We argued that the measurement error for a full box and the measurement error for an empty box are the same at Planck scales. Indeed, the largest mass that can be put in a box of size R is a black hole with a Schwarzschild radius of the same value. That is also the largest possible mass measurement error. But an empty box, a piece of vacuum, also has a *smallest* mass measurement error.

The existence of a smallest mass measurement error is so important that it merits special attention. Mass measurement errors always prevent humans from stating that a region of space has zero mass. Similarly, a minimal mass measurement error prevents nature from 'knowing' that the mass of a region is zero. The origin of this mass measurement error is quantum indeterminacy. Energy and mass are always blurred in quantum theory. We are not used to applying this fact to the vacuum, but at Planck scales we have to. We know from quantum field theory that the vacuum, like any other system, has a mass; of course, its value when averaged over a long time is zero. For finite measuring times, there will be an indeterminacy in the mass value of a vacuum.

A box is empty if it does not contain anything. But emptiness is not well defined in relation to photons whose wavelength is greater than or equal to the size R of the box. The

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

mass measurement error for an 'empty' box – corresponding to what we call a vacuum – is due to the indeterminacy relation, and is equal to the mass whose Compton wavelength matches the size of the box. As we saw earlier, the same mass value is found in every other Gedanken experiment – for example, trying to determine the gravitational mass by weighing the 'piece' of vacuum or by measuring its kinetic energy.

Page 1413

Ref. 1294

Another – ultimately equivalent – way to show that a region of vacuum has a finite mass error is to look at how the vacuum energy depends on the positional indeterminacy of the border of the region. Any region is defined by its border. The positional indeterminacy of the border will induce a mass error for the contents of the box, in the same way as a time limit does. Again, the resulting mass error for a region of vacuum is equal to the mass for which the box size is the Compton wavelength.

Summarizing, for a box of size R, nature allows only mass values and mass measurement error values m between two limits:

$$\text{(full box)} \quad \frac{c^2 R}{G} \geqslant m \geqslant \frac{\hbar}{cR} \quad \text{(empty box)} \,. \tag{944}$$

We see directly that for sizes R of the order of the Planck length, the two limits coincide: they both give the Planck mass

$$M_{\text{Pl}} = \frac{\hbar}{c\, l_{\text{Pl}}} = \sqrt{\frac{\hbar c}{G}} \approx 10^{-8}\,\text{kg} \approx 10^{19}\,\text{GeV}/c^2 \,. \tag{945}$$

In other words, for boxes of Planck size, we cannot distinguish a full box from an empty one. This means that there is no difference between vacuum and matter at Planck scales. Of course, a similar statement holds for vacuum and radiation. At Planck scales, vacuum cannot be distinguished from particles of any kind.

How else can we show that matter and vacuum cannot be distinguished?

The statement that it is impossible to distinguish vacuum from particles is a strong one. Such a strong statement needs additional proof.

Mass can also be measured by probing its inertial aspect: that is, by colliding the unknown mass M, at a known velocity V, with a known probe particle of mass m and momentum $p = mv$. We then have

$$M = \frac{\Delta p}{\Delta V} \,, \tag{946}$$

where the differences are taken between the values before and after the collision. The error δM of such a measurement is simply given by

$$\frac{\delta M}{M} = \frac{\delta \Delta v}{\Delta v} + \frac{\delta m}{m} + \frac{\delta \Delta V}{\Delta V} \,. \tag{947}$$

At Planck scales we have $\delta \Delta v / \Delta v \approx 1$, because the velocity error is always – like the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

velocities themselves – of the order of the speed of light. In other words, at Planck scales the mass measurement error is so large that we cannot determine whether a mass is different from zero: vacuum is indistinguishable from matter.

We reach the same conclusion if we take light with wavelength λ as the probe particle. In this case, expression (946) leads to a mass error

$$\frac{\delta M}{M} = \frac{\delta \Delta\lambda}{\Delta\lambda} + \frac{\delta \Delta V}{\Delta V} \,. \tag{948}$$

In order that photon scattering can probe Planck dimensions, we need a wavelength of the order of the Planck value; but in this case the first term is approximately unity. Again we find that at Planck scales the energy *indeterminacy* is always of the same size as the energy value to be measured. Measurements cannot distinguish between vanishing and non-vanishing mass at Planck scales. This result appears for all methods of mass measurement that can be imagined. (Try it.) At Planck scales, matter cannot be distinguished from vacuum.

Challenge 1701 e

Incidentally, the same arguments are valid if instead of the mass of matter we measure the energy of radiation: it is also impossible to distinguish radiation from vacuum at high energies.

The indistinguishability of particles and vacuum, together with the existence of minimum space-time intervals, suggests that space, time, radiation and matter are macroscopic approximations to a common underlying *discrete* structure. This structure is often called *quantum geometry*. What do the common constituents of all these aspects of nature look like? We will provide several arguments showing that these constituents are *extended* and *fluctuating*.

Ref. 1296

> Also, die Aufgabe ist nicht zu sehen, was noch nie jemand gesehen hat, sondern über dasjenige was jeder schon gesehen hat zu denken was noch nie jemand gedacht hat.*
>
> Erwin Schrödinger

THE SIZE AND SHAPE OF ELEMENTARY PARTICLES

Size is the length of vacuum taken by an object. This definition comes naturally in everyday life, quantum theory and relativity. However, near the Planck energy, vacuum and matter cannot be distinguished: it is impossible to define the boundary between the two, and thus it is impossible to define the size of an object. As a consequence, every object becomes as extended as the vacuum. So we need to be careful about our definition.

What happens if Planck energy is *approached*, advancing step by step to higher energy? Every measurement requires comparison with a standard. A standard is made of matter and comparison is performed using radiation (see Figure 606). Thus any measurement requires distinction between matter, radiation and space-time. However, distinction between matter and radiation is possible only up to the (grand) unification energy, which is about 1/800 of the Planck energy. Measurements do not allow us to prove that particles are point-like.

* 'Our task is not to see what nobody has ever seen, but to think what nobody has ever thought about that which everybody has seen already.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

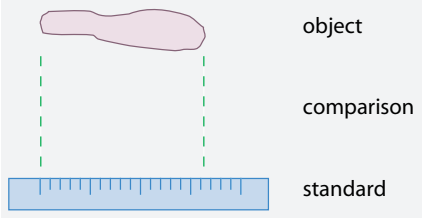

FIGURE 606 Measurement requires matter and radiation

Let us take a step back. Do measurements at least allow us to say whether particles can be contained inside small spheres?

Do boxes exist?

The first and simplest way to determine the size of a compact particle such as a sphere, or something akin to it, is to measure the size of a *box* it fits in. To be sure that the particle fits inside, we must first must be sure that the box is tight: that is, whether anything (such as matter or radiation) can leave the box.

But there is no way to ensure that a box has no holes. Potential-energy 'hills' cannot get higher than the maximum energy, namely the Planck energy; and the tunnelling effect cannot be ruled out. In short, there is no way to make a completely tight box.

Furthermore, at the unification energy there is no way to distinguish between the box and the object enclosed in it, as particles can be transformed from one type into another.

Let us cross-check this result. In everyday life, we call particles 'small' when they can be enclosed. Enclosure is possible in daily life because walls are impenetrable. But walls are only impenetrable for matter particles up to about 10 MeV and for photons up to about 10 keV. In fact, boxes do not even exist at medium energies. So we certainly cannot extend the idea of 'box' to high energies.

Since we cannot state that particles are compact, or of finite size, using boxes, we need to try other methods.

Can the Greeks help? – The limits of knives

The Greeks deduced the existence of atoms by noting that matter cannot be divided indefinitely. In contrast, whenever we think of space (or space-time) as made of points, we assume that it can be subdivided without end. Zeno strongly criticized this assumption. He was right: at Planck energy, any subdivision is impossible. Any attempt to divide space must stop when (or before) we reach Planck scales. Cutting is the insertion of a wall, and knives are limited just as walls are. The limits of walls imply limits to determination of size.

In particular, the limits to walls and knives imply that at Planck energies, a cut does not necessarily lead to two separate parts. One cannot state that the two parts have been really separated: the possibility of a thin connection between them can never be excluded. In short, one cannot prove compactness by cutting objects at Planck scales.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Are cross sections finite?

Particles are not point-like; they are not even compact. Are they, at least, of finite size?

To determine the size of a particle, we can try to determine its departure from point-likeness. At high energy, detecting this departure requires scattering. For example, we can suspend the particle in a trap and then shoot a probe at it. What happens in a scattering experiment at high energies? This question has been studied by Leonard Susskind and his colleagues. When shooting at the particle with a high-energy probe, the scattering process is characterized by an interaction time. Extremely short interaction times imply sensitivity to the size and shape fluctuations due to the quantum of action. An extremely short interaction time provides a cut-off for high-energy shape and size fluctuations, and thus determines the measured size. As a result, the size measured for any microscopic, but extended, object *increases* when the probe energy is increased towards the Planck value.

Ref. 1297

In summary, even though at experimentally achievable energies the size is always smaller than a measurable amount, when one approaches the Planck energy, the size increases above all bounds. So at high energies we cannot give an upper limit to the size of a particle. In other words, since particles are not point-like at everyday energies, at Planck energies they are enormous: particles are extended.

That is quite a statement. Right at the start of our mountain ascent, we distinguished objects from their environment. Objects are by definition localized, bounded and compact. All objects have a boundary, i.e., a surface which does not itself have a boundary. Objects are also bounded in abstract ways: boundedness is a property of the symmetries of an object, such as its gauge group. In contrast, the environment is not localized, but extended and unbounded.

These basic assumptions fail us at Planck scales. At Planck energy, it is impossible to determine whether something is bounded or compact. Compactness and localization are only approximate properties; they are not applicable at high energies. The idea of a point particle is an approximate concept, valid only at low energies.

Let us perform another check on our conclusion that particles at Planck scales are as extended as the vacuum.

Can one take a photograph of a point?

> “Καιρὸν γνῶθι.*”
>
> Pittacus

Humans – or any other types of observers – can only observe a part of the world with finite resolution in time and in space. In this respect, humans resemble a film camera. The highest possible resolution was (almost) discovered in 1899: the Planck time and the Planck length. No human, no film camera and no apparatus can measure space or time intervals smaller than the Planck values. But what would happen if we took photographs with shutter times approaching the Planck time?

Ref. 1298

Ref. 1294, Ref. 1299

* ‘Recognize the right moment.’ Also rendered as: ‘Recognize thine opportunity.’ Pittacus (Πιττακος) of Mytilene (*c.* 650–570 BCE), was a Lesbian tyrant and lawmaker; he was also one of the ‘Seven Sages’ of ancient Greece.

TABLE 126 Effects of various camera shutter times on photographs

Duration	Blur	Observation possibilities
1 h	high	Ability to see faint quasars at night if motion is compensated
1 s	high	Everyday motion completely blurred
20 ms	lower	Interruption by eyelids; small changes impossible to see
10 ms	lower	Effective eye/brain shutter time; tennis ball impossible to see when hitting it
0.25 ms	lower	Shortest commercial photographic camera shutter time; ability to photograph fast cars
1 µs	very low	Ability to photograph flying bullets; strong flashlight required
c. 10 ps	lowest	Study of molecular processes; ability to photograph flying light pulses; laser light required to get sufficient illumination
10 fs	higher	Light photography impossible because of wave effects
100 zs	high	X-ray photography impossible; only γ-ray imaging left over
shorter times	very high	Photographs darker as illumination decreases; gravitational effects significant
10^{-41} s	highest	Imaging meaningless

Imagine that you have the world's best shutter and that you are taking photographs at shorter and shorter times. Table 126 gives a rough overview of the possibilities. At shorter shutter times, photographs get darker. When the shutter time reaches the oscillation time of light, strange things happen: light has no chance to pass undisturbed; signal and noise become indistinguishable; and the moving shutter will produce colour shifts. In contrast to our everyday experience, the picture would get more *blurred* at extremely short shutter times. Photography is impossible not only at long but also at short shutter times.

The difficulty of taking photographs is independent of the wavelength used. The limits move, but do not disappear. With a shutter time of τ, photons of energy lower than $\hbar/\tau$ cannot pass undisturbed. The blur is small when shutter times are those of everyday life, but *increases* when shutter times are shortened towards Planck times. As a result, there is no way to detect or confirm the existence of point objects by taking pictures. Points in space, as well as instants of time, are *imagined* concepts: they do not belong in a precise description of nature.

At Planck shutter times, only signals with Planck energy can pass through the shutter. Since at these energies matter cannot be distinguished from radiation or from empty space, all objects, light, and vacuum look the same. It is impossible to say what nature looks like at very short times.

But the situation is worse than this: a Planck shutter cannot exist at all, as it would need to be as small as a Planck length. A camera using it could not be built, as lenses do not work at this energy. Not even a camera obscura – without any lens – would work, as diffraction effects would make image production impossible.

In other words, the idea that at short shutter times a photograph of nature shows a frozen image of everyday life, like a stopped film, is completely wrong.* Indeed, at a single

* In fact, a shutter does not exist even at medium energy: shutters, like walls, stop existing at around 10 MeV.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

instant of time nature is not frozen at all. Zeno criticized this idea in his discussions of motion, though not as clearly as we can do now. At short times, nature is blurred. In particular, point particles do not exist.

In summary, whatever the intrinsic shape of what we call a 'point' might be, we know that, being always blurred, it is first of all a cloud. Whatever method is used to photograph of a point particle, it always shows an extended entity. Let us study its shape in more detail.

What is the shape of an electron?

Since particles are not point-like, they have a shape. How can we determine it? We determine the shape of an everyday object by *touching* it from all sides. This works with plants, people or machines. It even works with molecules, such as water molecules. We can put them (almost) at rest, for example in ice, and then scatter small particles off them. Scattering is just a higher-energy version of touching. However, scattering cannot determine shapes of objects smaller than the wavelength of the probes used. To determine the shape of an object as small as an electron, we need the highest energies available. But we already know what happens when approaching Planck scales: the shape of a particle becomes the shape of all the space surrounding it. Shape cannot be determined in this way.

Another way to determine the shape is to build a tight box around the system under investigation and fill it with molten wax. We then let the wax cool and observe the hollow part. However, near Planck energies, boxes do not exist. We are unable to determine the shape in this way.

A third way to measure the shape of an object is to cut it into pieces and then study the pieces. But *cutting* is just a low-energy version of a scattering process. It does not work at high energies. Since the term 'atom' just means 'uncuttable' or 'indivisible', neither atoms nor indivisible particles can exist. Indeed, there is no way to prove that an object is indivisible. Our everyday intuition leads us completely astray at Planck energies.

We could try to distinguish transverse and longitudinal shape, with respect to the direction of motion. However, for transverse shape we get the same issues as for scattering; transverse shape diverges for high energy. And to determine longitudinal shape, we need at least two infinitely high potential walls. We already know that this is impossible.

A further, indirect way of measuring shapes is to measure the moment of inertia. A finite moment of inertia means a compact, finite shape. But when the measurement energy is increased, rotation, linear motion and exchange become mixed up. We do not get meaningful results. Ref. 1294

Yet another way to determine shapes is to measure the *entropy* of a collection of particles we want to study. This allows us to determine the dimensionality and the number of internal degrees of freedom. But at high energies, a collection of electrons would become a black hole. We will study this issue separately below, but again we find no new information.

Are these arguments watertight? We assumed three dimensions at all scales, and that the shape of the particle itself is fixed. Maybe these assumptions are not valid at Planck scales. Let us check the alternatives. We have already shown that because of the fundamental measurement limits, the dimensionality of space-time cannot be determined at

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 1294 Planck scales. Even if we could build perfect three-dimensional boxes, holes could remain in other dimensions. It does not take long to see that all the arguments against compactness work even if space-time has additional dimensions.

Is the shape of an electron fixed?

Only an object composed of localized entities, such as a house or a molecule, can have a fixed shape. The smaller the system, the more quantum fluctuations play a role. No entity with a finite size – in particular, no elementary particle – can have a fixed shape. In every Gedanken experiment involving a finite shape, the shape itself fluctuates. But we can say more.

The distinction between particles and environment rests on the idea that particles have *intrinsic* properties. In fact, all intrinsic properties, such as spin, mass, charge, and parity, are localized. But we have seen that no intrinsic property is measurable or definable at Planck scales. Thus it is impossible to distinguish particles from the environment. In addition, at Planck energy particles have all the properties that the environment has. In particular, particles are extended.

In short, we cannot prove by experiments that at Planck energy elementary particles are finite in size in all directions. In fact, all experiments one can think of are compatible with extended particles, with 'infinite' size. More precisely, a particle always reaches the borders of the region of space-time under exploration. In simple words, we can also say that particles have *tails*.

Not only are particles extended, but their shape cannot be determined by the methods just explored. The only remaining possibility is that suggested by quantum theory: *the shape of a particle fluctuates*.

We reach the same conclusions for radiation particles. The box argument shows that radiation particles are also extended and fluctuating.

Incidentally, we have also settled an important question about elementary particles. We have already seen that any particle that is smaller than its own Compton wavelength
Page 1038 must be elementary. If it were composite, there would be a lighter component inside it; this lighter particle would have a larger Compton wavelength than the composite particle. This is impossible, since the size of a composite particle must be larger than the Compton wavelength of its components.*

However, an elementary particle *can* have constituents, provided that they are not compact. The difficulties of compact constituents were described by Sakharov in the
Ref. 1300 1960s. If the constituents are extended, the argument does not apply, as extended entities have no localized mass. As a result, a flying arrow – Zeno's famous example – cannot be said to be at a given position at a given time, if it is made of extended entities. Shortening the observation time towards the Planck time makes an arrow disappear in the cloud that makes up space-time.**

* Examples are the neutron, positronium, or the atoms. Note that the argument does not change when the elementary particle itself is unstable, like the muon. The possibility that all components are heavier than the composite, which would avoid this argument, does not seem to lead to satisfying physical properties: for example, it leads to intrinsically unstable composites.

Ref. 1301 ** Thus at Planck scales there is no quantum Zeno effect.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Summary of the first argument for extension

In summary, only the idea of points leads to problems at Planck scales. If space-time and matter are imagined to be made, at Planck scales, of *extended and fluctuating* entities, the problems disappear. We note directly that for extended entities the requirement of a non-local description is satisfied; in addition, for fluctuating entities the requirement of a statistical description of the vacuum is satisfied. The argument forbidding composition of elementary particles is circumvented, as extended entities have no clearly defined mass. Thus the concept of Compton wavelength cannot be defined or applied to extended constituents, and elementary particles can have constituents if they are extended. But if the components are extended, how can compact 'point' particles be formed from them? We will look at a few options shortly.

Ref. 1294

Challenge 1702 e

THE SHAPE OF POINTS IN VACUUM

> Thus, since there is an impossibility that [finite] quantities are built from contacts and points, it is necessary that there be indivisible material elements and [finite] quantities.
>
> Aristotle, *Of Generation and Corruption*

Ref. 1302

We are used to the idea that empty space is made of spatial points. Let us check whether this is true at high energy. At Planck scales, no measurement can give zero length, zero mass, zero area or zero volume. There is no way to state that something in nature is a point without contradicting experimental results. Furthermore, the idea of a point is an extrapolation of what is found in small empty boxes getting smaller and smaller. But we have just seen that at high energies small boxes cannot be said to be empty. In fact, boxes do not exist at all, as they can never have impenetrable walls at high energies.

What's more, the idea of a point as a limiting subdivision of empty space is untenable. At small distances, space cannot be subdivided, as division requires some sort of dividing wall, which is impossible.

Even the idea of repeatedly putting a point between two others cannot be applied. At high energy, it is impossible to say whether a point is exactly on the line connecting the outer two points; and near Planck energy, there is no way to find a point between them at all. In fact, the term 'in between' makes no sense at Planck scales.

We thus find that space points do not exist, just as point particles do not exist. But there are other reasons why space cannot be made of points. Common sense tells us that points need to be kept *apart* somehow, in order to form space. Indeed, mathematicians have a strong argument for why physical space cannot be made of mathematical points: the properties of mathematical spaces described by the Banach–Tarski paradox are quite different from those of the physical vacuum. The Banach–Tarski paradox states that a sphere made of mathematical points can be cut into five pieces which can be reassembled into two spheres each of the same volume as the original sphere. Mathematically, there are sets of points for which volume makes no sense. Physically speaking, we can say that the concept of volume does not exist for continuous space; it is only definable if an intrinsic length exists. This is the case for matter, and it must also be the case for vacuum.

Ref. 1294

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

But any concept with an intrinsic length must be described by one or several extended components.* In summary, we need *extended* entities to build up space-time.

In mathematics it is impossible to define the dimension of a set of points on the basis of the set structure alone. Any compact one-dimensional set has as many points as any compact three-dimensional set – indeed, as any compact set of any dimensionality greater than zero. To build up the physical three-dimensional vacuum, we need entities that organize their neighbourhood. The fundamental entities must possess some sort of ability to form bonds, which will construct or fill precisely three dimensions. Bonds require extended entities. A collection of tangled entities extending to the maximum scale of the region under consideration would work perfectly. Of course, the precise shape of the fundamental entities is not yet known. In any case, we again find that any constituents of physical three-dimensional space must be extended.

In summary, we need extension to define dimensionality and to define volume. This is not surprising. We deduced above that the constituents of particles are extended. Since vacuum is not distinguishable from matter, we would expect the constituents of vacuum to be extended as well. Stated simply, if elementary particles are not point-like, then space-time points cannot be either.

Measuring the void

To check whether space-time constituents are extended, let us perform a few additional Gedanken experiments. First, let us measure the size of a point of space-time. The clearest definition of size is in terms of the cross section. How can we determine the cross section of a point? We can determine the cross section of a piece of vacuum and then determine the number of points inside it. However, at Planck energies, we get a simple result: the cross section of a volume of empty space is independent of depth. At Planck energies, vacuum has a surface, but no depth. In other words, at Planck energy we can only state that a Planck layer covers the surface of a region. We cannot say anything about its interior. One way to picture this result is to say that space points are long tubes.

Another way to determine the size of a point is to count the points found in a given volume of space-time. One approach is to count the possible positions of a point particle in a volume. However, at Planck energies point particles are extended and indistinguishable from vacuum. At Planck energy, the number of points is given by the surface area of the volume divided by the Planck area. Again, the surface dependence suggests that particles are long tubes.

Another approach to counting the number of points in a volume is to fill a piece of vacuum with point particles.

What is the maximum number of particles that fit inside a piece of vacuum?

The maximum mass that fits into a piece of vacuum is a black hole. But in this case too, the maximum mass depends only on the *surface* of the given region of vacuum. The maximum mass increases less rapidly than the volume. In other words, the number of

Ref. 1303 * Imagining the vacuum as a collection of entities, such as spheres, with Planck size in all directions would avoid the Banach–Tarski paradox, but would not allow us to deduce the number of dimensions of space and
Challenge 1703 s time. It would also contradict all the other results of this section. Therefore we do not explore it further.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

points in a region is only proportional to the surface area of the region. We are forced to conclude that vacuum must be made of extended entities crossing the whole region, independently of its shape.

Summary of the second argument for extension

Page 258 More than two thousand years ago, the Greeks argued that matter must be made of par-
Ref. 1304 ticles because salt can be dissolved in water and because fish can swim through water. Now that we know more about Planck scales, we have to reconsider this argument. Like fish swimming through water, particles can move through vacuum; but since vacuum has no bounds, and cannot be distinguished from matter, vacuum cannot be made of localised particles. However, there is another possibility that allows for motion of particles through a vacuum: both vacuum and particles might be made of a web of extended entities. Let us study this possibility in more detail.

THE LARGE, THE SMALL AND THEIR CONNECTION

> I could be bounded in a nutshell and count myself a king of infinite space, were it not that I have bad dreams.
>
> William Shakespeare, *Hamlet*

If two observables cannot be distinguished, there is a symmetry transformation connecting them. For example, by a change of observation frame, an electric field may change into a magnetic one. A symmetry transformation means that we can change the viewpoint (i.e., the frame of observation) in such a way that the same observation is described by one quantity from one viewpoint and by the corresponding quantity from the other viewpoint.

When measuring a length at Planck scales it is impossible to say whether we are measuring the length of a piece of vacuum, the Compton wavelength of a body, or the Schwarzschild diameter of a body. For example, the maximum size for an elementary object is its Compton wavelength. The minimum size for an elementary object is its Schwarzschild radius. The actual size of an elementary object is somewhere in between. If we want to measure the size precisely, we have to go to Planck energy; but then all these quantities are the same. In other words, at Planck scales, there is a symmetry transformation between Compton wavelength and Schwarzschild radius. In short, *at Planck scales there is a symmetry between mass and inverse mass.*

As a further consequence, at Planck scales there is a symmetry between size and inverse size. Matter–vacuum indistinguishability means that there is a symmetry between
Ref. 1305 length and inverse length at Planck energies. This symmetry is called *space-time duality* or *T-duality* in the literature of superstrings.* Space-time duality is a symmetry between situations at scale $n\,l_{\mathrm{Pl}}$ and at scale $f\,l_{\mathrm{Pl}}/n$, or, in other words, between R and $(f\,l_{\mathrm{Pl}})^2/R$, where the empirically determined number f has a value somewhere between 1 and 1000.

* There is also an *S-duality*, which connects large and small coupling constants, and a *U-duality*, which is the combination of S- and T-duality.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Duality is a genuine non-perturbative effect. It does not exist at low energy, since duality automatically also relates energies E and $E_{\mathrm{Pl}}^2/E = \hbar c^3/GE$, i.e., it relates energies below and above Planck scale. Duality is not evident in everyday life. It is a quantum symmetry, as it includes Planck's constant in its definition. It is also a general-relativistic effect, as it includes the gravitational constant and the speed of light. Let us study duality in more detail.

Is small large?

> [Zeno of Elea maintained:] If the existing are many, it is necessary that they are at the same time small and large, so small to have no size, and so large to be without limits.
>
> Simplicius, *Commentary on the Physics of Aristotle*, 140, 34

Ref. 1306

To explore the consequences of duality, we can compare it to rotational symmetry in everyday life. Every object in daily life is symmetrical under a full rotation of 2π. For the rotation of an observer, angles make sense only as long as they are smaller than 2π. If a rotating observer were to insist on distinguishing angles of $0, 2\pi, 4\pi$ etc., he would get a new copy of the universe at each full turn.

Similarly, in nature, scales R and l_{Pl}^2/R cannot be distinguished. Lengths make no sense when they are smaller than l_{Pl}. If, however, we insist on using even smaller values and on distinguishing them from large ones, we get a new copy of the universe at those small scales. Such an insistence is part of the standard continuum description of motion, where it is assumed that space and time are described by the real numbers, which are defined over arbitrarily small intervals. Whenever the (approximate) continuum description with infinite extension is used, the $R \leftrightarrow l_{\mathrm{Pl}}^2/R$ symmetry pops up.

Duality implies that diffeomorphism invariance is only valid at medium scales, not at extremal ones. At extremal scales, quantum theory has to be taken into account in the proper manner. We do not yet know how to do this.

Space-time duality means that introducing lengths smaller than the Planck length (as when one defines space points, which have size zero) means at the same time introducing things with very large ('infinite') value. Space-time duality means that for every small enough sphere the inside equals the outside.

Duality means that if a system has a small dimension, it also has a large one, and vice versa. There are thus no small objects in nature. So space-time duality is consistent with the idea that the basic entities are extended.

Unification and total symmetry

So far, we have shown that at Planck energy, time and length cannot be distinguished. Duality shows that mass and inverse mass cannot be distinguished. As a consequence, length, time, and mass cannot be distinguished from each other. Since every observable is a combination of length, mass and time, *space-time duality means that there is a symmetry*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

between all observables. We call it the *total symmetry*.*

Total symmetry implies that there are many specific types of duality, one for each pair of quantities under investigation. Indeed, in string theory, the number of duality types discovered is increasing every year. It includes, among others, the famous electric–magnetic duality we first encountered in electrodynamics, coupling constant duality, surface–volume duality, space-time duality, and many more. All this confirms that there is an enormous amount of symmetry at Planck scales. Similar symmetries have been known right from the beginning of string theory.

Page 718
Ref. 1307
Ref. 1305

Most importantly, total symmetry implies that gravity can be seen as equivalent to all other forces. Space-time duality shows that unification is possible. Physicists have always dreamt about unification. Duality tells us that this dream can indeed be realized.

It may seem that total symmetry completely contradicts what was said in the previous section, where we argued that all symmetries are lost at Planck scales. Which result is correct? Obviously, both of them are.

At Planck scales, all low-energy symmetries are indeed lost. In fact, all symmetries that imply a *fixed* energy are lost. However, duality and its generalizations combine both small and large dimensions, or large and small energies. Most of the standard symmetries of physics, such as gauge, permutation and space-time symmetries, are valid at each fixed energy separately. But nature is not made this way. The precise description of nature requires us to take into consideration large and small energies at the same time. In everyday life, we do not do that. The physics of everyday life is an approximation to nature valid at low and fixed energies. For most of the twentieth century, physicists tried to reach higher and higher energies. We believed that precision increases with increasing energy. But when we combine quantum theory and gravity we are forced to change this approach. To achieve high precision, we must take high and low energy into account at the same time.**

The great differences between the phenomena that occur at low and high energies are the main reason why unification is so difficult. We are used to dividing nature along a scale of energies: high-energy physics, atomic physics, chemistry, biology, and so on. But we are not allowed to think in this way any more. We have to take all energies into account at the same time. That is not easy, but we do not have to despair. Important conceptual progress was made in the last decade of the twentieth century. In particular, we now know that we need only *one concept* for all things that can be measured. Since there is only one concept, there are many ways to study it. We can start from any (low-energy) concept in physics and explore how it looks and behaves when we approach Planck scales. In the present section, we are looking at the concept of 'point'. Obviously, the conclusions must be the same whatever concept we start with, be it electric field, spin, or any other. Such studies thus provide a check for the results in this section.

Challenge 1704 d

* A symmetry between size and Schwarzschild radius, i.e., a symmetry between length and mass, will lead to general relativity. Additionally, at Planck energy there is a symmetry between size and Compton wavelength. In other words, there is a symmetry between length and inverse mass. This means that there is a symmetry between coordinates and wave functions. This is a symmetry between states and observables. It leads to quantum theory.

** Renormalization energy does connect different energies, but not in the correct way; in particular, it does not include duality.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Summary of the third argument for extension

Unification implies thinking in terms of duality and the concepts that follow from it. The large and the small are connected. This points to extended entities. We also need to understand exactly what happens to duality when we restrict ourselves to low energies, as we do in everyday life. This question is left for the next section.

Challenge 1705 e

DOES NATURE HAVE PARTS?

> Pluralitas non est ponenda sine necessitate.*
> William of Occam

There is another argument, independent of those given above, that points towards a model of nature based on extended entities. Let us take a broader view. Any concept for which we can distinguish parts is described by a set. We usually describe nature as a set of objects, positions, instants and so on. The most famous set-theoretic description of nature is the oldest known, given by Democritus: 'The world is made of indivisible particles and void.' This description was extremely successful in the past: there were no discrepancies with observations. However, after 2500 years, the conceptual difficulties of this approach are obvious.

We now know that Democritus was wrong, first of all, because vacuum and matter cannot be distinguished at Planck scales. Thus the word 'and' in his sentence is already a mistake. Secondly, because of the existence of minimal scales, the void cannot be made of 'points', as we usually assume. Thirdly, the description fails because particles are not compact objects. Finally, total symmetry implies that we cannot distinguish parts in nature. Nothing can be distinguished from anything else with complete precision, and thus the particles or points in space that make up the naive model of the world cannot exist.

In summary, quantum theory and general relativity together show that in nature, *all differences are only approximate*. Nothing can really be distinguished from anything else with complete precision. In other words, there is no way to define a 'part' of nature, whether for matter, space, time, or radiation. *Nature cannot be a set.*

The conclusion that nature is not a set does not come as a surprise. We have already encountered another reason to doubt that nature is a set. Whatever definition we use for the term 'particle', Democritus cannot be correct for a purely logical reason. The description he provided is *not complete*. Every description of nature that defines nature as a set of parts misses certain aspects. Most importantly, it misses the *number* of these parts. In particular, the number of particles and the number of dimensions of space-time must be specified if we describe nature as made from particles and vacuum. We saw above that it is rather dangerous to make fun of the famous statement by Arthur Eddington

Page 860

* 'Multitude should not be introduced without necessity.' This famous principle is commonly called *Occam's razor*. William of Ockham (b. 1285/1295 Ockham, d. 1349/50 München), or Occam in the common Latin spelling, was one of the great thinkers of his time. In his famous statement he expresses that only those concepts which are strictly necessary should be introduced to explain observations. It can be seen as the requirement to abandon *beliefs* when talking about nature. But at this stage of our mountain ascent it has an even more direct interpretation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 1308

> I believe there are 15,747,724,136,275,002,577,605,653,961,181,555,468,044,717,914, 527,116,709,366,231,425,076,185,631,031,296 protons in the universe and the same number of electrons.

In fact, practically all physicists share this belief, although they usually either pretend to favour some other number, or worse, keep the number unspecified. We have seen during our walk that in modern physics many specialized sets are used to describe nature. We have used vector spaces, linear spaces, topological spaces and Hilbert spaces. But we consistently refrained, like all physicists, from asking about the origin of their sizes (mathematically speaking, of their dimensionality or cardinality). In fact, it is just as unsatisfying to say that the universe contains some specific number of atoms as it is to say that space-time is made of point-like events arranged in $3+1$ dimensions. Both are statements about set sizes, in the widest sense. In a complete, unified description of nature the number of smallest particles and the number of space-time points must not be part of the description, but must *result* from the description.

Any part of nature is by definition smaller than the whole of nature, and different from other parts. As a result, no description of nature by a set can possibly yield the number of particles or the dimensionality of space-time. As long as we insist on using space-time or Hilbert spaces for the description of nature, we *cannot* understand the number of dimensions or the number of particles.

That is not too bad, as we know already that nature is *not* made of parts. We know that parts are only approximate concepts. In short, if nature were made of parts, it could not be a unity, or a 'one.' On the other hand, if nature is a unity, it cannot have parts.* Nature cannot be separable exactly. It cannot be made of particles.

To sum up, nature cannot be a set. Sets are lists of distinguishable elements. When general relativity and quantum theory are unified, nature shows no elements: *nature stops being a set at Planck scales*. This result clarifies a discussion we started earlier in relation to classical physics. There we discovered that matter objects were defined using space and time, and that space and time were defined using objects. Along with the results of quantum theory, this implies that in modern physics particles are defined in terms of the vacuum and the vacuum in terms of particles. This is clearly not a good idea. But we have just seen that since the two concepts are indistinguishable from each other, we cannot define them in terms of each other. Everything is the same. In fact, there is no 'every' and no 'thing'. Since nature is not a set, the circular reasoning is dissolved.

Space-time duality also implies that space is not a set. It implies that events cannot be distinguished from each other, and thus do not form elements of some space. Phil Gibbs Ref. 1310 has given the name *event symmetry* to this property of nature. This thought-provoking term, although still containing the term 'event', emphasizes the fact that it is impossible to use a set to describe space-time.

In short, nature cannot be made of vacuum and particles. This is a bizarre result. Atomists, from Democritus to Galileo, have been persecuted throughout history. Were their

* As a curiosity, practically the same discussion can already be found in Plato's *Parmenides*, written in the Ref. 1309 fourth century BCE. There, Plato musically ponders different arguments on whether nature is or can be a *unity* or a *multiplicity*, i.e., a set. It seems that the text is based on the real visit to Athens by Parmenides and Zeno. (Their home city, Elea, was near Naples.) Plato does not reach a conclusion. Modern physics, however, does.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

battles all in vain? Let us continue to clarify our thoughts.

Does the universe contain anything?

To state that the universe contains something implies that we are able to distinguish the universe from its contents. However, we now know that precise distinctions are impossible. If nature is not made of parts, it is wrong to say that the universe *contains* something.

Let us go further. We need a description of nature that allows us to state that at Planck energies nothing can be distinguished from anything else. For example, it must be impossible to distinguish particles from each other or from the vacuum. There is only one solution: everything – or at least, what we call 'everything' in everyday life – must be made of the same single entity. All particles are made of one 'piece'. Every point in space, every event, every particle and every instant of time must be made of the same single entity.

An amoeba

> "A theory of nothing describing everything is better than a theory of everything describing nothing."

We have found that parts are approximate concepts. The parts of nature are not strictly smaller than nature itself. As a result, any 'part' must be extended. Let us try to extract some more information about the constituents of nature.

In any unified theory, all the concepts that appear must be only *approximately* parts of the whole. Thus we need an entity Ω, describing nature, which is not a set but which can be approximated by one. This is strange. We are all convinced very early in our lives that we are a *part* of nature. Our senses provide us with this information. We are not used to thinking otherwise. But now we have to.

Let us straight away eliminate a few options for Ω. One concept without parts is the empty set. Perhaps we need to construct a description of nature from the empty set? We could be inspired by the usual construction of the natural numbers from the empty set. Page 828 However, the empty set makes only sense as the opposite of some full set. So the empty set is not a candidate for Ω.

Another possible way to define approximate parts is to construct them from multiple copies of Ω. But in this way we would introduce a new set through the back door. Furthermore, new concepts defined in this way would not be approximate.

We need to be more imaginative. How can we describe a whole which has no parts, but which has parts approximately? Let us recapitulate. The world must be described by a single entity, sharing all properties of the world, but which can be approximated as a set of parts. For example, the approximation should yield a set of space points and a set of particles. But also, whenever we look at any 'part' of nature, without any approximation, we should not be able to distinguish it from the whole world. Composite entities are not always larger than their constituents. On the other hand, composed entities must usually *appear* to be larger than their constituents. For example, space 'points' or 'point' particles are tiny, even though they are only approximations. Which concept without boundaries can be at their origin? Using usual concepts, the world is everywhere at the same time;

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

if nature is to be described by a single constituent, this entity must be extended.

The entity has to be a single one, but it must *seem* to be multiple: it has to be multiple approximately, as nature shows multiple aspects. The entity must be something folded. It must be possible to count the folds, but only approximately. (An analogy is the question of how many grooves there are on an LP or a CD: depending on the point of view, local or global, one gets different answers.) Counting folds would correspond to a length measurement.

The simplest model would be a single entity which is extended and fluctuating, goes to infinity, and allows approximate localization, thus allowing approximate definition of parts and points.* In more vivid imagery, nature could be described by some deformable, folded and tangled entity: a giant, knotted amoeba. An amoeba slides between the fingers whenever one tries to grab a part of it. A perfect amoeba flows around any knife trying to cut it. The only way to hold it would be to grab it in its entirety. However, for someone himself made of amoeba strands, this is impossible. He can only grab it approximately, by catching part of it and approximately blocking it, for example using a small hole so that the escape takes a long time.

Summary of the fourth argument for extension

The lack of particles and of sets in nature leads to describing nature by a single entity. Nature is thus modelled by an entity which is *one single 'object'* (to eliminate distinguishability), which is *extended* (to eliminate localizability) and which is *fluctuating* (to ensure approximate continuity). Nature is a far-reaching, fluctuating fold, similar to an amoeba. The tangled branches of the amoeba allow a definition of length via counting of the folds. In this way, *discreteness* of space, time, and particles could also be realized; the quantization of space-time, matter and radiation thus follows. Any flexible and deformable entity is also a perfect candidate for the realization of diffeomorphism invariance, as required by general relativity.

A simple candidate for the extended fold is the image of a fluctuating, flexible *tube*. Counting tubes implies determining distances or areas. The minimum possible count (one) gives the minimum distance, from which quantum theory is derived. In fact, we can use as a model any flexible object with a small dimension, such as a tube, a thin sheet, a ball chain or a woven collection of rings. These options give the different, but probably equivalent, models currently being explored in simplicial quantum gravity, in Ashtekar's variables and in superstrings.

THE ENTROPY OF BLACK HOLES

We are still collecting approaches to determining the shape of particles. One way is to study situations where they appear in large numbers. Systems composed of many particles behave differently depending on whether the particles are point-like or extended. In particular, their entropy is different. Studying large-number entropy thus allows us to determine the shape of components. The most revealing situations are those in which

Challenge 1706 ny

* Is this the only way to describe nature? Is it possible to find another description, particularly if space and time are not used as background? The answers are unclear at present.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

large numbers of particles are crammed in a small volume. Therefore we study the entropy of black holes. A black hole is a body whose gravity is so strong that even light cannot escape. Black holes tell us a lot about the fundamental entities of nature. It is easily deduced from general relativity that any body whose mass m fits inside the so-called Schwarzschild radius

$$r_S = 2Gm/c^2 \tag{949}$$

is a black hole.

A black hole can be formed when a whole star collapses under its own weight. Such a black hole is a macroscopic body, with a large number of constituents. Therefore it has an entropy. The entropy S of a macroscopic black hole was determined by Bekenstein and Hawking, and is given by

Ref. 1311, Ref. 1312

$$S = \frac{k}{l_{Pl}^2}\frac{A}{4} \quad \text{or} \quad S = k\frac{4\pi G m^2}{\hbar c} \tag{950}$$

where k is the Boltzmann constant and $A = 4\pi r_S^2$ is the surface of the black hole horizon. This important result has been derived in many different ways. The various derivations also confirm that space-time and matter are equivalent, by showing that the entropy value can be interpreted as an entropy either of matter or of space-time. In the present context, the two main points of interest are that the entropy is *finite*, and that it is *proportional to the area* of the black hole horizon.

Ref. 1313

In view of the existence of minimum lengths and times, the finiteness of the entropy is not surprising: it confirms the idea that matter is made of a finite number of discrete entities per given volume. It also shows that these entities behave statistically: they fluctuate. In fact, quantum gravity implies a finite entropy for any object, not only for black holes. Bekenstein has shown that the entropy of an object is always smaller than the entropy of a (certain type of) black hole of the same mass.

Ref. 1314

The entropy of a black hole is proportional to its horizon area. Why? This question has been the topic of a stream of publications.* A simple way to understand the entropy–surface proportionality is to look for other systems in nature whose entropy is proportional to system surface instead of system volume. In general, the entropy of a collection of flexible one-dimensional objects, such as polymer chains, shares this property. Indeed, the entropy of a polymer chain made of N monomers, each of length a, whose ends are kept a distance r apart, is given by

Ref. 1315

Ref. 1317

Ref. 1318

$$S(r) = k\frac{3r^2}{2Na^2} \quad \text{for} \quad Na \gg \sqrt{Na} \gg r\,. \tag{951}$$

This formula can be derived in a few lines from the properties of a random walk on a lattice, using only two assumptions: the chains are extended; and they have a characteristic internal length a given by the smallest straight segment. Expression (951) is only valid if the polymers are effectively infinite: in other words, if the length Na of the chain and

Ref. 1316

* The result can be derived from quantum statistics alone. However, this derivation does not yield the proportionality coefficient.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the *elongation* $a\sqrt{N}$, are much larger than the radius r of the region of interest. If the chain length is comparable to or smaller than the region of interest, one gets the usual extensive entropy, satisfying $S \sim r^3$. Thus *only flexible extended entities yield an* $S \sim r^2$ *dependence.*

However, there is a difficulty. From the expression for the entropy of a black hole we deduce that the elongation $a\sqrt{N}$ is given by $a\sqrt{N} \approx l_{\text{Pl}}$; thus it is much smaller than the radius of a general macroscopic black hole, which can have a diameter of several kilometres. On the other hand, the formula for long entities is only valid when the chains are longer than the distance r between the end points.

This difficulty disappears when we remember that space near a black hole is strongly curved. All lengths have to be measured in the same coordinate system. It is well known that for an outside observer, any object of finite size falling into a black hole seems to cover the complete horizon for long times (whereas for an observer attached to the object it falls into the hole in its original size). In short, an extended entity can have a proper length of Planck size but still, when seen by an outside observer, be as long as the horizon of the black hole. We thus find that black holes are made of extended entities.

Ref. 1297

Another viewpoint can confirm this result. Entropy is (proportional to) the number of yes-or-no questions needed to know the exact state of the system. This view of black holes has been introduced by Gerard 't Hooft. If a system is defined by its surface, as a black hole is, its components must be extended.

Finally, imagining black holes as made of extended entities is also consistent with the so-called no-hair theorem: black holes' properties do not depend on what falls into them, as all matter and radiation particles are made of the same extended components. The final state only depends on the number of entities. In short, the entropy formula for a black hole is consistent with the idea that it is made of a big tangle of extended entities, fluctuating in shape.

Summary of the fifth argument for extension

Black hole entropy is best understood as resulting form extended entities of space-time and matter.

EXCHANGING SPACE POINTS OR PARTICLES AT PLANCK SCALES

Let us now focus on the exchange behaviour of fundamental entities in nature. We saw above that 'points' in space have to be abandoned in favour of continuous, fluctuating entities common to space, time and matter. Is such an entity a boson or a fermion? If we exchange two points of empty space, in everyday life, nothing happens. Indeed, at the basis of quantum field theory is the relation

$$[x, y] = xy - yx = 0 \tag{952}$$

between any two points with coordinates x and y, making them bosons. But at Planck scales, because of the existence of minimal distances and areas, this relation must at least

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

be changed to

$$[x, y] = l_{\mathrm{Pl}}^2 + \dots \,. \tag{953}$$

This means that 'points' are neither bosons nor fermions.* They have more complex exchange properties. In fact, the term on the right-hand side will be energy-dependent, to an increasing extent as we approach Planck scales. In particular, as we have seen, gravity implies that double exchange does not lead back to the original situation at Planck scales.

Ref. 1294

Entities obeying this or similar relations have been studied in mathematics for many decades: they are called braids. Thus at Planck scales space-time is not made of points, but of braids or their generalizations. Again, quantum theory and general relativity taken together show that the vacuum must be made of extended entities.

Ref. 1319

Ref. 1319

All particles behave in a similar way: we know that at low, everyday energies, particles of the same type are *identical*. Experiments sensitive to quantum effects show that there is no way to distinguish them: any system of several identical particles has permutation symmetry. On the other hand, we know that at Planck energy all low-energy symmetries disappear. We also know that at Planck energy permutation cannot be carried out, as it implies exchanging positions of two particles. At Planck energy, nothing can be distinguished from vacuum; thus no two entities can be shown to have identical properties. Indeed, no two particles can be shown to be indistinguishable, as they cannot even be shown to be separate.

What happens when we slowly approach Planck energy? At everyday energies, permutation symmetry is defined by commutation or anticommutation relations between particle creation operators

$$a^\dagger b^\dagger \pm b^\dagger a^\dagger = 0 \,. \tag{954}$$

At Planck energies this cannot be correct. Quantum gravity effects modify the right-hand side: they add an energy-dependent term, which is negligible at experimentally accessible energies but which becomes important at Planck energy. We know from our experience with Planck scales that, in contrast to everyday life, exchanging particles twice cannot lead back to the original situation. A double exchange at Planck energy cannot have no effect, because at Planck energy such statements are impossible. The simplest extension of the commutation relation (954) for which the right-hand side does not vanish is *braid symmetry*. This again suggests that particles are made of extended entities.

Ref. 1294

Ref. 1319

Summary of the sixth argument for extension

Extrapolating particle indistinguishability to Planck scales points to extended entities.

THE MEANING OF SPIN

Finally, we will show that even at everyday energy, the extension of particles makes sense. Any particle is a part of the universe. A part is something that is different from anything else. Being 'different' means that exchange has some effect. *Distinction means possibility of exchange.* In other words, any part of the universe is described by its exchange behaviour.

* The same reasoning applies to the fermionic or Grassmann coordinates used in supersymmetry.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

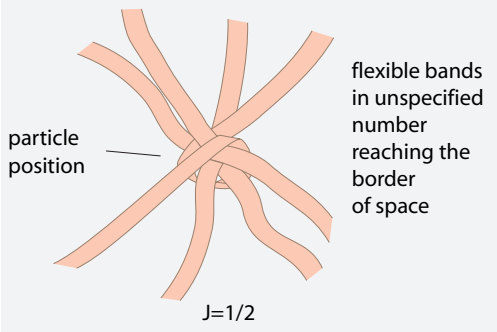

FIGURE 607 A possible model for a spin 1/2 particle

In everyday life, exchange can be seen as composed of rotations. Parts are described by their rotation behaviour. This is why, for microscopic particles, exchange behaviour is specified by spin. *Spin distinguishes particles from vacuum.*[*]

We note that volume does not distinguish vacuum from particles; neither does rest mass or charge: there are particles without rest mass or charge, such as photons. The only observables that might distinguish particles from vacuum are spin and momentum. In fact, linear momentum is only a limiting case of angular momentum. We again find that rotation behaviour is the basic aspect distinguishing particles from vacuum.

If spin is the central property that distinguishes particles from vacuum, finding a model for spin is of central importance. But we do not have to search for long. There is a model for spin 1/2 that is part of physics folklore. Any belt provides an example, as
Page 1052 we discussed in detail when exploring permutation symmetry. Any localized structure with any number of long tails attached to it – and reaching the border of the region of space under consideration – has the same properties as a spin 1/2 particle. It is a famous exercise to show that such a model, shown in Figure 607, is indeed invariant under 4π rotations but not under 2π rotations, and that two such particles get entangled when exchanged, but get untangled when exchanged twice. This model has all the properties of spin 1/2 particles, independently of the precise structure of the central region, which remains unknown at this point. The tail model even has the same problems with highly curved space as real spin 1/2 particles have. We will explore this idea in detail shortly.

The tail model thus confirms that rotation is partial exchange. More interestingly, it
Ref. 1320 shows that rotation implies connection with the border of space-time. Extended particles can be rotating. Particles can have spin 1/2 provided that they have tails going to the border of space-time. If the tails do not reach the border, the model does not work. Spin 1/2 thus even seems to *require* extension. We again find that extended entities serve as a good description for particles.

[*] With a flat (or other) background, it is possible to define a *local* energy–momentum tensor. Thus particles can be defined. Without a background, this is not possible, and only global quantities can be defined. Without a background, even particles cannot be defined. Therefore, in this section we assume that we have a slowly varying space-time background.

Summary of the seventh argument for extension

Extrapolating particle spin to Planck scales points to extended entities.

CURRENT RESEARCH

> To understand is to perceive patterns.
>
> Isaiah Berlin

The Greeks deduced the existence of atoms from the fact that fish can swim through
Ref. 1304 water. They argued that only if water is made of atoms could a fish make its way through it, by pushing the atoms aside. We can ask a similar question of a particle flying through a vacuum: why is it able to do so? A vacuum cannot be a fluid or a solid composed of small entities, as its dimensionality would not then be fixed. Only one possibility remains: both vacuum and particles are made of a web of extended entities.

The idea of describing matter as composed of extended entities dates from the 1960s. That of describing nature as composed of 'infinitely' extended entities dates from the 1980s. In addition to the arguments presented so far, current research provides several other approaches that arrive at the same conclusion.

* *

Bosonization, the construction of fermions using an infinite number of bosons, is a cen-
Ref. 1321 tral property of modern unification attempts. It also implies coupling duality, and thus the extension of fundamental constituents.

* *

String theory, and in particular its generalization to membranes, is explicitly based on
Ref. 1322 extended entities, as the name implies. The fundamental entities are indeed assumed to reach the limits of space-time.

* *

Ref. 1323 Research into quantum gravity – in particular the study of spin networks and spin foams – has shown that the vacuum must be thought of as a collection of extended entities.

* *

In the 1990s, Dirk Kreimer showed that high-order *QED* diagrams are related to knot
Ref. 1324 theory. He thus proved that extension arrives by the back door even when electromagnetism is described in terms of point particles.

* *

A recent discovery in particle physics, 'holography', connects the surface and volume of
Ref. 1325 physical systems at high energy. Even if it were not part of string theory, it would still imply extended entities.

* *

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Other fundamental non-localities in the description of nature, such as wave function collapse, can be seen as the result of extended entities.

Page 1086

* *

At the start of the twenty-first century there are a number of new approaches, such as string net condensation or knotted particle models. All these make use of extended entities.

Conceptual checks of extension

Is nature really described by extended entities? The idea is taken for granted in all current frameworks in theoretical physics. How can we be sure about it? The arguments presented above provide several possible checks.

Challenge 1707 ny

— As Ed Witten likes to say, any unified model of nature must be supersymmetric and dual. The idea of extended entities would be immediately dead if it were shown not to be compatible with these requirements.
— Any model of nature must be easily extendible to a model for black holes. If not, it cannot be correct.
— The model must be consistent with the results of quantum gravity, for example on the area and volume quantization.
— Extended entities must appear if one starts from *any* physical (low-energy) concept – not only from length measurements – and studies how it behaves at Planck scales.
— Any contradiction between the idea of extension and string theory or M-theory would lead to strong doubts.
— If the measurement of length could be shown not to be related to the counting of folds, the model would be invalidated.
— A single Gedanken experiment invalidating the extended entity idea would prove it wrong.

Experimental falsification of models based on extended entities

Physics is an experimental science. What kind of data could show that extension is incorrect?

— Observing a single particle in cosmic rays with energy above the Planck energy would bring this approach to a sudden stop. (The present record is a million times lower.)
— Finding any property of nature not consistent with extended entities would spell the end of the idea.
— Finding an elementary particle of spin 0 would invalidate the idea. In particular, finding the Higgs boson and showing that it is elementary, i.e., that its size is smaller than its own Compton wavelength, would invalidate the model.
— Most proposed experimental checks of string theory can also yield information on the idea of extended entities. For example, Paul Mende has proposed a number of checks on the motion of extended objects in space-time. He argues that an extended object moves differently from a mass point; the differences could be noticeable in scattering or dispersion of light near masses.

Ref. 1327

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

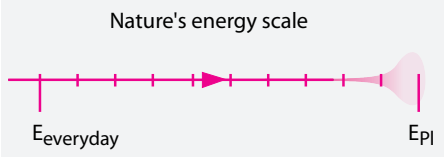

FIGURE 608 Planck effects make the energy axis an approximation

— In July 2002, the Italian physicist Andrea Gregori made a surprising prediction, valid for any model using extended entities that reach the border of the universe: if particles are extended in this way, their mass should depend on the size of the universe. Thus particle masses should change with time, especially around the big bang. This new idea is still a topic of research.

Ref. 1328

Incidentally, most of these scenarios would signal the end for almost all current unification attempts.

Possibilities for confirmation of extension models

— The best confirmation would be to find a concrete model for the electron, the muon, the tau, and their neutrinos. In addition, a concrete model for photons and gravitons is needed. With these models, finding a knot-based definition for the electrical charge and the lepton number would be a big step forward. All quantum numbers should be topological quantities deduced from these models and should behave as observed.
— Estimating the coupling constants and comparing them with the experimental values is of course the main dream of modern theoretical physics.
— A detailed proof that extended entities imply exactly three plus one space-time dimensions is still needed.
— Estimating the total number of particles in the visible universe would provide the final check of any extended entity model.

Generally speaking, the *only* possible confirmations are those from the one-page table of unexplained properties of nature given in Chapter 51. No other confirmations are possible. The ones mentioned above are the main ones.

Page 1340

Curiosities and fun challenges about extension

> No problem is so formidable that you can't walk away from it.
>
> Charles Schultz

This section has already provided enough food for thought, but here is some more.

* *

If measurements become impossible near Planck energy, we cannot even draw a diagram with an energy axis reaching that value. (See Figure 608.) Is this conclusion valid in all cases?

Challenge 1708 ny

* *

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1709 s Quantum theory implies that even if tight walls exist, the lid of a box made of them could never be tightly shut. Can you provide the argument?

* *

Challenge 1710 s Would a detector able to detect Planck-mass particles have to be be of infinite size? What about a detector able to detect a particle moving with Planck energy?

* *

Challenge 1711 e Can you provide an argument against the idea of extended entities? If so, publish it (and email it to the author).

* *

Challenge 1712 ny Does duality imply that the cosmic background fluctuations (at the origin of galaxies and clusters) are the same as vacuum fluctuations?

* *

Challenge 1713 ny Does duality imply that a system with two small masses colliding is the same as a system with two large masses gravitating?

* *

Challenge 1714 d It seems that in all arguments so far we have assumed that time is continuous, even though we know it is not. Does this change the conclusions?

* *

Duality also implies that in some sense large and small masses are equivalent. A mass m in a radius r is equivalent to a mass m_{Pl}^2/m in a radius l_{Pl}^2/r. In other words, duality transforms mass density from ρ to $\rho_{\mathrm{Pl}}^2/\rho$. Vacuum and maximum density are equivalent. Vacuum is thus dual to black holes.

* *

Duality implies that the notion of initial conditions for the big bang makes no sense, as we saw earlier by considering the minimal distance. As duality implies a symmetry between large and small energies, the big bang itself becomes a vague concept.

* *

Challenge 1715 s Total symmetry and space-time duality together imply that there is a symmetry between all values an observable can take. Do you agree?

* *

Challenge 1716 s Can supersymmetry be an aspect or special case of total symmetry, or is it something else?

* *

Challenge 1717 s Any description is a mapping from nature to mathematics, i.e., from observed differences (and relations) to thought differences (and relations). How can we do this accurately, if differences are only approximate? Is this the end of physics?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Challenge 1718 d What do extended entities imply for the big bang?

* *

Challenge 1719 d Can you show that going to high energies or selecting a Planck-size region of space-time is equivalent to visiting the big bang?

* *

Ref. 1328, Ref. 1329 One needs a description for the expansion of the universe in terms of extended entities. Some approaches are currently being explored; no final conclusions can be drawn yet.
Challenge 1720 ny Can you speculate about the solution?

An intermediate status report

> Wir müssen wissen, wir werden wissen.*
> David Hilbert, 1930

Many efforts towards unification advance by digging deeper and deeper into the details of quantum field theory and general relativity. We have taken the opposite approach: we took a step back and looked at the general picture. We found several arguments, all leading to the same conclusion: space-time points and point particles are made of *extended* entities.

Somehow it seems that the universe is best described by a fluctuating, many-branched entity, a cross between a giant amoeba and a heap of worms. Another analogy is a pot of boiling and branched spaghetti. Such a model of quantum geometry is beautiful and simple, and these two criteria are often taken as an indication, before any experimental tests, of the correctness of a description. We have toured topics such as the existence of Planck limits, three-dimensionality, curvature, renormalization, spin, bosonization, the cosmological constant problem, and the search for a 'background-free' description of
Ref. 1330 nature. We will study and test specific details of the model in the next section. Each of these tests concerns one of only three possible topics: the construction of space-time, the construction of particles, and the construction of the universe. These are the only issues remaining on our ascent of Motion Mountain. We will discuss them in the next section. Before we do so, we enjoy two small thoughts.

Sexual preferences in physics

Fluctuating entities can be seen to answer an old and not-so-serious question. When we discussed the definition of nature as made of tiny balls moving in a vacuum, we described
Page 258 this as a typically male idea. This implies that the female part is missing. Which part would that be?

From the present point of view, the female part of physics might be the quantum description of the vacuum. The unravelling of the structure of the vacuum, as an extended container of localized balls, could be seen as the female half of physics. If women had
Ref. 1331 developed physics, the order of its discoveries would surely have been different. Instead

* 'We must know, we will know.' This was Hilbert's famous personal credo.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of studying matter, as men did, women might have studied the vacuum first.

In any case, the female and the male approaches, taken together, lead us to the description of nature in terms of extended entities. Extended entities, which show that particles are not balls and that the vacuum is not a container, transcend the sexist approaches and lead to the unified description. In a sense, extended entities are thus the politically correct approach to nature.

A PHYSICAL APHORISM

Ref. 1197, Ref. 1198

To 'show' that we are not far from the top of Motion Mountain, we give a less serious argument as final curiosity. Salecker and Wigner, and then Zimmerman, formulated the fundamental limit for the measurement precision τ attainable by a clock of mass M. It is given by $\tau = \sqrt{\hbar T/Mc^2}$, where T is the time to be measured. We can then ask what time T can be measured with a precision of a Planck time t_{Pl}, given a clock of the mass of the whole universe. We get a maximum time of

$$T = \frac{t_{\mathrm{Pl}}^2 c^2}{\hbar} M \,. \tag{955}$$

Challenge 1721 e

Inserting numbers, we find rather precisely that the time T is the present age of the universe. With the right dose of humour we can see this result as a sign that time is now ripe, after so much waiting, for us to understand the universe down to the Planck scale. We are getting nearer to the top of Motion Mountain. Be prepared for even more fun.

STRING THEORY – EXTENSIOIN AND A WEB OF DUALITIES

> "Throw physic to the dogs; I'll none of it."
> William Shakespeare, *Macbeth*.

String theory, *superstring theory* or *membrane theory* – all are names for related approaches – is the most investigated hypothesis ever. String theory explores a specific approach of particles as extended entities. The theory contains a maximum speed, a minimum action and a maximum force (or tension). String theory thus incorporates special relativity, quantum theory and general relativity. String theory is thus a candidate for the unified theory of motion.

Ref. 1326

In its attempt to achieve a unified description, string theory uses four ideas that go beyond standard general relativity and quantum theory:

1. String theory describes particles as *extended* entities. The original string theory is based on one-dimensional strings. In a further generalization, the new membrane or M-theory describes particles as higher-dimensional membranes.
2. String theory uses *supersymmetry*. Supersymmetry is the symmetry that relates matter to radiation, or equivalently, fermions to bosons. Supersymmetry is the most general local interaction symmetry that we know about.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

3. String theory uses *higher dimensions* to introduce extended entities and to unify interactions. A number of space-time dimensions much higher than 3 + 1, typically 11, seems to be necessary for a consistent theory of strings. At present, however, the topology and size of the dimensions above the fourth is still unclear.
4. String theory makes heavy use of *dualities*. In the context of high-energy physics, dualities are symmetries between large and small values of physical observables. Important examples are space-time duality and coupling constant duality. Dualities are global interaction and space-time symmetries. They are essential if we want to include gravitation in our description of nature. Dualities also imply holography, the idea that physical systems are completely fixed by the states on their bounding surface. String theory uses dualities to express the equivalence between space-time and matter–radiation. Ref. 1332

By incorporating these four ideas, string theory acquires a number of appealing characteristics. First of all, the theory is unique: it has no adjustable parameters. Furthermore, as we would expect from a theory involving extended entities, string theory includes gravity. In addition, string theory describes interactions. It describes gauge fields, such as the electromagnetic field. String theory is thus an extension – and retains all the essential points – of quantum field theory.

String theory has many large symmetries, which arise from its many dualities. These symmetries connect many situations that seem intuitively to be radically different: this makes the theory fascinating but also difficult to picture.

Finally, in string theory there are special cancellations of anomalies and inconsistencies. Historically, the first example was the Green–Schwarz anomaly cancellation; but string theory also solves many other mathematical problems of quantum field theory.

In short, string theorists have shown that general relativity and quantum field theory can be unified using extended entities.

Strings and membranes – why string theory is so difficult

What is string theory? There are two answers to this question. First, we may follow its historical development. Unfortunately, that is almost the hardest of all possible ways to learn and understand string theory. The history of string theory, from around 1970 to 2008, was characterized by short periods of excitement followed by long periods of disappointment. The main reason for this ineffective evolution was that most researchers only studied topics that everybody else was also studying. Young researchers' fear of unemployment and the general fear of missing something out meant that people were reluctant to research topics that nobody else was looking at. Thus string theory had an extremely difficult birth.

The full description of string theory along historical lines starts from the motion of classical strings, and then proceeds to string field theory, while incorporating dualities, higher dimensions and supersymmetry on the way. Each step can be described by a Lagrangian.

The first idea of string theory, as the name implies, is the use of strings to describe particles. Strings replace point particles as the fundamental model. This formulation of string theory takes for granted the existence of a space-time background. The Lagrangian of the first step can be deduced from a new symmetry, the *Virasoro algebra*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

– CS – more to be added in the future – CS –

Edward Witten likes to say that quantum theory cures the infinities that appear in e^2/r when the distance r goes to zero; in the same way, string theory cures the infinities that appear in m^2/r when the distance r goes to zero.

Also following Witten, in string theory, the interactions follow from the particle definitions: interactions do not have to be added. That is why string theory is so predictive. In particular, it predicts gravity, gauge theory, and supersymmetry.

About gravity, one of the pretty results of string theory is that strings and black holes
Ref. 1333 are complementary to each other. This was argued by Polchinsky, Horowitz and Susskind.

Another reason why string theory is so appealing is that it can be deduced from an extremely small number of fundamental ideas. These ideas lead to M-theory, the most recent formulation of string theory.

M-theory assumes that the basic entities of nature are *membranes* of various dimensions. M-theory incorporates dualities and holography. The existence of interactions can be deduced. Supersymmetry – and, in particular, 'super Yang–Mills' theory – can also be deduced. The entropy formula for black holes also follows from M-theory. Finally, supergravity has been deduced from M-theory. This means that the existence of space-time follows from M-theory. M-theory is thus a candidate for a theory of motion. Let us now turn to the comparison with experiment.

Masses and couplings

One of the main results of QCD, the theory of strong interactions, is the explanation of
Ref. 1334 mass relations such as

$$m_{\text{proton}} \sim \mathrm{e}^{-k/\alpha_{\text{unif}}} m_{\text{Pl}} \quad \text{and} \quad k = 11/2\pi \,,\ \alpha_{\text{unif}} \approx 1/25 \,. \tag{956}$$

Here, the value of the coupling constant α_{unif} is taken at the grand unification energy, usually estimated to be about a factor of 1000 below the Planck energy. In other words, a general understanding of masses of bound states of the strong interaction, such as the proton, requires little more than a knowledge of the unification energy and the coupling constant at that energy. The approximate value $\alpha_{\text{unif}} = 1/25$ is an extrapolation from the
Page 1297 low-energy value, based on experimental data.

Any unified theory must allow one to calculate the three coupling constants as a function of energy, and thus also the value α_{unif} at the unification energy itself. At present, most researchers regard the search for the vacuum state as the main difficulty facing string theory and M-theory. Without knowledge of the vacuum state, no calculations of the masses and coupling constants are possible.

The vacuum state of string theory or M-theory is expected to be one of an extremely involved set of topologically distinct manifolds. It is estimated that there are around 10^{500} candidate vacuum states. The universe contains 10^{80} atoms; it thus seems easier to find a particular atom in the universe that to find the correct vacuum state.

One can also describe the situation in the following way. String theory and M-theory predict states with Planck mass and with zero mass. The zero-mass particles are then thought to get their tiny mass (compared with the Planck mass) from the Higgs mecha-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

nism. However, the Higgs mechanism, including its coupling constants, has not yet been deduced from string theory. In other words, so far, string theory has not predicted any masses for elementary particles. This disappointing situation is the reason why some scientists dismiss string theory and M-theory altogether. Time will tell.

Ref. 1335

Outlook

> Es ist nicht Großes ohne Leidenschaft vollbracht worden, noch kann es ohne solche vollbract werden.*
>
> Friedrich Hegel, *Enzyklopädie*.

It is estimated that 10 000 man-years have been invested in the search for string theory: compare this with about 5 for Maxwell's electrodynamics, 10 for general relativity, and a similar number for the foundation of quantum theory.

Historically, the community of string theorists took over 10 years to understand that strings were not the basic entities of string theory. The fundamental entities are membranes. Then string theorists took another 10 years, and more, to understand that membranes are not the most practical fundamental entities for calculation. The search for the most practical entities is still ongoing. It is probable that *knotted* membranes must be taken into consideration.

Why is M-theory so hard? Doing calculations on knotted membranes is difficult. In fact, it is *extremely* difficult. Mathematicians and physicists all over the world are still struggling to find simple ways to do such calculations.

In short, a new approach to calculation with extended entities is needed. We can then ask the following question. M-theory is based on four basic ideas: extension, higher dimensions, supersymmetry and duality. Can we dispense with any of these assumptions? Duality is related to extension, for which enough experimental and theoretical evidence exists, as we have argued before. However, supersymmetry and higher dimensions are completely speculative. Let us leave them aside, and continue our adventure.

POSTFACE

Perhaps once you will read Plato's Phaedrus, one of the beautiful philosophical Greek texts. In it, Socrates is made to say that he almost never left the city walls because to him, as a 'lover of learning, trees and the open country do not teach anything, whereas men in the town do.' This is a veiled critique of Democritus, the most important and famous philosopher in Greece during Plato's time. Democritus was the natural philosopher par excellence, and arguably had learned from nature – with its trees and open country – more than anybody else after him.

After this mountain ascent you can decide for yourself which of these two approaches is more congenial to you. It might be useful to know that Aristotle refused to choose and cultivated them both. There is no alternative in life to following one's own mind, and to enjoy doing so. If you enjoyed this particular trip, show it to your friends. For yourself, after this walk, sense intensively the pleasure of having accomplished something important. Many before you did not have the occasion. Enjoy the beauty of the view offered. Enjoy the vastness of horizon it provides. Enjoy the impressions that it creates inside you. Collect them and rest. You will have a treasure that will be useful in many occasions. Then, when you feel the desire of going further, get ready for another of the adventures life has to offer.

Plato's *Phaedrus*, written around 380 BCE, is available in many pocket editions. Do not waste your time learning ancient Greek to read it; the translated versions are as beautiful as the original. Half the text is about love and gave rise to the expression 'platonic love', even though its original meaning has been strongly distorted in the meantime, as you will find out.

Plato's lifelong avoidance of the natural sciences had two reasons. First of all, he was jealous of Democritus. Plato never even cites Democritus in his texts. Democritus was the most prolific, daring, admired and successful philosopher of his time (and maybe of all times). Democritus was a keen student of nature. His written works did not survive, because his studies were not congenial to the followers of christianity, and thus they were not copied by the monks in the Middle Ages. The loss of these texts is related to the second reason that kept Plato away from the natural sciences: he wanted to save his life. Plato had learned one thing from men in the town: talking about nature is dangerous. Starting around his lifetime, for over 2000 years people practising the natural sciences were regularly condemned to exile or to death for impiety. Fortunately, this is only rarely the case today. But such violence still occurs, and is worth remembering the dangers that those preceding us had to overcome in order to enjoy this adventure.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

1230 One way out is proposed in J. Magueijo & L. Smolin, Lorentz invariance with an invariant energy scale, *Physical Review Letters* **88**, p. 190403, 26 April 2002. They propose a modification of the mass energy relation of the kind

$$E = \frac{\gamma mc^2}{1 + \frac{\gamma mc^2}{E_{\text{Pl}}}} \quad \text{and} \quad p = \frac{\gamma mv}{1 + \frac{\gamma mc^2}{E_{\text{Pl}}}} \,. \tag{957}$$

Another, similar approach of recent years, with a different proposal, is called 'doubly special relativity'. A recent summary is G. Amelino-Camelia, Doubly-special relativity: first results and key open problems, arxiv.org/abs/gr-qc/0210063. The paper shows how conceptual problems hinder the advance of the field, as does R. Aloisio, A. Galante, A. F. Grillo, E. Luzio & F. Méndez, Approaching space-time through velocity in doubly special relativity, preprint at arxiv.org/abs/gr-qc/0410020. Cited on page 1416.

1254 See, for example, H. Wussing & P. S. Alexandrov, editors, *Die Hilbertschen Probleme*, Akademische Verlagsgesellschaft Geest & Portig, 1983, or Ben H. Yandell, *The Honours Class: Hilbert's Problems and their Solvers*, A.K. Peters, 2002. Cited on page 1442.

1255 A large part of the study of dualities in string and M theory can be seen as investigations into the detailed consequences of extremal identity. For a review of dualities, see P. C. Argyres, Dualities in supersymmetric field theories, *Nuclear Physics Proceedings Supplement* **61**, pp. 149–157, 1998, preprint available at arxiv.org/abs/hep-th/9705076. A classical version of duality is discussed by M. C. B. Abdalla, A. L. Gadelka & I. V. Vancea, Duality between coordinates and the Dirac field, arxiv.org/abs/hep-th/0002217. Cited on page 1446.

1256 If you are more interested in sexuality than in love, the best book to read is the fascinating text by Olivia Judson, *Dr. Tatjana's Sex Advice to all Creation*, Metropolitan Books, 2002. Cited on page 1447.

1257 A provocative attempt to explain the lack of women in physics is made in Margaret Wertheim, *Pythagoras' Trousers – God, Physics and the Gender Wars*, Fourth Estate, 1997. Cited on page 1447.

1258 The consequences of memory loss in this case are already told by Voltaire, *Aventure de la mémoire*, 1775. Cited on page 1449.

1259 A picture of objects in a red-hot oven and at room temperature is shown in C. H. Bennett, Demons, Engines and the Second Law, *Scientific American* **255**, pp. 108–117, November 1987. Cited on page 1449.

1260 An introduction to how the sense of time arises as a result of signals in the ganglia and in the temporal lobe of the brain is found in R. B. Ivry & R. Spencer, The neural representation of time, *Current Opinion in Neurobiology* **14**, pp. 225–232, 2004. Cited on page 1450.

1261 This famous statement is found at the beginning of chapter XI, 'The Physical Universe', in Arthur Eddington, *The Philosophy of Physical Science*, Cambridge, 1939. Cited on page 1451.

1262 See Chapter 30 on brain and language for details and references. Cited on page 1452.

1263 Details can be found in Chapter 52 of this text, a reworked version of the article published in French as C. Schiller, Le vide diffère-t-il de la matière? in E. Gunzig & S. Diner, editors, *Le Vide – Univers du tout et du rien – Des physiciens et des philosophes s'interrogent*, Les Éditions de l'Université de Bruxelles, 1998. Cited on pages 1455 and 1456.

1264 For details of the arguments leading to duality, see section 53 This section also includes

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

arguments supporting the notion that the universe is not a even a set, and thus proposes a solution to Hilbert's sixth problem. Cited on page 1457.

1265 Bohr explained the indivisibilty of the quantum of action in his famous Como lecture. N. Bohr, *Atomtheorie und Naturbeschreibung*, Springer, Berlin, 1931. More statements about the indivisibility of the quantum of action can be found in N. Bohr, *Atomic Physics and Human Knowledge*, Science Editions, New York, 1961. For summaries of Bohr's ideas by others see Max Jammer, *The Philosophy of Quantum Mechanics*, Wiley, first edition, 1974, pp. 90–91, and John Honner, *The Description of Nature – Niels Bohr and the Philosophy of Quantum Physics*, Clarendon Press, 1987, p. 104. Cited on page 1460.

1266 For an overview of the quantum of action as a basis of quantum theory, see C. Schiller, An appetizer – quantum theory for poets and lawyers, part of this text. Cited on page 1460.

Page 976

1267 The first published statements of the principle of maximum force were in the present textbook and independently in the paper by G. W. Gibbons, The maximum tension principle in general relativity, *Foundations of Physics* **32**, pp. 1891–1901, 2002, or arxiv.org/abs/hep-th/0210109. Cited on pages 1461 and 1474.

1268 Maximal luminosity is often mentioned in connection with gravitational wave detection; nevertheless, the general maximum is never mentioned. See for example L. Ju, D. G. Blair & C. Zhao, Detection of gravitational waves, *Reports on Progress in Physics* **63**, pp. 1317–1427, 2000. See also C. Misner, K. Thorne & J. A. Wheeler, *Gravitation*, Freeman, 1973, page 980. Cited on page 1462.

1269 See for example Wolfgang Rindler, *Relativity – Special, General and Cosmological*, Oxford University Press, 2001, p. 70 ff, or Ray d'Inverno *Introducing Einstein's Relativity*, Clarendon Press, 1992, p. 36 ff. Cited on page 1463.

1270 T. Jacobson, Thermodynamics of spacetime: the Einstein equation of state, *Physical Review Letters* **75**, pp. 1260–1263, 1995, preprint at arxiv.org/abs/gr-qc/9504004. Cited on page 1464.

1271 C. Schiller, Maximum force: a simple principle encompassing general relativity, part of this text and downloadable as www.motionmountain.eu/MotionMountain-Part2b.pdf. Cited on page 1465.

1272 Indeterminacy relations in general relativity are discussed in C. A. Mead, Possible connection between gravitation and fundamental length, *Physical Review B* **135**, pp. 849–862, 1964. See also P. K. Townsend, Small-scale structure of space-time as the origin of the gravitational constant, *Physical Review D* **15**, pp. 2795–2801, 1977, or the paper by M.-T. Jaekel & S. Renaud, Gravitational quantum limit for length measurement, *Physics Letters A* **185**, pp. 143–148, 1994. Cited on page 1465.

1273 M. Kramer & al., Tests of general relativity from timing the double pulsar, prerpint at arxiv.org/abs/astro-ph/060941. Cited on page 1465.

1274 Minimal length and minimal time intervals are discussed, for example, by G. Amelino-Camelia, Limits on the measurability of space-time distances in (the semiclassical approximation of) quantum gravity, *Modern Physics Letters A* **9**, pp. 3415–3422, 1994, and by Y. J. Ng & H. Van Dam, Limit to space-time measurement, *Modern Physics Letters A* **9**, pp. 335–340, 1994. Many other authors have explored the topic. Cited on page 1467.

1275 Maximal curvature, as well as area and volume quantization, are discussed by A. Ashtekar, Quantum geometry and gravity: recent advances, arxiv.org/abs/gr-qc/0112038 and by A. Ashtekar, Quantum geometry in action: big bang and black holes, arxiv.org/abs/math-ph/0202008. Cited on page 1467.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

1276 This was kindly pointed out by Achim Kempf. The story is told in A. D. Sakharov, *General Relativity and Gravitation* **32**, p. 365, 2000, a reprint of a paper of 1969. Cited on page 1468.

1277 Several incorrect counterclaims to the entropy limit were made in R. Bousso, The holographic principle, *Review of Modern Physics* **74**, pp. 825–874, 2002, preprint at arxiv.org/abs/hep-th/0203101. Bousso has changed his position in the mean time. Cited on pages 1468 and 1480.

1278 G. Amelino-Camelia, Doubly-special relativity: first results and key open problems, *International Journal of Modern Physics* **11**, pp. 1643–1669, 2002, preprint at arxiv.org/abs/gr-qc/0210063. See also J. Magueijo & L. Smolin, Lorentz invariance with an invariant energy scale, *Physical Review Letters* **88**, p. 190403, 2002, or arxiv.org/abs/hep-th/0112090. Cited on page 1468.

1279 Maximons, elementary particles of Planck mass, are discussed by A. D. Sakharov, Vacuum quantum fluctuations in curved space and the theory of gravitation, *Soviet Physics – Doklady* **12**, pp. 1040–1041, 1968. Cited on page 1469.

1280 Minimal entropy is discussed by L. Szilard, Über die Entropieverminderung in einem thermodynamischen System bei Eingriffen intelligenter Wesen, *Zeitschrift für Physik* **53**, pp. 840–856, 1929. This classic paper can also be found in English translation in his collected works. Cited on page 1470.

1281 See for example A. E. Shalyt-Margolin & A. Ya. Tregubovich, Generalized uncertainty relation in thermodynamics, arxiv.org/abs/gr-qc/0307018, or J. Uffink & van Lith-van Dis, Thermodynamic uncertainty relations, *Foundations of Physics* **29**, pp. 655–692, 1999. Cited on page 1470.

1282 Gamma ray bursts are discussed by G. Preparata, R. Ruffini & S.-S. Xue, The dyadosphere of black holes and gamma-ray bursts, *Astronomy and Astrophysics* **338**, pp. L87–L90, 1998, and C. L. Bianco, R. Ruffini & S.-S. Xue, The elementary spike produced by a pure e^+e^- pair-electromagnetic pulse from a black hole: the PEM pulse, *Astronomy and Astrophysics* **368**, pp. 377–390, 2001. Cited on page 1471.

1283 See for example the review in C. W. J. Beenakker & al., Quantum transport in semiconductor nanostructures, pp. 1–228, in H. Ehrenreich & D. Turnbull, editors, *Solid State Physics*, volume 44, Academic Press, 1991. The prediction of a future Nobel Prize was made and conveyed to the authors by C. Schiller in 1992. Cited on page 1471.

CHALLENGE HINTS AND SOLUTIONS

Challenge 1624, page 1401: The other scale is the horizon of the universe, as we will see shortly.

Challenge 1625, page 1402: Sloppily speaking, such a clock is not able to move its hands in such a way to guarantee precise time reading.

Challenge 1628, page 1416: The final energy E produced by a proton accelerator increases with its radius R roughly as $E \sim R^{1.2}$; as an example, CERN's SPS achieves about 450 GeV for a radius of 740 m. Thus we would get a radius of more than 100 000 light years (larger than our galaxy) for a Planck energy accelerator. An accelerator achieving Planck energy is impossible.

A unification energy accelerator would be about 1000 times smaller. Nature has no accelerator of this power, but gets near it. The maximum measured value of cosmic rays, 10^{22} eV, is about one thousandth of the unification energy. The mechanisms of acceleration are obscure. Black holes are no sources for unification energy particles, due to their gravitational potential. But also the cosmic horizon is not the source, for some yet unclear reasons. This issue is still a topic of research.

Challenge 1629, page 1416: The Planck energy is $E_{\text{Pl}} = \sqrt{\hbar c^5/G} = 2.0\,\text{GJ}$. Car fuel delivers about 43 MJ/kg. Thus the Planck energy corresponds to the energy of 47 kg of car fuel, about a tankful.

Challenge 1630, page 1416: Not really, as the mass error is equal to the mass only in the Planck case.

Challenge 1631, page 1416: It is improbable that such deviations can be found, as they are masked by the appearance of quantum gravity effects. However, if you do think that you have a prediction for a deviation, publish it.

Challenge 1633, page 1417: There is no gravitation at those energies and there are no particles. There is thus no paradox.

Challenge 1634, page 1418: The issue is still being debated; a good candidate for a minimum momentum of a single particle is given by the $\hbar/R$, where R is the radius of the universe. Is this answer satisfying?

Challenge 1635, page 1418: The Planck acceleration is given by $a_{\text{Pl}} = \sqrt{c^7/\hbar G} = 5.6 \cdot 10^{51}\,\text{m/s}^2$.

Challenge 1636, page 1418: All mentioned options could be valid at the same time. The issue is not closed and clear thinking about it is not easy.

Challenge 1637, page 1419: The energy is the unification energy, about 800 times smaller than the Planck energy.

Challenge 1638, page 1419: This is told in detail in the section on maximum force starting on page 1458.

Challenge 1639, page 1424: Good! Publish it.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1640, page 1426: See the table on page 203.

Challenge 1641, page 1426: The cosmic background radiation is a clock in the widest sense of the term.

Challenge 1663, page 1441: For the description of nature this is a contradiction. Nevertheless, the term 'universe', 'set of all sets' and other mathematical terms, as well as many religious concepts are of this type.

Challenge 1666, page 1442: For concept of 'universe'.

Challenge 1670, page 1443: Plotinus in the *Enneads* has defined 'god' in exactly this way. Later, Augustine in *De Trinitate* and in several other texts, and many subsequent theologians have taken up this view. (See also Thomas Aquinas, *Summa contra gentiles*, 1, 30.) The idea they propose is simple: it is possible to clearly say what 'god' is *not*, but it is impossible to say what 'god' *is*. This statement is also part of the official *Roman Catholic Catechism*: see part one, section one, chapter one, IV, 43, found at www.vatican.va/archive/ENG0015/__PC.HTM. Similar statements are found in Judaism, Hinduism and Buddhism.

Certain legal scholars would also propose a different concept that fits the definition – namely 'administration': it is difficult to say what it is, but easy to say what it is not.

More seriously, the properties common to 'universe' and to 'god' suggest the conclusion that both are the same. Indeed, the analogy between the two concepts can be expanded to a proof. (This is left to the reader.) In fact, this might be the most interesting of all proofs of the existence of gods, as it lacks all the problems that the more common 'proofs' have. Despite its interest, this proof of equivalence is not found in any book on the topic yet. The reason is twofold. First, the results of modern physics showing that the concept of universe has all these strange properties are not common knowledge yet. Secondly, the result of the proof, the identity of 'god' and the universe – also called *pantheism* – is a heresy for most religions. It thus is an irony that the catholic catechism, together with modern physics, can be used to show that pantheism is a hidden aspect of christianity.

If one is ready to explore the identity of universe and 'god', one finds that a statement like 'god created the universe' translates as 'the universe implies the universe'. The original statement is thus not a lie any more, but is promoted to a tautology. Similar changes appear for many other – but not all – statements using the term 'god'. Enjoy the exploration.

Challenge 1671, page 1443: If you find one, publish it! And send it to the author as well.

Challenge 1673, page 1445: If you find one, publish it and also send it to the author.

Challenge 1677, page 1448: Any change in rotation speed of the Earth would change the sea level.

Challenge 1678, page 1449: Just measure the maximum water surface the oil drop can cover, by looking at the surface under a small angle.

Challenge 1679, page 1450: Keep the fingers less than 1 cm from your eye.

Challenge 1680, page 1456: As vacuum and matter cannot be distinguished, both share the same properties. In particular, both scatter strongly at high energies.

Challenge 1681, page 1459: Take $\Delta f \; \Delta t \geqslant 1$ and substitute $\Delta l = c/\Delta f$ and $\Delta a = c/\Delta t$.

Challenge 1697, page 1482: To the knowledge of the author, no such limits have been published.

Challenge 1698, page 1482: The system limits cannot be chosen in other ways; after the limits have been corrected, the limits given here should still apply.

Challenge 1700, page 1483: It is probably that they remain - but who knows for sure yet?

Challenge 1703, page 1497: The number of spatial dimensions must be given first, in order to talk about spheres.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1704, page 1500: This is a challenge to you to find out and publish; it is fun, may bring success and would yield an independent check of the results of the section.

Challenge 1709, page 1512: The lid of a box must obey the indeterminacy relation. It cannot be at perfect rest with respect to the rest of the box.

Challenge 1710, page 1512: Of course not, as there are no infinite quantities in nature. The question is whether the detector would be as large as the universe or smaller. What is the answer?

Challenge 1714, page 1512: No. Time is continuous only if *either* quantum theory and point particles *or* general relativity and point masses are assumed. The argument shows that only the combination of both theories with continuity is impossible.

Challenge 1715, page 1512: Yes, as nature's inherent measurement errors cannot clearly distinguish between them.

Challenge 1716, page 1512: Of course.

Challenge 1717, page 1512: We still have the chance to find the best approximate concepts possible. There is no reason to give up.

Challenge 1718, page 1513: A few thoughts. A beginning of the big bang does not exist; something similar is given by that piece of continuous entity which is encountered when going backwards in time as much as possible. This has several implications.

— Going backwards in time as far as possible – towards the 'beginning' of time – is the same as zooming to smallest distances: we find a single strand of the amoeba.
— In other words, we speculate that the whole world is one single piece, knotted, branched and fluctuating.
— Going far away into space – to the border of the universe – is like taking a snapshot with a short shutter time: strands everywhere.
— Whenever we sloppily say that extended entities are 'infinite' in size, we only mean that they reach the horizon of the universe.

In summary, no starting point of the big bang exists, because time does not exist there. For the same reason, no initial conditions for particles or space-time exist. In addition, this shows there was no creation involved, since without time and without possibility of choice, the term 'creation' makes no sense.

Challenge 1719, page 1513: The equivalence follows from the fact that all these processes require Planck energy, Planck measurement precision, Planck curvature, and Planck shutter time.

SUBJECT INDEX

Page numbers in *italic* typeface refer to pages where the keyword is defined or presented in detail. The subject index thus acts as a glossary.

field lines 710
field of scalars *889*
field theory *710*
field, mathematical *876*
field, physical *670*
Fields medal 1314
fields, morphogenetic 847
fifth, perfect 236
figure-eight 1324
figures in corners 31
filament 280
film 977
fine structure *1047*
fine structure constant 719, 754, *912*, 921, *922*, *1046*, *1047*, 1178, 1423
fine structure constant, limit on 1272
fine tuning *1345*
fine-structure constant *1050*, 1051
fingers 726
fingers prove the wave properties of light 726
finite 294, *825*, *860*
finite number *853*
fire 14, 280, 787, *1242*
fire colour 1163
firefly 1180
firework colour 1163
first law of black hole mechanics *478*
first law of horizon mechanics *478*
first property of quantum measurements *1087*
Fischer groups 900
fish in water 1498, 1509
fish's eyes 269
fish, weakly-electric 683
flagella *86*
flagella, prokaryote 1309, 1379
flagellar motor 103
flagellum 1309
flame 37, 135, 295, 787
flashlamp colour 1163
flatness 61
flatness, asymptotic 559
flattening of the Earth 116
flavour symmetry *1262*
flavours *1259*
fleas 139
flies 32
flight simulation 881
flip film 31, 32
flip film, explanation of 73
floor, stability of 1152
flow 277
flow of time 51, 52, 623
flows must vary 1017
fluctuations *1076*
fluctuations, zero-point 1190
fluid mechanics *192*
fluids, body 264
fluorescence 791
fluorescence microscopy *766*
fluorine 1355
flute 226
flux 956
flux, electric 679
fly, common 148, 1120
flying saucers 245
flying systems 1303
foam 1130
focal point 367
focus 367
fogbow *751*
football, hairy 908
force 95, 105, *473*, 559
force limit 473
force, central *95*
force, definition of 179
force, maximum 471
force, maximum, assumptions 482
force, minimum in nature *496*
force, perfect 626

Content Overview

Preface 10
Advice for learners 11
Using this book 11
A request 12
An appetizer 13

First Part : Fall, Flow and Heat

1 Why should we care about motion? 22
2 From motion measurement to continuity 39
3 How to describe motion – kinematics 73
4 From objects and images to conservation 89
5 From the rotation of the earth to the relativity of motion 116
6 Motion due to gravitation 142
7 Classical mechanics and the predictability of motion 178
8 Measuring change with action 194
9 Motion and symmetry 209
10 Simple motions of extended bodies – oscillations and waves 226
11 Do extended bodies exist? – Limits of continuity 250
12 From heat to time-invariance 278
13 Self-organization and chaos – the simplicity of complexity 302
14 From the limitations of physics to the limits of motion 314
A Notation and conventions 319
Bibliography 330
Challenge hints and solutions 355
Credits 391

Second Part : Relativity

15 Maximum speed, observers at rest, and motion of light 401
16 General relativity: gravitation, maximum speed and maximum force 471
17 The new ideas on space, time and gravity 498
18 Motion in general relativity – bent light and wobbling vacuum 520
19 Why can we see the stars? – Motion in the universe 564
20 Black holes – falling forever 604
21 Does space differ from time? 619
22 General relativity in ten points – a summary for the layman 626
Bibliography 632
Challenge hints and solutions 655
Credits 663

Third Part : Light, Charges and Brains

23 Liquid electricity, invisible fields and maximum speed 669
24 The description of electromagnetic field evolution 706

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

25 What is light? 723
26 Images and the eye – optics 760
27 Charges are discrete – the limits of classical electrodynamics 773
28 Electromagnetic effects 776
29 Classical physics in a nutshell 798
30 The story of the brain 804
31 Thought and language 817
32 Concepts, lies and patterns of nature 836
B Numbers and spaces 875
C Units, measurements and constants 909
D Sources of information on motion 927
Bibliography 933
Challenge hints and solutions 955
Credits 970

Fourth Part : Quantum Theory: The Smallest Change

33 Minimum action – quantum theory for poets 976
34 Light – the strange consequences of the quantum of action 994
35 Motion of matter – beyond classical physics 1016
36 Colours and other interactions between light and matter 1041
37 Permutation of particles – are particles like gloves? 1052
38 Rotations and statistics – visualizing spin 1063
39 Superpositions and probabilities – quantum theory without ideology 1074
Bibliography 1099
Challenge hints and solutions 1110
Credits 1114

Fifth Part : Pleasure, Technology and Stars

40 Motion for enjoying life 1119
41 Changing the world with quantum theory 1146
42 Quantum electrodynamics – the origin of virtual reality 1189
43 Quantum mechanics with gravitation – the first approach 1204
44 The structure of the nucleus – the densest clouds 1222
45 The sun, the stars and the birth of matter 1248
46 The strong interaction 1257
47 The weak nuclear interaction and the handedness of nature 1275
48 The standard model of elementary particle physics – as seen on television 1290
49 Dreams of unification 1295
50 Bacteria, flies and knots 1303
51 Quantum physics in a nutshell 1332
E Composite particle properties 1348
Bibliography 1363
Challenge hints and solutions 1383
Credits 1390

Sixth Part : Motion Without Motion

52 General relativity versus quantum theory 1396
53 Nature at large scales – Is the universe something or nothing? 1425
54 The physics of love – a summary of the first five-and-a-half parts 1447
55 Maximum force and minimum distance – physics in limit statements 1458
56 The shape of points – extension in nature 1487
57 Unification (not yet available) 1518
58 The top of the mountain (not yet available) 1519
Postface 1520
Bibliography 1521
Challenge hints and solutions 1534
Credits 1537
Name index 1538
Subject index 1566
